TO COME

*This volume is dedicated to our colleagues,
David R. Boone, Don J. Brenner,
Richard W. Castenholz, and Noel R. Krieg, who
retired from the Board of Trustees of Bergey's Manual
Trust as this edition was in preparation. We deeply
appreciate their efforts as editors and authors; they
have devoted their time and many years in helping
the Trust meet its objectives.*

Preface to Volume Two of the Second Edition of *Bergey's Manual® of Systematic Bacteriology*

There is a long-standing tradition for the Editors of *Bergey's Manual* to open their respective editions with the observation that the new edition is a departure from the earlier ones. As this volume goes to press, however, we recognize a need to deviate from this practice, by offering a separate preface to each volume within this edition. In part, this departure is necessary because the size and complexity of this edition far exceeded our expectations, as has the amount of time that has elapsed between publication of the first volume of this edition and this volume.

Earlier, we noted that systematic procaryotic biology is a dynamic field, driven by constant theoretical and methodological advances that will ultimately lead to a more perfect and useful classification scheme. Clearly, the pace has been accelerating as evidenced in the super-linear rate at which new taxa are being described. Much of the increase can be attributed to rapid advances in sequencing technology, which has brought about a major shift in how we view the relationships among *Bacteria* and *Archaea*. While the possibility of a universally applicable natural classification was evident as the First Edition was in preparation, it is only recently that the sequence databases became large enough, and the taxonomic coverage broad enough to make such an arrangement feasible. We have relied heavily upon these data in organizing the contents of this edition of *Bergey's Manual of Systematic Bacteriology*, which will follow a phylogenetic framework based on analysis of the nucleotide sequence of the small ribosomal subunit RNA, rather than a phenotypic structure. This departs from the First Edition, as well as the Eighth and Ninth Editions of the *Determinative Manual*. While the rationale for presenting the content of this edition in such a manner should be evident to most readers, they should bear in mind that this edition, as in all preceding ones represents a progress report, rather than a final classification of procaryotes.

The Editors remind the readers that the *Systematics Manual* is a peer-reviewed collection of chapters, contributed by authors who were invited by the Trust to share their knowledge and expertise of specific taxa. Citation should refer to the author, the chapter title, and inclusive pages rather than to the Editors. The Trust is indebted to all of the contributors and reviewers, without whom this work would not be possible. The Editors are grateful for the time and effort that each expended on behalf of the entire scientific community. We also thank the authors for their good grace in accepting comments, criticisms, and editing of their manuscripts. We would also like to thank Drs. Hans Trüper, Brian Tindall, and Jean Euzéby for their assistance on matters of nomenclature and etymology.

We would like to express our thanks to the Department of Microbiology and Molecular Genetics at Michigan State University for housing our headquarters and editorial office and for providing a congenial and supportive environment for microbial systematics. We would also like to thank Connie Williams not only for her expert secretarial assistance, but also for unflagging dedication to the mission of Bergey's Manual Trust and Drs. Julia Bell and Denise Searles for their expert editorial assistance and diligence in verifying countless pieces of critical information and to Dr. Timothy G. Lilburn for constructing many of the phylogenetic trees used in this volume. We also extend our thanks to Alissa Wesche, Matt Chval and Kristen Johnson for their assistance in compilation of the bibliography.

A project such as the *Systematics Manual* also requires the strong and continued support of a dedicated publisher, and we have been most fortunate in this regard. We would also like to express our gratitude to Springer-Verlag for supporting our efforts and for the development of the Bergey's Document Type Definition (DTD). We would especially like to thank our Executive Editor, Dr. William Curtis for his courage, patience, understanding, and support; Catherine Lyons for her expertise in designing and developing our DTD, and Jeri Lambert and Leslie Grossberg of Impressions Book and Journal Services for their efforts during the pre-production and production phases. We would also like to acknowledge the support of ArborText, Inc., for providing us with state-of-the-art SGML development and editing tools at reduced cost. Lastly, I would like to express my personal thanks to my fellow trustees for providing me with the opportunity to participate in this effort, to Drs. Don Brenner, Noel Krieg, and James Staley for their enormous efforts as volume editors and to my wife, Nancy, and daughter, Jane, for their continued patience, tolerance and support.

Comments on this edition are welcomed and should be directed to Bergey's Manual Trust, Department of Microbiology and Molecular Genetics, 6162 Biomedical and Physical Sciences Building, Michigan State University, East Lansing, MI, USA 48824-4320. Email: garrity@msu.edu

George M. Garrity

Preface to the First Edition of *Bergey's Manual*® *of Systematic Bacteriology*

Many microbiologists advised the Trust that a new edition of the *Manual* was urgently needed. Of great concern to us was the steadily increasing time interval between editions; this interval reached a maximum of 17 years between the seventh and eighth editions. To be useful the *Manual* must reflect relatively recent information; a new edition is soon dated or obsolete in parts because of the nearly exponential rate at which new information accumulates. A new approach to publication was needed, and from this conviction came our plan to publish the *Manual* as a sequence of four subvolumes concerned with systematic bacteriology as it applies to taxonomy. The four subvolumes are divided roughly as follows: (a) the Gram-negatives of general, medical or industrial importance; (b) the Gram-positives other than actinomycetes; (c) the archaeobacteria, cyanobacteria and remaining Gram-negatives; and (d) the actinomycetes. The Trust believed that more attention and care could be given to preparation of the various descriptions within each subvolume, and also that each subvolume could be prepared, published, and revised as the area demanded, more rapidly than could be the case if the *Manual* were to remain as a single, comprehensive volume as in the past. Moreover, microbiologists would have the option of purchasing only that particular subvolume containing the organisms in which they were interested.

The Trust also believed that the scope of the *Manual* needed to be expanded to include more information of importance for systematic bacteriology and bring together information dealing with ecology, enrichment and isolation, descriptions of species and their determinative characters, maintenance and preservation, all focused on the illumination of bacterial taxonomy. To reflect this change in scope, the title of the *Manual* was changed and the primary publication becomes *Bergey's Manual of Systematic Bacteriology*. This contains not only determinative material such as diagnostic keys and tables useful for identification, but also all of the detailed descriptive information and taxonomic comments. Upon completion of each subvolume, the purely determinative information will be assembled for eventual incorporation into a much smaller publication which will continue the original name of the *Manual*, *Bergey's Manual of Determinative Bacteriology*, which will be a similar but improved version of the present *Shorter Bergey's Manual*. So, in the end there will be two publications, one systematic and one determinative in character.

An important task of the Trust was to decide which genera should be covered in the first and subsequent subvolumes. We were assisted in this decision by the recommendations of our Advisory Committees, composed of prominent taxonomic authorities to whom we are most grateful. Authors were chosen on the basis of constant surveillance of the literature of bacterial systematics and by recommendations from our Advisory Committees.

The activation of the 1976 Code had introduced some novel problems. We decided to include not only those genera that had been published in the Approved Lists of Bacterial Names in January 1980 or that had been subsequently validly published, but also certain genera whose names had no current standing in nomenclature. We also decided to include descriptions of certain organisms which had no formal taxonomic nomenclature, such as the endosymbionts of insects. Our goal was to omit no important group of cultivated bacteria and also to stimulate taxonomic research on "neglected" groups and on some groups of undoubted bacteria that have not yet been cultivated and subjected to conventional studies.

The invited authors were provided with instructions and exemplary chapters in June 1980 and, although the intended deadline for receipt of manuscripts was March 1981, all contributions were assembled in January 1982 for the final preparations. The *Manual* was forwarded to the publisher in June 1982.

Some readers will note the consistent use of the stem -var instead of -type in words such as biovar, serovar and pathovar. This is in keeping with the recommendations of the Bacteriological Code and was done against the wishes of some of the authors.

We have deleted much of the synonymy of scientific names which was contained in past editions. The adoption of the new starting date of January 1, 1980 and publication of the Approved Lists of Bacterial Names has made mention of past synonymy obsolete. We have included synonyms of a name only if they have been published since the new starting date, or if they were also on the Approved Lists and, in rare cases with certain pathogens, if the mention of an old name would help readers associate the organism with a clinical problem. If the reader is interested in tracing the history of a name we suggest he or she consult past editions of the *Manual* or the *Index Bergeyana* and its *Supplement*. In citations of names we have used the abbreviation AL to denote the inclusion of the name on the Approved Lists of Bacterial Names and VP to show the name has been validly published.

In the matter of citation of the *Manual* in the scientific literature we again stress the fact that the *Manual* is a collection of authored chapters and the citation should refer to the author, the chapter title and its inclusive pages, not the Editor.

To all contributors, the sincere thanks of the Trust is due; the Editor is especially grateful for the good grace with which the authors accepted comments, criticisms and editing of their manuscripts. It is only because of the voluntary and dedicated efforts of these authors that the *Manual* can continue to serve the science of bacteriology on an international basis.

A number of institutions and individuals deserve special acknowledgment from the Trust for their help in bringing about the publication of this volume. We are grateful to the Department of Biology of the Virginia Polytechnic Institute and State University for providing space, facilities and, above all, tolerance for the diverted time taken by the Editor during the preparation of the book. The Department of Microbiology at Iowa State University of Science and Technology continues to provide a welcome home for the main editorial offices and archives of the Trust and we acknowledge their continued support. A grant (LM-03707) from the National Library of Medicine, National Institutes of Health to assist in the preparation of this and the next volume of the *Manual* is gratefully acknowledged.

A number of individuals deserve special mention and thanks for their help. Professor Thomas O. McAdoo of the Department of Foreign Languages and Literatures at the Virginia Polytechnic Institute and State University has given invaluable advice on the etymology and correctness of scientific names. Those assisting the Editor in the Blacksburg office were R. Martin Roop II, Don D. Lee, Eileen C. Falk and Michael W. Friedman and their help is sincerely appreciated. In the Ames office we were ably assisted by Gretchen Colletti and Diane Triggs during the early period of preparation and by Cynthia Pease during the major portion of the editing process. Mrs. Pease has been responsible for the construction of the List of References and her willingness to handle the cumbersome details of text editing on a big computer is gratefully acknowledged.

John G. Holt

Preface to the First Edition of *Bergey's Manual® of Determinative Bacteriology*

The elaborate system of classification of the bacteria into families, tribes and genera by a Committee on Characterization and Classification of the Society of American Bacteriologists (1911, 1920) has made it very desirable to be able to place in the hands of students a more detailed key for the identification of species than any that is available at present. The valuable book on "Determinative Bacteriology" by Professor F. D. Chester, published in 1901, is now of very little assistance to the student, and all previous classifications are of still less value, especially as earlier systems of classification were based entirely on morphologic characters.

It is hoped that this manual will serve to stimulate efforts to perfect the classification of bacteria, especially by emphasizing the valuable features as well as the weaker points in the new system which the Committee of the Society of American Bacteriologists has promulgated. The Committee does not regard the classification of species offered here as in any sense final, but merely a progress report leading to more satisfactory classification in the future.

The Committee desires to express its appreciation and thanks to those members of the society who gave valuable aid in the compilation of material and the classification of certain species. . . .

The assistance of all bacteriologists is earnestly solicited in the correction of possible errors in the text; in the collection of descriptions of all bacteria that may have been omitted from the text; in supplying more detailed descriptions of such organisms as are described incompletely; and in furnishing complete descriptions of new organisms that may be discovered, or in directing the attention of the Committee to publications of such newly described bacteria.

David H. Bergey, *Chairman*
Francis C. Harrison

Phylum XIV. Proteobacteria *phyl. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Pro.te.o.bac.te′ ri.a. Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Proteobacteria* the phylum of bacteria having 16S rRNA gene sequences related to those of the members of the order *Pseudomonadales*.

The phylum *Proteobacteria* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA gene sequences. The phylum contains Gram-negative bacteria in the classes *Alphaproteobacteria*, *Betaproteobacteria*, *Gammaproteobacteria*, *Deltaproteobacteria*, and *Epsilonproteobacteria*.

Type order: **Pseudomonadales** Orla-Jensen 1921, 270.

Class III. **Gammaproteobacteria** *class. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Gam.ma.pro.te.o.bac.te′ ri.a. Gr. n. *gamma* name of third letter of Greek alphabet; Gr. n. *Proteus* ocean god able to change shape; Gr. n. *bakterion* a small rod; M.L. fem. pl. n. *Gammaproteobacteria* class of bacteria having 16S rRNA gene sequences related to those of the members of the order *Pseudomonadales*.

The class *Gammaproteobacteria* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the class contains the orders *Acidithiobacillales*, *Aeromonadales*, *Alteromonadales*, *Cardiobacteriales*, *Chromatiales*, *Enterobacteriales*, *Legionellales*, *Methylococcales*, *Oceanospirillales*, *Pasteurellales*, *Pseudomonadales*, *Thiotrichales*, *Vibrionales*, and *Xanthomonadales*.

Type order: **Pseudomonadales** Orla-Jensen 1921, 270.

Order I. **Chromatiales** *ord. nov.*

Johannes F. Imhoff

Chro.ma.ti.a′ les. M.L. neut. n. *Chromatium* type genus of the order; *-ales* ending to denote an order; M.L. fem. pl. n. *Chromatiaceae* the *Chromatium* order.

The order *Chromatiales* consists of unicellular Gram-negative bacteria belonging to the *Gammaproteobacteria*. Cells are spherical, vibrioid, spiral, or rod shaped. Multiply by binary fission, motile by flagella or nonmotile; some contain gas vesicles.

The order *Chromatiales* contains anoxygenic phototrophic bacteria, known as phototrophic purple sulfur bacteria, able to perform photosynthesis under anoxic conditions without oxygen production. In addition, the order contains nonphototrophic, purely chemotrophic relatives. Color of cell suspensions of the phototrophic species ranges from purple-violet to purple-red, red, orange-brown, yellowish brown, brownish red, brown, and green. Common to all phototrophic species is the **presence of bacteriochlorophyll *a* or *b*** (see Table BXII.γ.1), and various carotenoids of the spirilloxanthin, okenone, or rhodopinal groups (Table BXII.γ.2). **Photosynthetic pigments are located in the cytoplasmic membrane, and in internal membrane systems** of different fine structure which originate from, and are continuous with, the cytoplasmic membrane.

Phototrophic species are able to grow by a photolithoautotrophic or photoorganoheterotrophic metabolism under anoxic conditions. The photosynthetic metabolism differs from that of the cyanobacteria, algae, and green plants in that water cannot serve as electron donor substrate. Photosynthetic CO_2 assimilation depends on the utilization of external electron donors such

TABLE BXII.γ.1. Bacteriochlorophylls of phototrophic purple bacteria

Pigment	Absorption maxima (nm) in living cells
Bacteriochlorophyll *a*	375–378, 590, 796–805, 820–898
Bacteriochlorophyll *b*	400, 605, 835–850, 980–1030

TABLE BXII.γ.2. Carotenoid groups of phototrophic purple bacteria[a]

Carotenoid group	Major components
Normal spirilloxanthin group	spirilloxanthin, lycopene, rhodopin
Alternative spirilloxanthin group	spheroidene, spheroidenone, chloroxanthin, (spirilloxanthin)
Okenone group	okenone
Rhodopinal group	rhodopinal, rhodopin, lycopenal, lycopene, lycopenol, spirilloxanthin

[a]Data from Schmidt (1978).

as reduced sulfur compounds, reduced iron, molecular hydrogen, or organic compounds. In the presence of sulfide and light, cells of phototrophic members of the *Chromatiales* (purple sulfur bacteria) form highly refractile globules of elemental sulfur either inside or outside their cells. CO_2 is photoassimilated through the reductive pentose phosphate cycle. Fixation of N_2 has been demonstrated in many species. All species contain cytochromes, quinones, and non-heme iron proteins of the ferredoxin type. In addition to their phototrophic capabilities, many species of this order can grow chemotrophically under microoxic to oxic conditions in the dark, but some species, such as *Arhodomonas aquaeolei* (see family *Ectothiorhodospiraceae*), may be purely chemotrophic and unable to grow phototrophically.

Type genus: **Chromatium** Perty 1852, 174 emend. Imhoff, Süling and Petri 1998b, 1138.

Further descriptive information

The available 16S rDNA sequence information for *Ectothiorhodospiraceae* (Imhoff and Süling, 1996) and *Chromatiaceae* species (DeWeerd et al., 1990; Wahlund et al., 1991; Caumette et al., 1997; Guyoneaud et al., 1997, 1998b; Imhoff et al., 1998b) supports the classification of these bacteria in two different families (Imhoff, 1984b). At the same time, it indicates the existence of different genera within the family *Ectothiorhodospiraceae* (Imhoff and Süling, 1996), and the inconsistency of the previous taxonomic classification of the family *Chromatiaceae* (see Pfennig and Trüper, 1989) with its phylogeny (Imhoff et al., 1998b). In addition, the phylogenetic relatedness of both families and their distance to other bacteria of the *Gammaproteobacteria* support their treatment within one order, for which the name *Chromatiales* is proposed. The order *Chromatiales* includes the phototrophic purple sulfur bacteria of the *Ectothiorhodospiraceae* and *Chromatiaceae* (Imhoff, 1984b, 1989; Pfennig and Trüper, 1989) and their purely chemotrophic relatives (see Figs. BXII.γ.3 and BXII.γ.4 of the chapter describing the family *Chromatiaceae*.). The purely chemotrophic bacteria known so far are specifically related to *Ectothiorhodospiraceae*. The 16S rDNA sequence of *Arhodomonas aquaeolei* (Adkins et al., 1993; Imhoff and Süling, 1996) is similar to those of *Halorhodospira* species, but clearly distinct at the genus level. In addition, sequences of *Nitrococcus mobilis* (Teske et al., 1994) and *Nitrosococcus oceani* (Head et al., 1993) place these bacteria in phylogenetic proximity to the *Ectothiorhodospiraceae*, though on a more distant level than the genus *Arhodomonas*.

***Differentiation of* Chromatiaceae *and* Ectothiorhodospiraceae** Traditionally, the most important and easily recognized distinguishing property within the phototrophic members of the order *Chromatiales* is the deposition of S^0 during growth on sulfide. Sulfur globules appear exclusively inside the cells (*Chromatiaceae*) or outside the cells (*Ectothiorhodospiraceae*). A clear distinction between the two families is also possible based on differences in quinone, lipid, and fatty acid composition (Imhoff and Bias-Imhoff, 1995). Several glucolipids are present in *Chromatiaceae* species, but absent from members of *Ectothiorhodospiraceae* (Imhoff et al., 1982a). In addition, the lipopolysaccharides show significant differences between members of the two families (Weckesser et al., 1979, 1995). The lipid A of all investigated *Chromatiaceae* species (*Allochromatium vinosum*, *Thermochromatium tepidum*, *Thiocystis violacea*, *Thiocapsa roseopersicina*, *Thiococcus pfennigii*) is characterized by a phosphate-free backbone with D-glucosamine as the only amino sugar, having terminally attached D-mannose and amide-bound $C_{14:0\ 3OH}$. In the lipid A of all tested *Ectothiorhodospiraceae* species (*Ectothiorhodospira vacuolata*, *E. shaposhnikovii*, *E. haloalkaliphila*, and *Halorhodospira halophila*), phosphate is present, 2,3-diamino-2,3-dideoxy-D-glucose is the major amino sugar (D-glucosamine is also present), D-mannose is lacking (D-galacturonic acid, and D-glucuronic acid are present instead) and, quite remarkably, $C_{10:0\ 3OH}$ is present as an amide-bound fatty acid (Zahr et al., 1992; Weckesser et al., 1995; Imhoff and Süling, 1996). These distinctive properties of the lipid A appear to be characteristic features of the two families. In addition, sequences of 16S rDNA are significantly different in representatives of the two families, as demonstrated by a number of characteristic signatures (Table BXII.γ.3) and by their overall dissimilarity (Figs. BXII.γ.3 and BXII.γ.4 of the chapter describing the family *Chromatiaceae*).

Key to the phototrophic members of the families of the Chromatiales

I. *Gammaproteobacteria* that contain bacteriochlorophyll *a* or *b* and different carotenoid pigments, have internal photosynthetic membrane structures and are able to grow phototrophically under anoxic conditions in the light.

   A. In the presence of both sulfide and light, globules of S^0 are formed inside the cells and further oxidized to sulfate.

      Chromatiaceae

   B. In the presence of both sulfide and light, globules of S^0 are formed outside the cells (only exceptionally also in the peripheral part of the cell) and may be further oxidized to sulfate. Growth is dependent on saline and alkaline growth conditions.

      Ectothiorhodospiraceae

TABLE BXII.γ.3. Differential characteristics of the phototrophic members of the families *Chromatiaceae* and *Ectothiorhodospiraceae*

Characteristic	*Chromatiaceae*	*Ectothiorhodospiraceae*
Sulfur deposition	inside cells	outside cells
Characteristics of polar lipids[a]	several glycolipids	glycolipids absent
Major fatty quinones[a]	Q8/MK8	Q7 or Q8/MK7 or MK8
Major fatty acids[a]:		
$C_{16:0}$	20–35%	11–25%
$C_{16:1}$	25–37%	<10%
$C_{18:1}$	38–45%	50–75%
Properties of lipopolysaccharides [b]:		
Major aminosugar	glucosamine	diamino-dideoxy-glucose
Phosphate	present	absent
D-Mannose	+	−
D-Galacturonic acid	−	+
D-Glucuronic acid	−	+
Amide-bound fatty acid	$C_{14:0\ 3OH}$	$C_{12:0\ 3OH}$
Signature 16S rDNA sequence [c]:		
Position 217	T	G/A[d]
Position 234–235	CA	TG/CG[d]
Position 821–822	TC	AG
Position 876–877	GA	CT
Position 985	A	T/G[d]

Family I. **Chromatiaceae** Bavendamm 1924, 125[AL] emend. Imhoff 1984b, 339

JOHANNES F. IMHOFF

Chro.ma.ti.a′ ce.ae. M.L. neut. n. *Chromatium* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Chromatiaceae* the *Chromatium* family.

Cells are spherical, ovoid, vibrioid, spiral, or rod shaped, multiply by binary fission, may contain gas vesicles, may be motile by flagella or nonmotile. Motile forms have either monotrichous or multitrichous polar flagella. **Gram negative, belong to the *Gammaproteobacteria*, and contain internal photosynthetic membranes**, which are continuous with the cytoplasmic membrane and of vesicular type in most species (Fig. BXII.γ.1), though some species have tubular internal membranes (Fig. BXII.γ.2) or lamellae. **As photosynthetic pigments, bacteriochlorophyll *a* or *b* and carotenoids of the spirilloxanthin, okenone, or rhodopinal groups are present** in most species, but other carotenoids such as tetrahydrospirilloxanthin, may occur. In general, the color of cultures of strains with carotenoids of the spirilloxanthin group is orange-brown to brownish red or pink, of those with okenone, purple-red, and of those with carotenoids of the rhodopinal group, purple-violet.

Under anoxic conditions in the light, all species are capable of photolithoautotrophic growth with sulfide or S^0 as electron donor. S^0 globules accumulate as an intermediate oxidation product inside the cells. Many species are able to use H_2 as an electron donor under reducing culture conditions, and some use reduced iron ions. All species are potentially mixotrophic and photoassimilate a number of simple organic compounds, of which acetate and pyruvate are the most widely used. Some species are able to photoassimilate organic substances in the absence of sulfide or sulfur, or grow photoorganoheterotrophically. Many species are strictly anaerobic and obligately phototrophic, while others are capable of chemolithoautotrophic or chemoorganoheterotrophic growth under microoxic to oxic conditions in the dark.

The pathway of autotrophic CO_2 assimilation was shown to be the reductive pentose phosphate cycle in all species tested so far. The fixation of dinitrogen has been demonstrated in several species. Storage materials are polysaccharides, poly-β-hydroxybutyrate, elemental sulfur, and polyphosphate. Vitamin B_{12} is required by several species.

In nature, members of the *Chromatiaceae* occur in the illuminated, anoxic, and sulfide-containing parts of a large variety of aquatic environments and sediments from moist and muddy soils, ditches, ponds, lakes, rivers, sulfur springs, estuaries, marine habitats, and even salt and soda lakes.

The mol% G + C of the DNA is: 45.5–70.4.

Type genus: **Chromatium** Perty 1852, 174 emend. Imhoff, Süling and Petri 1998b, 1138.

TAXONOMIC COMMENTS

In the eighth edition of the *Determinative Manual*, the family *Chromatiaceae* was described to include the genus *Ectothiorhodospira*, purple sulfur bacteria that form sulfur globules outside the cells (Pfennig and Trüper, 1974). With the establishment of the new family *Ectothiorhodospiraceae* and an emended description of the family *Chromatiaceae* Bavendamm 1924 (Imhoff, 1984b), the family *Chromatiaceae* exclusively comprises phototrophic sulfur bacteria capable of depositing globules of S^0 inside the cells. This description agrees with Molisch's (1907) definition of the *"Thiorhodaceae"* and is in line with their phylogenetic separation from

FIGURE BXII.γ.1. Ultrathin section of a cell of *Thiocystis gelatinosa* DSM 215 showing internal photosynthetic membranes as numerous small vesicles, which are evenly distributed throughout the cell. Bar = 1 μm (Courtesy of H.G. Trüper and J.B. Waterbury.)

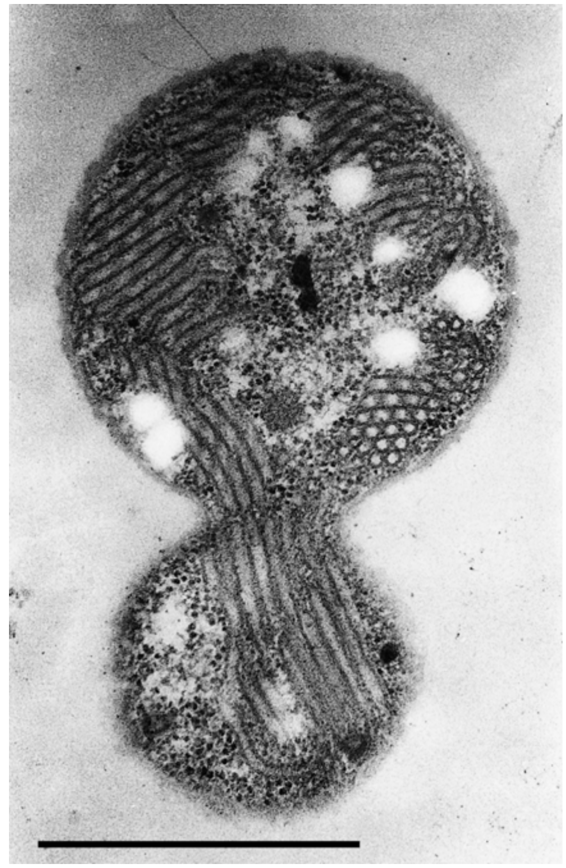

FIGURE BXII.γ.2. Ultrathin section of a cell of *Thiococcus pfennigii* strain 9111 showing tubular internal photosynthetic membranes in longitudinal and cross section. Bar = 0.5 μm (Courtesy of H.G. Trüper and J.B. Waterbury.)

other phototrophic purple sulfur bacteria (Fowler et al., 1984; Imhoff and Süling, 1996; Imhoff et al., 1998b).

In the past, the taxonomy of the phototrophic purple bacteria, including the family *Chromatiaceae*, was entirely based on simple phenotypic characteristics (see the previous editions of this *Manual*, Pfennig and Trüper, 1974, 1989). Until recently, little molecular and sequence-based information, such as rRNA oligonucleotide data for selected species (Fowler et al., 1984) and a few 16S rDNA sequences (DeWeerd et al., 1990; Wahlund et al., 1991), was available for *Chromatiaceae* species. During the past few years, complete 16S rDNA sequences for most of the *Chromatiaceae* species have been determined (see Caumette et al., 1997; Guyoneaud et al., 1998b; Imhoff et al., 1998b). At the time of writing, 16S rDNA sequences of quite a few type strains of purple sulfur bacteria have not yet been determined or are not available: *Chromatium weissei*, *Thiospirillum jenense*, *Thiodictyon elegans*, *Thiodictyon bacillosum*, *Lamprobacter modestohalophilus*, and *Thiopedia rosea*.

The results of 16S rDNA sequence analysis, shown in Figs. BXII.γ.3 and BXII.γ.4, revealed that separate major phylogenetic branches of the family *Chromatiaceae* contain i) truly marine and halophilic species; ii) species that are motile by polar flagella, do not contain gas vesicles, and are primarily freshwater species; and iii) species with ovoid to spherical cells that are primarily freshwater species (some also occur in brackish and marine habitats), the majority of which are nonmotile (except *Lamprocystis roseopersicina*), and most of which contain gas vesicles. Because the phylogenetic relationships were not in congruence with traditional classification, a reclassification based on 16S rDNA sequence similarity, supported by selected phenotypic properties, was proposed (Guyoneaud et al., 1998b; Imhoff et al., 1998b). Positive correlation between 16S rDNA sequence similarity values and particular phenotypic properties of the species were taken as an indication of the importance of these properties in achieving a phylogenetically oriented taxonomy that includes both genetic and phenotypic information (Imhoff et al., 1998b).

Ecological source and adaptation to specific environmental conditions are of importance for phylogeny and taxonomy. Evolution occurs in particular natural environments, and separate phylogenetic lineages are expected to result from bacterial evolution in distinct habitats that, due to their particular properties (e.g., extremes of temperature, salinity, and pH), allow only the development of specifically adapted bacteria. In principle, major phylogenetic branches of the family *Chromatiaceae* can be distinguished on the basis of their salt requirement, which implies a separate evolutionary development in the marine and in the freshwater environment. This suggests that the salt response is an important taxonomic criterion in a phylogenetically oriented taxonomic system of these bacteria. The salt requirement has been considered in the taxonomy of purple nonsulfur bacteria and *Ectothiorhodospiraceae*. It proved to be of relevance for distinguishing the genera *Halorhodospira* and *Ectothiorhodospira* (Imhoff and Süling, 1996), *Rhodovulum*, *Rhodobacter* (Hiraishi and Ueda, 1994), and genera of the spiral, purple nonsulfur *Alphaproteobacteria*, the former *Rhodospirillum* species (Imhoff et al., 1998b).

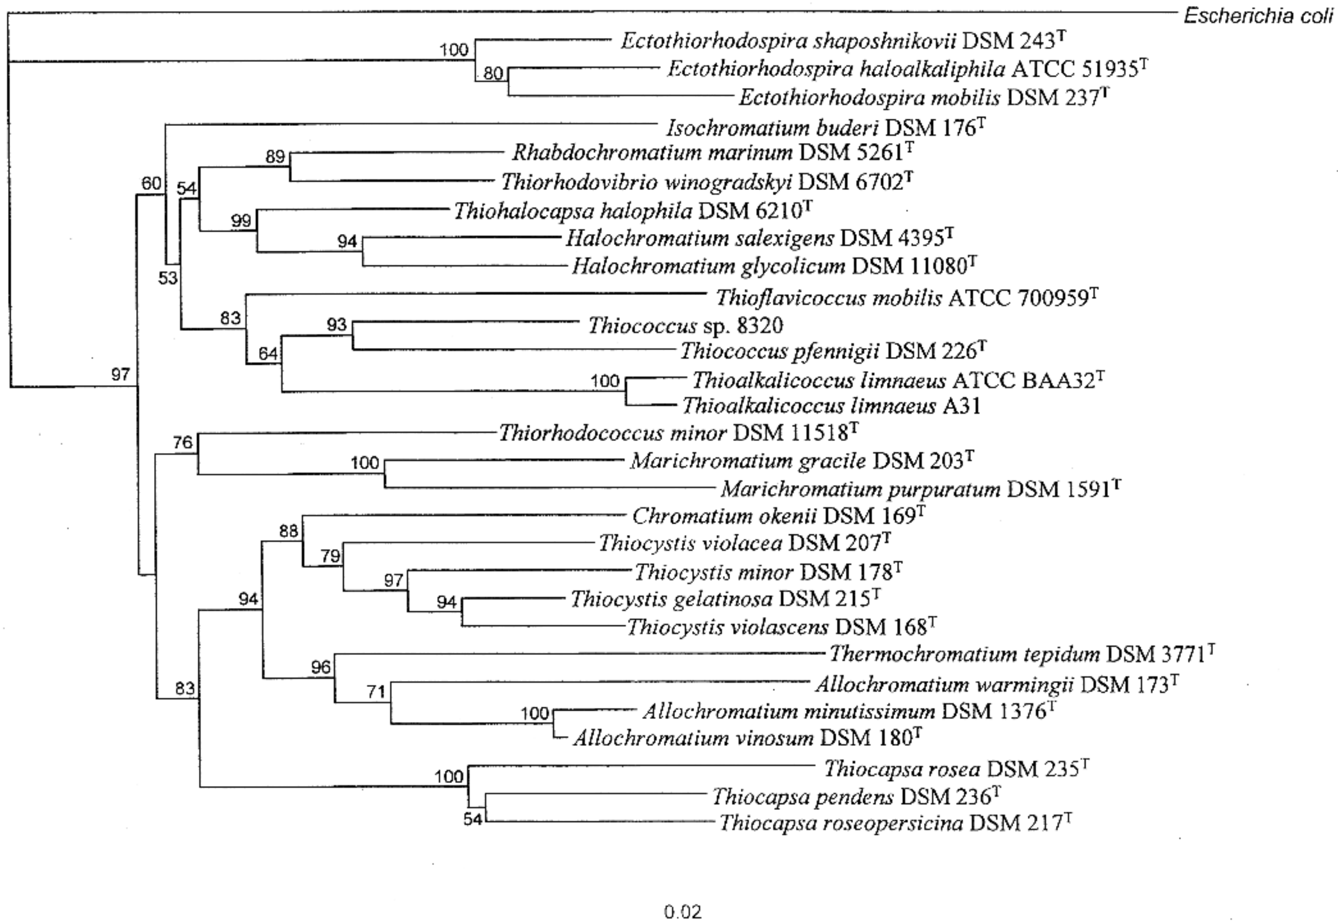

FIGURE BXII.γ.3. 16S rDNA-derived phylogenetic tree of the family *Chromatiaceae* including species of *Chromatium*, *Thiocystis*, *Allochromatium*, *Thermochromatium*, and the halophilic species *Isochromatium*, *Rhabdochromatium*, *Thiorhodovibrio*, *Thiohalocapsa*, *Thiococcus*, *Halochromatium*, *Thiorhodococcus* and *Marichromatium*. Representatives of *Thiocapsa* and *Thiolamprovum* and *Ectothiorhodospira* were included to complete the view on purple sulfur bacteria. The phylogeny of these genera is shown in more detail in Fig. BXII.γ.4 and in Fig. BXII.γ.19 in the chapter on *Ectothiorhodospiraceae*. Sequence data used were published previously (Imhoff et al., 1998b). Sequence alignments, calculation of distance data and tree construction were performed as described earlier (Petri and Imhoff 2000).

Within the family *Chromatiaceae*, both the phylogenetic relationship and the salt responses enable us to distinguish the halophilic *Halochromatium* species from the marine *Marichromatium* and the freshwater *Allochromatium* species, all of which were previously known as species of the genus *Chromatium* (Imhoff et al., 1998b). A differentiation of groups of species is also possible based on compatible solute production. Different compatible solutes are accumulated as osmotica by *Chromatiaceae* species compared to *Ectothiorhodospiraceae* species (Severin et al., 1992; Imhoff, 1993; Welsh and Herbert, 1993). Ectoine, trehalose, and glycine betaine are common among *Ectothiorhodospira* and *Halorhodospira* species, but not found in *Chromatiaceae*. Instead of trehalose, the less compatible sugar sucrose was found as the major component in freshwater species including *Allochromatium vinosum*, *Thiocystis violacea*, *Thiocystis minor*, *Thiocapsa roseopersicina*, and *Thiocapsa rosea* (Welsh and Herbert, 1993). Among the halophilic and marine species (*Halochromatium salexigens*, *Thiohalocapsa halophila*, and *Marichromatium purpuratum*), glycine betaine appears to occur as the major component, along with sucrose and *N*-acetyl-glutaminylglutamine amide (Severin et al., 1992; Imhoff, 1993).

Although morphological properties of the cells appear to be of lower phylogenetic significance, it is apparent that one group of freshwater *Chromatiaceae* species contains motile single cells without gas vesicles (e.g., *Chromatium* and *Allochromatium* species, see Fig. BXII.γ.3), and the possession of gas vesicles is restricted to a second group with predominantly spherical to ovoid cells that are nonmotile (e.g., *Thiocapsa* and *Thiolamprovum* species, with the exception of *Lamprocystis roseopersicina*, see Fig. BXII.γ.4).

The DNA base ratio within the family *Chromatiaceae*, expressed as the mol% G + C content, has been found to span a large scale. Thus, in the previous edition of the *Manual* the genus *Chromatium* (Pfennig, 1989b) had values ranging from 48.0 to 70.4. Because the mol% G + C content is crudely indicative of the genetic relatedness of bacteria, these values already suggested excessive diversity within the genus *Chromatium*. A phylogenetic system would be expected to group bacteria that have much less variation in their mol% G + C content together. Indeed, after rearrangement of the species of the family *Chromatiaceae* according to their genetic relatedness on the basis of 16S rDNA sequence analysis (Guyoneaud et al., 1998b; Imhoff et al., 1998b), a quite narrow range of mol% G + C content is found within most of the newly established genera. The ranges are ~63–66 in the cluster including species of *Thiocapsa*, *Lamprocystis*, and *Thiolamprovum*, 69–70 in *Marichromatium* species, 64–66 in *Halochromatium* species, and 48–50 in the true *Chromatium* species. This correlation appears of such significance, that any case of high

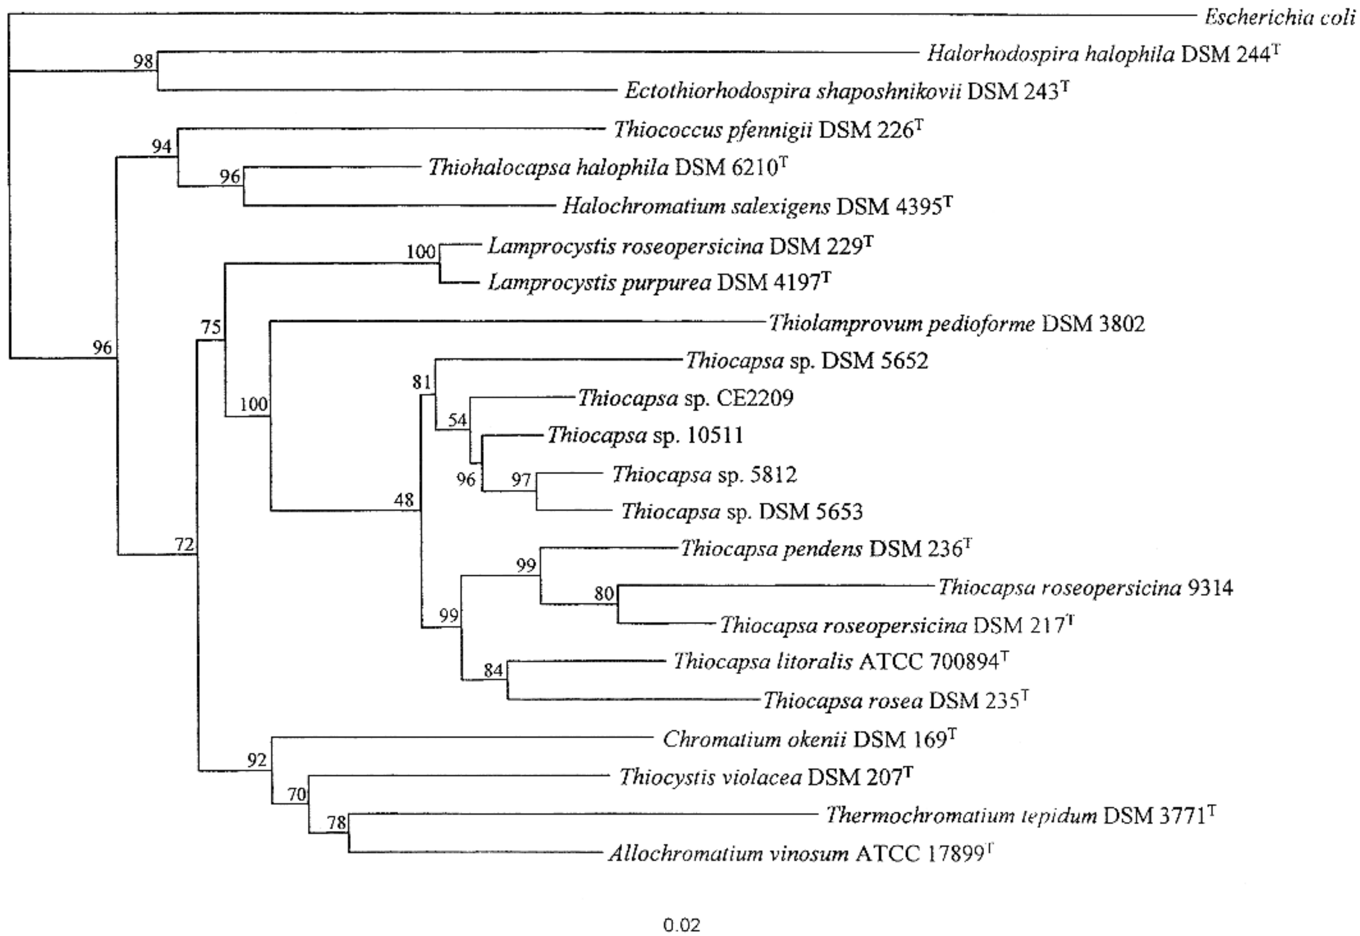

FIGURE BXII.γ.4. 16S rDNA-derived phylogenetic tree of the family *Chromatiaceae* including species of *Thiocapsa*, *Lamprocystis* and *Thiolamprovum*. Representatives of *Ectothiorhodospiraceae* and other *Chromatiaceae* genera were included to complete the view on purple sulfur bacteria. The phylogeny of these genera is shown in more detail in Fig. BXII.γ.3 and in Figure BXII.γ.19 in the chapter on *Ectothiorhodospiraceae*. Sequence data used were published previously (Guyoneaud et al., 1998b; Imhoff et al., 1998b). Sequence alignments, calculation of distance data and tree construction were performed as described earlier (Petri and Imhoff 2000).

intrageneric and intraspecies variation of the mol% G + C content necessitates experimental examination. For example, the high intraspecies variation that has been noted for *Allochromatium vinosum* (61.3–66.3), *Allochromatium warmingii* (55.1–60.2), and *Thiocystis violacea* (62.8–67.9) suggests misclassification of some strains. Further studies are needed to clarify these problems.

Although fatty acid and quinone composition is of great significance for classification of purple nonsulfur bacteria of the *Alphaproteobacteria* and *Betaproteobacteria*, and these compounds are well-accepted tools for taxonomic differentiation of phototrophic bacteria (Imhoff, 1991, 1984a; Imhoff and Bias-Imhoff, 1995; Thiemann and Imhoff, 1996), both show only minor variation and therefore are of minor significance for differentiation within the family *Chromatiaceae* (Imhoff and Bias-Imhoff, 1995). Polar lipids have been analyzed so far in only a limited number of *Chromatiaceae* species. First results, obtained with several freshwater species, showed significant correlations with the new classification, i.e., identical polar lipid composition was found i) in *Allochromatium vinosum* and *Allochromatium warmingii*, ii) in all four *Thiocystis* species, and iii) in the two *Chromatium* species (Imhoff, unpublished results). Thus, polar lipid composition may well turn out to be a relevant property for distinguishing between genera or groups of genera of the family *Chromatiaceae*. This implies that the polar lipid composition reflects phylogenetic relationships and is a rather stable property in evolutionary terms. More analytical data on members of the family *Chromatiaceae* are required to support this concept.

Further Comments Physiological properties have always been important characteristics in taxonomy, although their taxonomic significance is ambiguous. On the one hand, members of the family *Chromatiaceae* are quite conservative in their use of sulfur sources and their restricted use of organic carbon sources: all species are able to grow photolithoautotrophically under anoxic conditions in the light using sulfide or S^0 as an electron donor. On the other hand, we can distinguish two major physiological groups, versatile and specialized species. (i) The specialized species depend on strictly anoxic conditions and are obligately phototrophic. Sulfide is required; thiosulfate and hydrogen are not used as electron donors. Only acetate and pyruvate (or propionate) are photoassimilated in the presence of sulfide and CO_2. These bacteria do not grow with organic electron donors, chemotrophic growth is not possible, and sulfate is not assimilated as a sulfur source. Among these species are *Chromatium okenii*, *Chromatium weissei*, *Allochromatium warmingii*, *Isochromatium buderi*, *Thiospirillum jenense*, and *Thiococcus pfennigii*. (ii) The versatile species photoassimilate a larger variety of organic substrates. Most of them are able to grow in the absence of reduced sulfur sources with organic substrates as electron donors for photosynthesis, and to assimilate sulfate as the sole sulfur

source. Some species even grow chemoautotrophically or chemoheterotrophically (Gorlenko, 1974; Kondrat' eva et al., 1976; Kämpf and Pfennig, 1980, 1986). Among these species are *Allochromatium vinosum*, *Thiocystis violacea*, *Thiocapsa roseopersicina*, *Thiocapsa rosea*, *Thiocapsa pendens*, and *Lamprobacter modestohalophilus*.

Depending on the environmental conditions in nature or on the culture conditions, all species are able to develop either in the form of single cells or in immobile cell aggregates of variable size and shape embedded in slime. The different modes of growth described by Winogradsky (1888) may be obtained experimentally by varying sulfide concentration, light intensity, pH, salinity, temperature, and oxygen tension. At high sulfide concentration (2–4 mM) and high light intensity (2000–4000 lux), all flagellated species become immobile as the result of slime formation that embeds groups of cells. For a given light intensity, the various species differ from each other with respect to the sulfide concentration at which the cells develop functional flagella and become motile. For a given sulfide concentration, the species differ with respect to the light intensity and mode of illumination (diurnal light and dark periods) which allow the cells to become motile. The lower the light intensity (100–200 lux), the higher the sulfide concentration at which a given strain can persist in the motile stage. These characteristics must be considered for reliable identification of pure cultures.

Differentiation of the genera of the *Chromatiaceae* Three major genetically distinct groups of the family *Chromatiaceae* are known: i) a group of truly halophilic and salt-requiring species of the genera, including *Thiorhodovibrio*, *Marichromatium*, *Isochromatium*, *Rhabdochromatium*, *Thiohalocapsa*, *Halochromatium*, *Thiorhodococcus*, *Thiococcus*, *Thioflavicoccus*, and *Thioalkalicoccus*; ii) a group that is dominated by spherical or rod-shaped nonmotile species, many of which produce gas vesicles and that are primarily freshwater bacteria (including species of the genera *Thiocapsa*, *Lamprocystis*, and *Thiolamprovum*); and iii) a group of motile species without gas vesicles that are primarily freshwater bacteria and include the genera *Chromatium*, *Allochromatium*, *Thermochromatium*, and *Thiocystis*. In both of the freshwater clusters, strains or species that may behave indifferently to low salt concentra-

TABLE BXII.γ.4. Differential characteristics of the motile *Chromatiaceae* without gas vesicles typically found in freshwater habitats[a]

Genus I. **Chromatium** *Perty 1852, 174[AL] emend. Imhoff, Süling and Petri 1998b, 1138*

JOHANNES F. IMHOFF

Chro.ma'ti.um. Gr. n. *chroma* color; M.L. neut. n. *Chromatium* one which is colored.

Cells are **straight or slightly curved rods**, more than 3 μm wide, single or in pairs, multiply by binary fission. **Motile** by a polar tuft of multitrichous flagella that can be seen in the light microscope, Gram negative, belong to the *Gammaproteobacteria*, and contain **internal photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Strictly anaerobic, obligately phototrophic, and require sulfide-reduced media. **Photolithoautotrophic growth occurs under anoxic conditions in the light with sulfide and S^0 as electron donors**. Thiosulfate and hydrogen are not used. During oxidation of sulfide, S^0 is transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. In the presence of sulfide or sulfur and bicarbonate, a few simple organic substrates are photoassimilated. Assimilatory sulfate reduction is lacking. Ammonia is used as nitrogen source, N_2 may be used, nitrate is not reduced. Storage materials: polysaccharides, poly-β-hydroxybutyrate, S^0, and polyphosphates. Vitamin B_{12} required.

Mesophilic freshwater bacteria with optimum growth temperatures from 20 to 35°C and without a distinct requirement for salt.

Habitat: water and sediment surface layers of stagnant freshwater habitats such as ditches, ponds, and lakes, containing hydrogen sulfide and exposed to light.

The mol% G + C of the DNA is: 48.0–50.0.

Type species: **Chromatium okenii** (Ehrenberg 1838) Perty 1852,174 (*Monas okenii* Ehrenberg 1838, 15.)

FURTHER DESCRIPTIVE INFORMATION

Under unfavorable culture conditions, cells of *Chromatium* species may not show active motility when viewed under the microscope. Diurnal light and dark phases, low concentrations of sulfide, and low light intensities may be required to sustain active flagellar motility. Optimal growth conditions are clearly recognized by the bioconvection patterns that arise because of the swarming activity of the cells and that can be seen with the naked eye (Pfennig, 1962).

ENRICHMENT AND ISOLATION PROCEDURES

Chromatium okenii and *C. weissei* have so far been found only in sulfide-containing freshwater habitats, which is of primary importance for the design of enrichment experiments. Because of the selectivity of any enrichment condition, even species and strains that were not detected in the original sample from the natural habitat may become dominant in liquid enrichment cultures. Therefore, enrichment cultures are only indicated when a certain species should be enriched and isolated from a natural sample, and selective conditions for this bacterium are known. When information on the diversity of culturable species in a natural sample is desired, enrichment cultures should be avoided and dilution series in agar deeps should be prepared directly from the natural sample. Agar cultures should be incubated under conditions similar to those used for liquid cultures of the desired bacteria. The defined medium[1] proved to be relatively nonspecific and may be used for the cultivation of not only *Chromatium* species, but also most of the freshwater and, with the addition of appropriate concentrations of NaCl, marine *Chromatiaceae* species. A somewhat simpler, but less widely applicable, culture medium was described by Pfennig and Trüper (1981). In agar shake dilution cultures, growth may be enhanced by the addition of 3 mM acetate to the defined medium.

Chromatium species have a selective advantage when cultures with relatively low sulfide concentrations (1–2 mM) are incubated at about 20°C, at low light intensities of 50–300 lux with diurnal light and dark phases (e.g., 16 h light, 8 h dark). They keep swarming throughout the whole bottle and can be further enriched by using cell suspensions from the upper part of the enrichment culture as inoculum for subsequent enrichments (Pfennig, 1962).

The sulfide concentration initially provided in fresh culture medium does not support much growth. To achieve reasonably high population densities in enrichments or pure cultures, repeated additions of neutralized sodium sulfide solution are necessary. Additions are made when the previously added sulfide is consumed and the transiently stored S^0 is nearly oxidized. The sulfide solution for feeding of cultures can be prepared by neutralizing a stirred sodium sulfide solution (60 mM) with a certain amount of sterile 2 M sulfuric acid to a pH of ~7.5. This neutralized solution has to be applied immediately. Preferably, a special device for preparation of sterile sulfide solution, neutralized and stored under CO_2-pressure, would be used (Siefert and Pfennig, 1984).

Pure cultures are obtained by repeated application of the agar shake dilution method. Water agar is prepared with 1.8% (w/v) of agar. Before the solution is prepared, the agar should be washed several times in distilled water. Depending on the salinity of the sample from nature or the enrichment culture medium, appropriate amounts of NaCl and $MgCl_2 \cdot 6H_2O$ are added. The agar solution is dispensed in 3-ml amounts into test tubes, which are stoppered with cotton plugs and autoclaved. The agar tubes are kept molten in a water bath at 50°C. Ready-prepared, defined

1. Defined medium for *Chromatium* and other freshwater and marine *Chromatiaceae* species after Pfennig (Pfennig, 1965, 1989b; Pfennig and Trüper, 1981, 1992): The medium is prepared in an Erlenmeyer flask with an outlet near the bottom at one side. Connected to the outlet is a silicon rubber tube with a pinchcock, and a bell for aseptic distribution of the medium into bottles or tubes. The flask is closed by a silicon rubber stopper with an inlet and an outlet for gas, and a screw-capped glass tube through which additions can be made or samplings taken.

The defined basal medium has the following composition (per liter of distilled water): KH_2PO_4, 0.34 g; NH_4Cl, 0.34 g; KCl, 0.34 g; $CaCl_2 \cdot 2H_20$, 0.25 g; NaCl (only for seawater medium), 20.0 g; $MgSO_4 \cdot 7H_2O$ (3.0 g for seawater medium), 0.5 g; and trace element solution, 1 ml. After the medium has been autoclaved and cooled under an atmosphere of N_2, the following components are added aseptically per liter of medium from sterile stock solutions, while access of air is prevented by continuous flushing with N_2: 15 ml of a 10% (w/v) solution of $NaHCO_3$ (saturated with CO_2 and autoclaved under a CO_2 atmosphere), 4 ml of a 10% (w/v) solution of $Na_2S \cdot 9H_20$ (autoclaved under an N_2 atmosphere), and 1 ml of a vitamin B_{12} solution containing 2 mg vitamin B_{12} in 100 ml of distilled water. The pH of the medium is adjusted to pH 7.2 by stirring under an atmosphere of CO_2 (0.5 bar pressure) for approx. 40 min. The medium is then dispensed aseptically under pressure of N_2 into sterile 100-ml bottles with metal screw caps containing autoclavable rubber seals. A small pea-sized air bubble is left in each bottle to meet possible pressure changes. Trace element solution (SL12 of Pfennig and Trüper, 1992) contains (per liter of distilled water): ethylenediaminetetraacetate-Na_2, 3.0 g; $FeSO_4 \cdot 7H_20$, 1.1 g; $CoCl_2 \cdot 6H_20$, 190 mg; $MnCl_2 \cdot 4H_20$, 40 mg; $ZnCl_2$, 42 mg; $Na_2MoO_4 \cdot 2H_20$, 18 mg; $NiCl_2 \cdot 6H_20$, 24 mg; H_3BO_3, 300 mg; and $CuCl_2 \cdot 2H_20$, 2 mg. The EDTA-Na_2 is dissolved first, followed by the other components. More information on preparation of media and on isolation procedures is described in Pfennig and Trüper (1992).

culture medium is prewarmed to 50°C, and 6-ml amounts are added to the tubes of liquefied agar. Exposure to air is minimized by dipping the tip of the pipette into the agar medium. Starting with a few drops of sample from nature or an enrichment culture as inoculum and using 6–8 tubes, serial dilutions are made. All tubes are then hardened in cold water and immediately sealed with a sterile overlay consisting of 1 part paraffin wax and 3 parts paraffin oil. The overlay should be 2 cm thick. Alternatively, the tubes are finally flushed with N_2/CO_2 (90:10) and sealed with butyl rubber stoppers. The tubes are kept in the dark for 6–12 h and subsequently incubated at the desired light intensity and temperature. During the first 2 days of incubation, the paraffin overlay is gently reheated to achieve a complete sealing effect. Well-separated pink, purple-red, purple-violet, or orange-brown colonies that develop in the higher dilutions can be removed for microscopic examination and further purification with sterile Pasteur pipettes, without breaking the tube. The cells are suspended in 0.5–1.0 ml of anoxic medium and used as the inoculum for subsequent agar shake cultures. The process is repeated until a pure culture is achieved.

When pure agar cultures are obtained, individual colonies are isolated and inoculated into liquid medium. It is advisable to start with small-sized bottles or screw-capped tubes (10 or 25 ml), and then to scale up to the regularly used sizes. Purity is checked both microscopically and by use of AC medium (Difco), adjusted to the appropriate salinity.

Maintenance Procedures

Pure cultures of *Chromatium* species can be maintained in the defined mineral medium, preferably in 100-ml screw-capped bottles. The freshly grown cultures are supplemented with neutralized sulfide solution to a final concentration of 1.5 mM, and kept in the light for about 2 h until the cells have formed intracellular sulfur globules. At this stage, the stock cultures can be stored at 4°C for 2–3 months. The cultures keep well if they are put back under dim light at room temperature and supplemented again with neutralized sulfide solution. After formation of sulfur globules, the cultures are put back into the refrigerator.

Long-term preservation of *Chromatium* species is successfully performed by storage in liquid nitrogen. For this purpose, dense cell suspensions of liquid cultures are supplemented with DMSO as a protective agent to a final concentration of 5%, using an autoclaved 50% DMSO stock solution. Such suspensions are dispensed into 2-ml plastic ampules, which are then sealed and freeze-stored. *Chromatium* species do not survive lyophilization and cannot be preserved in this way.

Differentiation of the genus *Chromatium* from other genera

According to 16S rDNA sequence analysis (Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*), the genus *Chromatium* belongs to the branch of the family *Chromatiaceae* that characteristically contains freshwater species with flagellar motility. Species of this genus have very low mol% G + C values (48–50), large-sized cells (more than 3 μm wide), require vitamin B_{12}, and lack the capability for chemotrophic growth. Characteristics for differentiation of *Chromatium* species from other phototrophic members of the *Chromatiaceae* are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*. The genetic relationship between *Chromatium* species and other members of the *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

In the past, all rod-shaped, motile, purple sulfur bacteria without gas vesicles that store S^0 inside their cells were classified as *Chromatium* species (Pfennig and Trüper, 1989). These species were not only phenotypically quite diverse, but also distantly related on a genetic basis, as indicated by the large variation in DNA base ratio within these bacteria (48.0–70.4 mol% G + C). 16S rDNA sequence analysis of recognized species of the family *Chromatiaceae* gave support for a new classification, in which the type species of the genus, *Chromatium okenii*, appeared distant and separate from most of the other species previously assigned to this genus. The only other species showing sufficient phenotypic similarity to *C. okenii* to allow assignment to this genus is *C. weissei* (Imhoff et al., 1998b), although 16S rDNA sequence data for this species are currently not available.

Differentiation of the species of the genus *Chromatium*

The most significant known difference between *C. okenii* and *C. weissei* is the cell width (Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*).

List of species of the genus Chromatium

1. **Chromatium okenii** (Ehrenberg 1838) Perty 1852, 174[AL]
(*Monas okenii* Ehrenberg 1838, 15.)
o.ken'i.i. M.L. gen. n. *okenii* of Oken, named for L. Oken, a German naturalist.

Cells straight or slightly curved rods, 4.5–6.0 × 8–16 μm, occasionally longer, motile by a polar tuft of flagella which is 1.5–2 times the cell length and visible by brightfield (Fig. BXII.γ.5) or phase-contrast microscopy. In the presence of sulfide and light, globules of elemental sulfur appear evenly distributed within the cell. Color of individual cells and of cell suspensions is purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoid okenone.

Strictly anaerobic and obligately phototrophic. Sulfide-reduced media required. Sulfide and S^0 used as photosynthetic electron donors. In the presence of sulfide and bi-

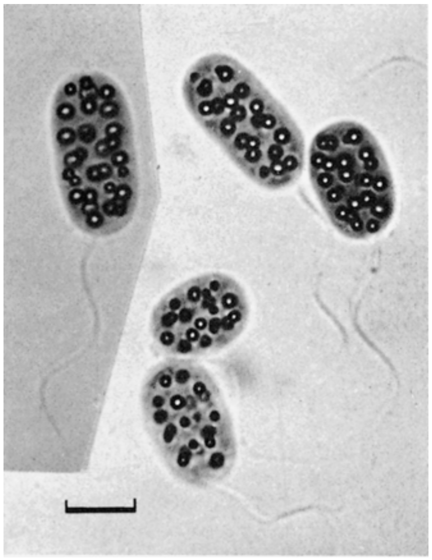

FIGURE BXII.γ.5. *Chromatium okenii* DSM 169 cultured photoautotrophically with sulfide. Note the evenly distributed intracellular globules of S^0 and the spiral tufts of polar flagella. Brightfield micrograph. Bar = 5 μm.

carbonate, acetate and pyruvate are photoassimilated. Not utilized: thiosulfate, molecular hydrogen, sugars, sugar alcohols, alcohols, higher fatty acids, amino acids, benzoate, formate, and most intermediates of the tricarboxylic acid cycle. Assimilatory sulfate reduction is absent. Nitrogen sources: ammonium salts, and urea. Vitamin B_{12} required.

Mesophilic freshwater bacterium with optimum growth at 20–35°C and pH 7.0 (range 6.5–7.3).

Habitat: water and sediment surface layers of stagnant freshwater habitats such as ditches, ponds, and lakes, containing hydrogen sulfide and exposed to light.

The mol% G + C of the DNA is: 48.0 (Bd).

Type strain: 1111, BN 6010, DSM 169.

GenBank accession number (16S rRNA): AJ223234, Y12376.

2. **Chromatium weissei** Perty 1852, 174[AL]

weis' se.i. M.L. gen. n. *weissei* of Weisse, named for J.F. Weisse, a German zoologist.

Cells are rod shaped, 3.5–4.5 × 7–14 μm. Nitrogenase activity is present. Other characteristics are as for *C. okenii.*

The mol% G + C of the DNA is: 48.0 (Bd).

Type strain: DSM 171.

Genus II. **Allochromatium** *Imhoff, Süling and Petri 1998b, 1140[VP]*

JOHANNES F. IMHOFF

Al'lo.chro.ma' ti.um. Gr. adj. *allos* the other; *Chromatium* a genus name; M.L. neut. n. *Allochromatium* the other *Chromatium*.

Cells straight to slightly curved rods, single or in pairs, multiply by binary fission, **motile by polar flagella**, Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Photolithoautotrophic growth occurs under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 is transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. Molecular hydrogen and thiosulfate may be used as electron donors. In the presence of sulfide and bicarbonate, organic substrates can be photoassimilated, potentially mixotrophic. **Some species may grow chemoautotrophically or chemoorganotrophically under microoxic to oxic conditions in the dark**. Storage materials: polysaccharides, poly-β-hydroxybutyrate, S^0, and polyphosphates. Vitamin B_{12} is required.

Mesophilic bacteria with growth at 25–35°C and pH 6.5–7.6. No distinct requirement for salt, except for strains that originate from the marine and brackish water environment and may tolerate or require low concentrations of salt.

Habitat: ditches, ponds, and lakes with stagnant freshwater containing hydrogen sulfide and exposed to the light; also sewage lagoons, estuaries, and salt marshes.

The mol% G + C of the DNA is: 55.1–66.3.

Type species: **Allochromatium vinosum** (Ehrenberg 1838) Imhoff, Süling and Petri 1998b, 1141 (*Chromatium vinosum* (Ehrenberg 1838) Winogradsky 1888, 99; *Monas vinosa* Ehrenberg 1838, 11.)

Enrichment and Isolation Procedures

Media and culture conditions are the same as described for *Chromatium* species. *Allochromatium vinosum* is one of the most common purple sulfur bacteria in nature. Since it is a nonfastidious purple sulfur bacterium, it can be readily isolated. *Allochromatium vinosum* is enriched at high sulfide concentrations (3–4 mM), at high light intensities of more than 1000 lux and at incubation temperatures of 20–30°C. This species is among the dominant members of the *Chromatiaceae* in enrichment cultures under strictly autotrophic conditions, but also in the presence of organic substrates and complex nutrients, if present in the sample. *Allochromatium* species can also be isolated directly by agar shake dilution cultures from samples collected in nature, as described for *Chromatium* species.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Allochromatium* from other genera

According to 16S rDNA sequence analysis, the genus *Allochromatium* belongs to the branch of the family *Chromatiaceae* containing motile freshwater species and characterized by rod-shaped bacteria. Characteristics for differentiation of *Allochromatium* species from other phototrophic members of the *Chromatiaceae* are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationships of *Allochromatium* species to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, are shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Although salt requirements are obviously important properties for the taxonomic characterization of *Chromatiaceae* species, the

congruence between phylogenetic position and salt response requires further attention in a few species. Species such as *Allochromatium vinosum* have been reported to occur in freshwater, brackish water, and marine habitats. Large differences in the mol% G + C content of the DNA of strains assigned to this species (61.3–66.3) may indicate genetic heterogeneity. So far, clear proof of identity of various isolates from marine habitats tentatively assigned to *Allochromatium vinosum* is lacking, because of improper physiological and genetic (DNA–DNA hybridization, 16S rDNA sequences) characterization. Further studies are needed, to show whether differences in base composition are related to the marine or freshwater nature of these bacteria.

The strain HPC, which was tentatively identified as a strain of *"Chromatium vinosum"* (Bauld et al., 1987), was certainly misidentified and does not belong to this species. This strain has an optimum salt concentration for growth of 2.5–4.5% NaCl, which may indicate membership to the genus *Halochromatium*. Further studies should allow its taxonomic position to be determined.

Phylogenetic relationships among the *Chromatiaceae*, their taxonomic reclassification and description of the new genera *Allochromatium*, *Halochromatium*, *Isochromatium*, *Marichromatium*, *Thiococcus*, *Thiohalocapsa*, and *Thermochromatium*. Int. J. Syst. Bacteriol. *48*: 1129–1143.

Differentiation of the species of the genus *Allochromatium*

The genus *Allochromatium* contains two easily distinguished groups of species. *A. vinosum* and *A. minutissimum* are physiologically versatile species that do not require growth factors, grow chemoautotrophically, have rather high tolerance towards sulfide, and use thiosulfate, hydrogen, and organic compounds as photosynthetic electron donors. *A. warmingii*, on the other hand, is a specialized species that requires vitamin B_{12} as a growth factor, tolerates only rather low concentrations of sulfide, and is a strictly anaerobic and phototrophic bacterium. Differential characteristics of *Allochromatium* species are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*. Presently known *Allochromatium* species can easily be distinguished on the basis of their cell diameter: Cells 2.0 μm wide, *A. vinosum*; cells 1–1.2 μm wide, *A. minutissimum*; cells 3.5–4.0 μm wide, *A. warmingii*.

List of species of the genus Allochromatium

1. **Allochromatium vinosum** (Ehrenberg 1838) Imhoff, Süling and Petri 1998b, 1141[VP] (*Chromatium vinosum* (Ehrenberg 1838) Winogradsky 1888, 99; *Monas vinosa* Ehrenberg 1838,11.)

vi.no′sum. L. neut. adj. *vinosum* full of wine.

Cells are rod shaped, 2 × 2.5–6 μm, occasionally longer. Globules of S^0 evenly distributed within the cell (Fig. BXII.γ.6). Single cells are colorless, color of growing cultures first yellowish to orange-brown, later brownish red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin group.

Grow phototrophically under anoxic conditions in the light or chemotrophically under microoxic to semioxic conditions in the dark (Kämpf and Pfennig, 1980). Both chemotrophic and phototrophic growth is possible under autotrophic and heterotrophic conditions. Photosynthetic electron donors: sulfide, sulfur, thiosulfate, sulfite, molecular hydrogen, formate, acetate, propionate, pyruvate, fumarate, malate, and succinate. Some strains utilize butyrate. Not utilized: sugars, sugar alcohols, alcohols, benzoate, citrate, and amino acids. Assimilatory sulfate reduction occurs (Thiele, 1968). Nitrogen sources: ammonium salts and N_2.

Mesophilic freshwater bacterium with optimum growth at 25–35°C and pH 7.0–7.3 (range 6.5–7.6). Marine isolates may tolerate or require low concentrations of NaCl.

Habitat: ponds and lakes with stagnant freshwater, sewage lagoons, brackish waters, estuaries, salt marshes, and marine habitats containing hydrogen sulfide and exposed to light. Among the most widely occurring species of the family *Chromatiaceae*.

The mol% G + C of the DNA is: 61.3–66.3 (Bd); type strain 64.3 (Bd).

Type strain: D, BN 5110, ATCC 17899, DSM 180.

GenBank accession number (16S rRNA): M26629.

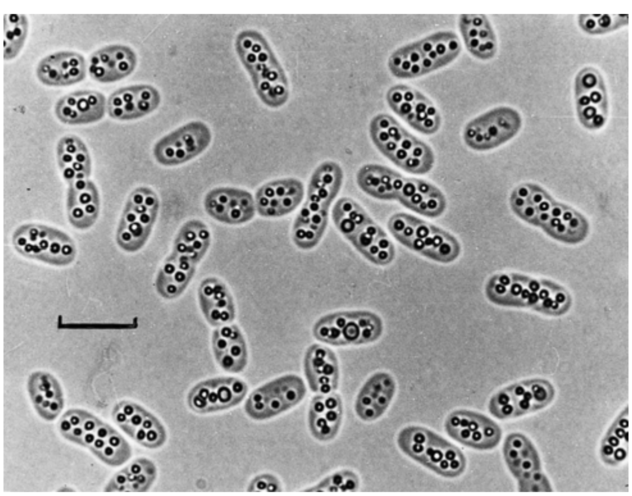

FIGURE BXII.γ.6. *Allochromatium vinosum* ATCC 17899 cultured photoautotrophically with sulfide. The cells contain sulfur globules. Brightfield micrograph. Bar = 5 μm.

2. **Allochromatium minutissimum** (Winogradsky 1888) Imhoff, Süling and Petri 1998b, 1141[VP] (*Chromatium minutissimum* Winogradsky 1888, 100.)

mi.nu.tis′si.mum. L. neut. sup. adj. *minutissimum* very small, smallest.

Cells are rod shaped, 1–1.2 × 2 μm. Other characteristics are the same as for *A. vinosum*.

The mol% G + C of the DNA is: 63.7 (Bd).

Type strain: MSV, BN 5310, DSM 1376.

GenBank accession number (16S rRNA): Y12369.

3. **Allochromatium warmingii** (Cohn 1875) Imhoff, Süling and Petri 1998b, 1141[VP] (*Chromatium warmingii* (Cohn 1875) Migula 1900, 1048; *Monas warmingii* Cohn 1875, 167.)

war.min′gi.i. M.L. gen. n. *warmingii* of Warming; named for E. Warming, a Danish botanist.

Cells ovoid to rod shaped, 3.5–4.0 × 5–11 μm, sometimes longer, motile by a flagellar tuft which is usually 1.5–2 times the cell length and visible by brightfield or phase-contrast microscopy. In the presence of sulfide and light, globules of S^0 are predominantly located at the two poles

of the cell. Dividing cells form additional sulfur globules near the central division plane (Fig. BXII.γ.7). Color of individual cells is grayish to slightly pink, color of cell suspensions pinkish to purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group.

Strictly anaerobic and obligately phototrophic. Sulfide-reduced media required. Sulfide and S^0 used as photosynthetic electron donors. In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Not utilized: thiosulfate, sugars, alcohols, higher fatty acids, amino acids, benzoate, formate, and most intermediates of the tricarboxylic acid cycle. Assimilatory sulfate reduction is absent. Nitrogen sources: ammonium salts, urea, and N_2. Vitamin B_{12} required.

Freshwater bacterium with optimum growth at 25–30°C and pH 7.0 (pH range 6.5–7.3).

Habitat: ditches, ponds, and lakes with stagnant freshwater containing hydrogen sulfide and exposed to light.

The mol% G + C of the DNA is: 55.1–60.2 (Bd); type strain 55.1 (Bd).

Type strain: 6512, ATCC 14959, BN 5810, DSM 173.

GenBank accession number (16S rRNA): Y12365.

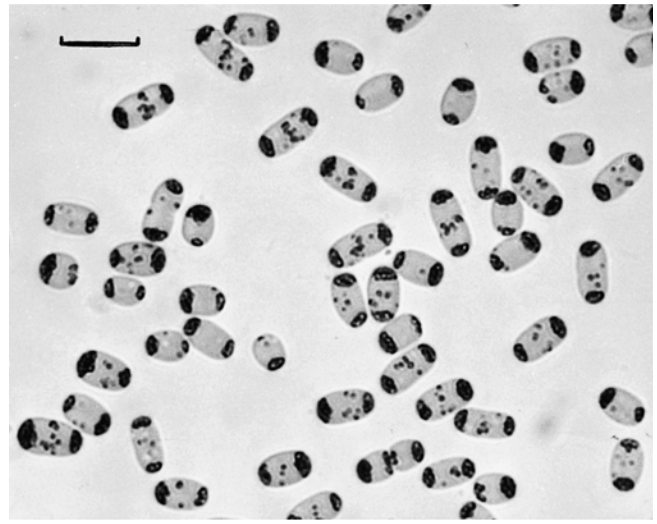

FIGURE BXII.γ.7. *Allochromatium warmingii* DSM 173 cultured photoautotrophically with sulfide. Note the polarly located globules of S^0. Dividing cells also deposited sulfur globules at the newly formed cross-walls. Bright-field micrograph. Bar = 5 μm.

Genus III. **Halochromatium** *Imhoff, Süling and Petri 1998b, 1139*[VP]

Johannes F. Imhoff and Pierre Caumette

Ha'lo.chro.ma' ti.um. Gr. gen. n. *halos* of the salt; *Chromatium* a genus name; M.L. neut. n. *Halochromatium* the *Chromatium* of the salt.

Cells straight to slightly curved rods, single or in pairs, multiply by binary fission. **Motile by polar flagella**, Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donor. During oxidation of sulfide, S^0 is formed as an intermediate and stored in the form of highly refractile globules inside the cells. Sulfate is the final oxidation product. Hydrogen may be used as electron donor. In the presence of sulfide and bicarbonate, organic substrates can be photoassimilated. **Chemolithotrophic and chemoorganotrophic growth under microoxic conditions in the dark is possible**.

Mesophilic bacteria with optimum growth at 20–35°C, and pH 7.2–7.6. **Elevated salt concentrations are required for growth**.

Habitat: Reduced sediments in salinas, microbial mats in hypersaline environments, and coastal lagoons with elevated salt concentrations, which are exposed to the light.

The mol% G + C of the DNA is: 64.6–66.3.

Type species: **Halochromatium salexigens** (Caumette, Baulaigue and Matheron 1988) Imhoff, Süling and Petri 1998b, 1140 (*Chromatium salexigens* Caumette, Baulaigue and Matheron 1988, 291.)

Enrichment and Isolation Procedures

Methods for enrichment and isolation are the same as those described for the genus *Chromatium*. *Halochromatium* species are generally found in microbial mats at the sediment surface of hypersaline environments, under salt (gypsum) deposits of salterns, in shallow salt lakes, and in evaporative lagoons with salinities of approx. 10–20%. From samples of purple layers in mats, these bacteria can be enriched or isolated by direct inoculation of deep agar dilution series in synthetic media containing 7–10% NaCl, as described by Caumette et al. (1988).

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Halochromatium* from other genera

Halochromatium species are characterized by their requirement for elevated salt concentrations and by having motile rod-shaped cells. Characteristics for differentiation of the genus *Halochromatium* from other members of the *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationships of *Halochromatium* species to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, are shown in Fig. BXII.γ.3of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

The two species presently comprising the genus *Halochromatium* were originally described as species of the genus *Chromatium*, because they have rod-shaped, motile cells without gas vesicles, features that previously defined the species of the genus *Chromatium* (Pfennig and Trüper, 1974, 1989). As a consequence of 16S rDNA sequence analyses, which showed their phylogenetic distance from true *Chromatium* species and other members of the family *Chromatiaceae*, they were transferred to the new genus *Halochromatium* (Imhoff et al., 1998b). *Halochromatium* species are among the most halophilic species of the family *Chromatiaceae* and belong to the branch of truly marine and halophilic *Chromatiaceae* species.

Differentiation of the species of the genus *Halochromatium*

Characteristic properties for distinguishing *Halochromatium* species are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*.

List of species of the genus Halochromatium

1. **Halochromatium salexigens** (Caumette, Baulaigue and Matheron 1988) Imhoff, Süling and Petri 1998b, 1140^{VP} (*Chromatium salexigens* Caumette, Baulaigue and Matheron 1988, 291.)

sal.ex' i.gens. L. n. *sal* salt; L. v. *exigo* demanding, to demand; M.L. part. adj. *salexigens* salt-demanding.

Cells straight or slightly curved rods, 2.0–2.5 × 4.0–7.5 µm, motile by means of a polar or subpolar tuft of flagella. Color of cell suspension pinkish red to slightly violet. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoids spirilloxanthin, anhydrorhodovibrin, rhodopin, lycopene, and rhodovibrin.

Grow photolithoautotrophically under anoxic conditions in the light with sulfide, S^0, sulfite, thiosulfate, and H_2 as electron donors. In the presence of sulfide and carbonate, acetate and pyruvate are photoassimilated. Chemolithotrophic growth under microoxic conditions in the dark is possible with sulfide and thiosulfate, chemoorganotrophic growth with acetate and pyruvate. Assimilatory sulfate reduction is absent. Vitamin B_{12} required.

Mesophilic and halophilic bacterium with optimum growth at 20–30°C and pH 7.4–7.6 (pH range 7.0–8.0). Sodium chloride required for growth, optimum salinity for growth at 8–11% NaCl, salinity range for growth from 4 to 20% NaCl.

Habitat: Reduced sediments in coastal salinas with salt deposits exposed to light.

The mol% G + C of the DNA is: 64.6 (Bd).

Type strain: SG3201, BN 6310, DSM 4395.

GenBank accession number (16S rRNA): X98597.

2. **Halochromatium glycolicum** (Caumette, Imhoff, Süling and Matheron 1997) Imhoff, Süling and Petri 1998b, 1140^{VP} (*Chromatium glycolicum* Caumette, Imhoff, Süling and Matheron 1997, 17.)

gly.co' li.cum. M.L. neut. adj. *glycolicum* related to the ability to use glycolate as substrate.

Cells straight to slightly curved rods, motile by polar flagella. Autotrophically grown cells 0.8–1.0 × 2–4 µm; in the presence of organic substrates 1.0–3.0 × 2–11 µm. Color of cell suspension pinkish red. Photosynthetic pigments are bacteriochlorophyll *a* and the major carotenoids spirilloxanthin and anhydrorhodovibrin, together with small amounts of rhodopin, lycopene, and rhodovibrin.

Grow photolithoautotrophically under anoxic conditions in the light with hydrogen, sulfide, S^0, sulfite, and thiosulfate as electron donors. In the presence of sulfide and hydrogen carbonate, glycolate, glycerol, fumarate, and succinate are photoassimilated. Formate, acetate, pyruvate, and casamino acids slightly increase the growth yield. Chemolithotrophic growth under microoxic conditions in the dark is possible with sulfide and thiosulfate, chemoorganotrophic growth with glycolate and glycerol. Assimilatory sulfate reduction is absent.

Mesophilic and halophilic bacterium with optimum growth at 25–35°C (no growth above 40°C) and pH 7.2–7.4 (pH range 6.2–9.0). Sodium chloride required for growth, optimum salinity at 4–6% NaCl, salinity range from 2–20% NaCl.

Habitat: Anoxic, sulfidic, and light-exposed habitats in hypersaline environments such as coastal lagoons subject to evaporative water losses, salt lakes, and salinas at elevated salt concentrations.

The mol% G + C of the DNA is: 66.3 (HPLC).

Type strain: SL3201, ATCC 700202, DSM 11080.

GenBank accession number (16S rRNA): X93472.

Genus IV. **Isochromatium** *Imhoff, Süling and Petri 1998b, 1141^{VP}*

Johannes F. Imhoff

I' so.chro.ma' ti.um. Gr. adj. *isos* equal, similar; *Chromatium* a genus name; M.L. neut. n. *Isochromatium* the similar *Chromatium*, the bacterium similar to *Chromatium*.

Cells straight to slightly curved rods, multiply by binary fission, **motile by a polar tuft of flagella**. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated.

Mesophilic bacteria with optimum growth at 25–35°C and a pH range from 6.5 to 7.6. **Salt is required for growth** at concentrations typical for marine bacteria.

Habitat: estuarine salt flats and salt marshes.

The mol% G + C of the DNA is: 62.2–62.8.

Type species: **Isochromatium buderi** (Trüper and Jannasch 1968) Imhoff, Süling and Petri 1998b, 1141 (*Chromatium buderi* Trüper and Jannasch 1968, 364.)

Enrichment and Isolation Procedures

The media described for *Chromatium* species can also be used for *Isochromatium* and other marine members of the family *Chromatiaceae*, if supplemented with 2–3% NaCl as required. The culture conditions and isolation procedures are the same as described for the genus *Chromatium*.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Isochromatium* from other genera

Characteristics for differentiation of the genus *Isochromatium* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The genetic relationship between *Isochromatium buderi* and other *Chromatiaceae* species, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Isochromatium buderi was previously known as *Chromatium buderi* (Trüper and Jannasch, 1968). It was transferred to the new genus *Isochromatium* based on significant genetic and physiological differences from *Chromatium* species and other members of the *Chromatiaceae* (Imhoff et al., 1998b). *Isochromatium buderi* belongs to the branch of truly marine and halophilic *Chromatiaceae* species.

List of species of the genus Isochromatium

1. **Isochromatium buderi** (Trüper and Jannasch 1968) Imhoff, Süling and Petri 1998b, 1141^{VP} (*Chromatium buderi* Trüper and Jannasch 1968, 364.)

   bu'der.i. M.L. gen. n. *buderi* of Buder; named for J. Buder, a German plant physiologist.

   Cells ovoid to rod shaped, 3.5–4.5 × 4.5–9 µm during exponential growth, about 3–4 µm in the stationary phase, motile by a polar tuft of flagella which is usually 1.5–2 times the cell length and may be visible in the light microscope. Globules of S^0 appear evenly distributed within the cell. Color of individual cells grayish, color of cell suspensions pinkish violet to purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group.

   Obligately phototrophic and strictly anaerobic. Sulfide and S^0 used as electron donors for photolithoautotrophic growth. In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Not utilized: thiosulfate, molecular hydrogen, sugars, alcohols, higher fatty acids, amino acids, benzoate, formate, and most intermediates of the tricarboxylic acid cycle. Assimilatory sulfate reduction is absent. Nitrogen sources: ammonium salts. Vitamin B_{12} required.

   Mesophilic marine bacterium requiring NaCl for growth. Optimum growth at 1–3% (w/v) NaCl, otherwise extremely pleomorphic, pH optimum for growth 7.2–7.4 (range 6.5–7.6), and temperature growth optimum 25–35°C.

   Habitat: estuarine salt flats and salt marshes.

   The mol% G + C of the DNA is: 62.2–62.8 (Bd), type strain: 62.2 (Bd).

   Type strain: 8111, ATCC 25588, DSM 176.

   GenBank accession number (16S rRNA): AJ224430.

Genus V. **Lamprobacter** *Gorlenko, Krasil'nikova, Kikina and Tatarinova 1988, 220*^{VP}
(Effective publication: Gorlenko, Krasil'nikova, Kikina and Tatarinova 1979, 765)

Vladimir M. Gorlenko and Johannes F. Imhoff

Lam'pro.bac'ter. Gr. adj. *lampros* bright, brilliant; M.L. masc. n. *bacter* rod; M.L. masc. n. *Lamprobacter* brilliant rod.

Cells are rod shaped or ovoid, 2.0–2.5 × 4–5 µm, multiply by binary fission, do not form aggregates. **Gas vesicles formed** in cell periphery or in the entire cytoplasm. **Motile by flagella** during certain stages of development. Motile cells normally devoid of gas vesicles. Gram negative, belong to the *Gammaproteobacteria*, and contain internal photosynthetic membranes of vesicular type with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with reduced sulfur compounds as electron donors. During oxidation of sulfide or thiosulfate, S^0 transiently stored inside the cells in the form of highly refractile globules. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. Chemotrophic growth under microoxic conditions in the dark.

The mol% G + C of the DNA is: 60–64.

Type species: **Lamprobacter modestohalophilus** Gorlenko, Krasil' nikova, Kikina and Tatarinova 1988, 220 (Effective publication: Gorlenko, Krasil' nikova, Kikina and Tatarinova 1979, 765.)

Further descriptive information

L. modestohalophilus exhibits considerable polymorphism under various growth conditions (Gorlenko et al., 1979). On the mineral medium of Pfennig (1965) with sulfide or thiosulfate, rod-shaped or ovoid cells of different strains may be 0.5–1.5 × 2.5–5 µm. These cells display dimorphism during normal development of cultures on bicarbonate-containing media with acetate, glycerol, or other organic compounds. In freshly transferred cultures, cells are rod shaped, motile by means of flagella, generally devoid of gas vesicles, and contain globules of S^0. Late in the exponential growth phase, cells lose their motility, gas vesicles appear, and slime capsules are formed. In stationary phase, slime capsules consolidate and cells are transformed into cysts. Cells

with gas vesicles tend to concentrate in the upper part of the bottle at room temperature. Gas vesicles, short point-ended cylinders of 60 × 80 nm to 120 × 140 nm, are grouped near the cell periphery, while sulfur is deposited in the central vesicle-free part of the cells. Multiple passages on mineral salts medium result in a temporary loss of the ability to produce motile cells, and bacteria that are surrounded by loose or dense slime capsules and contain gas vesicles during all stages of growth. Cells are large and irregularly shaped at high NaCl concentrations and an acid pH of 5.9–6.6, but are thin, elongated, and slightly bent at a pH of 8.0 or higher.

The cell wall is of the Gram-negative type and, characteristically, the outer membrane is overlaid by an external layer (S-layer) consisting of hexagonal subunits which are 20 nm long. Vegetative cells possess a loose fibrous slime capsule. Slime capsules of the cyst-like cells are dense, with a clear margin. The photosynthetic membrane system occupies the major part of the cytoplasm in bacteria growing anaerobically in the light. Storage materials are abundantly produced during growth with glycerol, both under chemotrophic (aerobically in the dark) as well as under phototrophic (anaerobically in the light) growth conditions.

Suspensions of bacteria grown anaerobically in the light appear purple-pink. *In vivo* absorption maxima at 370, 655, 804, and 827 nm and a shoulder at 880 nm indicate the presence of bacteriochlorophyll *a*, while a major peak at 518 nm and shoulders at 486 and 549 nm reveal the presence of carotenoids of the okenone group. By chemical analysis, the major components were identified as okenone (64.2%), the compound thiothece-OH-484 (18.5%), also present in *Thiocystis gelatinosa* (Schmidt, 1978), and spirilloxanthin (10.5%) (Sidorova et al., 1998).

Among the organic compounds that are photoassimilated, glycerol, acetate, pyruvate, lactate, maltose, and lactose strongly increase the yield. Glycerol metabolism involves the functioning of glycerol kinase and α-glycerophosphate dehydrogenase independent of pyridine nucleotides (Krasil'nikova et al., 1979). Organic acids are assimilated through the incomplete tricarboxylic acid cycle. The glyoxylate cycle is absent (Krasil'nikova, 1985; Krasil'nikova and Kondrat'eva, 1979). Sugars are utilized through the Embden–Meyerhof pathway.

Optimum conditions for chemotrophic growth in the dark are ~10% O_2 in the gas phase. Phototrophic growth in the light is suppressed at O_2 concentrations above 2%. In a stab culture in 0.8% agar medium in the dark, growth occurs 1 cm below the surface. Thiosulfate or S^0 are required as electron donor and sulfur source for assimilatory purposes (Krasil'nikova, 1981). Optimum concentration of thiosulfate is 0.2%. At a concentration of 0.5% $Na_2S_2O_3 \cdot 5H_20$, growth of aerobic cultures is strongly inhibited. In the dark, thiosulfate is oxidized to S^0 and sulfate. S^0 is deposited inside the cells as an intermediate product, accumulation of S^0 and generation of sulfate occur in parallel. Vitamin B_{12} is required for chemotrophic aerobic growth (Kondrat'eva et al., 1981). Best growth in the dark occurs with glycerol as carbon source, while lactate, pyruvate, and propionate also stimulate growth.

Enrichment and Isolation Procedures

L. modestohalophilus is widely distributed in microbial mats of shallow, warm, and saline water bodies (0.5–12% NaCl) with high sulfide content of the southern Crimea, the Donetsk region (Ukraine), and Turkmenia (former U.S.S.R.). *Lamprobacter* was not found in the White Sea littoral zone.

When water and mud samples are inoculated into a medium containing 0.5–4% NaCl, 0.05% $Na_2S \cdot 9H_20$, 0.1% $Na_2S_2O_3 \cdot 5H_20$, and 0.1% sodium acetate, bacteria containing gas vesicles are concentrated in the upper part of the culture vessel. This fraction is removed by using a sterile capillary and is transferred into agar dilution series, as described for the genus *Lamprocystis*.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*. For intervals of 1–3 months, cultures can be maintained in liquid medium stored in a refrigerator at low light intensity.

Differentiation of the genus *Lamprobacter* from other genera

The genus *Lamprobacter* is characterized and distinguished from other members of the family *Chromatiaceae* by rod-shaped motile cells that develop gas vesicles under certain growth conditions. Characteristics used for differentiation of the genus *Lamprobacter* from other members of the *Chromatiaceae* are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*.

List of species of the genus Lamprobacter

1. **Lamprobacter modestohalophilus** Gorlenko, Krasil'nikova, Kikina and Tatarinova 1988, 220[VP] (Effective publication: Gorlenko, Krasil'nikova, Kikina and Tatarinova 1979, 765.) *mo.des'to.ha.lo'phi.lus.* L. n. *modestus* moderate; Gr. n. *hals* salt; Gr. adj. *philos* loving; M.L. masc. adj. *modestohalophilus* moderate salt-loving.

   Cells are rod shaped or ovoid, 2.0–2.5 × 4–5 μm, polymorphic under changing conditions of incubation (Fig. BXII.γ.8). Life cycle with two alternating morphological forms: nonmotile cells with gas vesicles and slime capsules, and cells motile by means of flagella and devoid of gas vesicles. Gas vesicles frequently located in the cell periphery, globules of S^0 in center of cells. Photosynthetic membranes of the vesicular type. Vesicles in cells grown in mineral medium measure about 70 nm in diameter. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the okenone group.

   Growth under anoxic conditions in the light and under microoxic conditions in the dark. Under anoxic conditions in the light, cell suspensions appear purple to pink. Under aerobic conditions in the dark, synthesis of pigments is reduced and cultures become colorless. Photosynthetic electron donors used are sulfide, thiosulfate, S^0, and hydrogen, but not sulfite. Electron donors in the dark are thiosulfate and sulfur. Sulfide and thiosulfate are oxidized to S^0 and sulfate. Assimilatory sulfate reduction is absent and reduced sulfur compounds are required.

   CO_2 assimilated via the Calvin cycle. In the presence of sulfide (or thiosulfate) and bicarbonate, alcohols (glycerol, *n*-propanol, *n*-butanol, ethanol, isobutanol, and isopropanol), and organic acids (lactate, pyruvate, and acetate) are photoassimilated. Methanol, isoamyl alcohol, sorbitol, dulcitol, mannitol, succinate, fumarate, malate, lactose, maltose, xylose, galactose, and fructose are not utilized. Growth inhibited by *n*-amyl alcohol, allyl alcohol, formate, propionate, benzoate, arabinose, rhamnose, and raffinose. Ni-

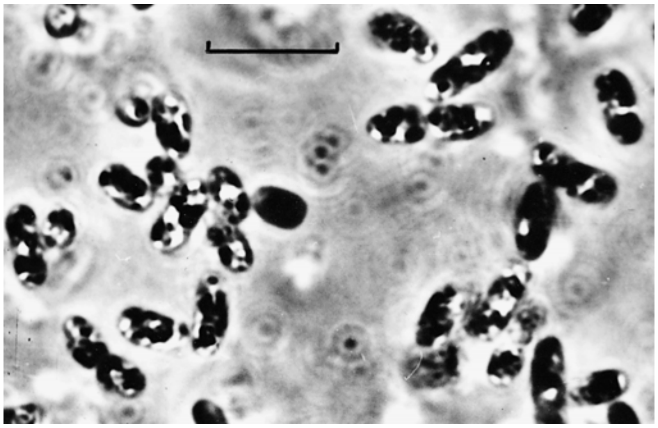

FIGURE BXII.γ.8. *Lamprobacter modestohalophilus* strain RO-1. Phase-contrast micrograph. Bar = 10 μm. (Reproduced with permission from V.M. Gorlenko et al., Izvestiya Akademii Nauk S.S.S.R. Seriya Biologicheskaya (Moskva) *5:* 765, 1979© MAIK Nauka/Interperiodic Publishing, Moscow.)

trogen sources used: ammonium salts, urea, casein hydrolysate, glutamic acid, and N_2. Hydrogenase and catalase activity occur. Storage materials: S^0, poly-β-hydroxybutyrate, polyphosphate, and polysaccharide. Vitamin B_{12} required.

Optimum growth is at 23–27°C, pH 7.4–7.6, 1–4% NaCl (up to 9% NaCl). Sodium chloride is required for growth. Favorable light intensity is 3000 lux.

Habitat: hydrogen sulfide-containing mud and water of saline water bodies with 1–11% salinity.

The mol% G + C of the DNA is: 60–64.

Type strain: Type strain INMI RO-1 is lost; no neotype strain designated.

Additional Remarks: Available candidate for neotype: "Syvash" (Institute of Microbiology, Russia Academy of Sciences, Moscow, Russia), isolated from a lagoon of salt lake Syvash (Crimea) with 6.7% salinity, pH range for growth 6.9–7.6, temperature range for growth from 20 to 30°C.

Genus VI. **Lamprocystis** *Schroeter 1886, 151[AL]*

JOHANNES F. IMHOFF

Lam' pro.cys' tis. Gr. adj. *lampros* bright, brilliant; Gr. n. *cystis* the bladder, a bag; M.L. fem. n. *Lamprocystis* brilliant bag.

Cells spherical to ovoid, 1.9–3.8 μm in diameter, diplococcus-shaped before cell division and may occur in irregular aggregates, multiply by binary fission, **nonmotile or motile by means of a single flagellum**, **form gas vesicles** in central part. Gram negative and belong to the *Gammaproteobacteria*. At high sulfide concentration (4–6 mM) and light intensity (1000–2000 lux), cells may grow as long, branching cell aggregates embedded in slime. Under favorable growth conditions, cell aggregates may break up into smaller clusters and spheroidal microcolonies, which become motile by flagella; finally, individual motile cells are liberated. Internal **photosynthetic membranes are of vesicular type** and contain the photosynthetic pigments bacteriochlorophyll *a* and carotenoids.

Photolithoautotrophic growth under anoxic conditions in the light with reduced sulfur compounds such as sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 is transiently stored in the peripheral part of the cells that is free of gas vesicles. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. Obligately phototrophic or facultatively chemotrophic under microoxic to oxic conditions in the dark.

The mol% G + C of the DNA is: 63.4–64.1.

Type species: **Lamprocystis roseopersicina** (Kützing 1849) Schroeter 1886, 151 (*Protococcus roseopersicinus* Kützing 1849, 196.)

ENRICHMENT AND ISOLATION PROCEDURES

Media and culture conditions are the same as described for *Chromatium* species. *Lamprocystis* species, like other purple sulfur bacteria containing gas vesicles, may be selectively enriched by making use of the buoyancy of their cells at lower temperatures of 4–10°C (Pfennig et al., 1968). For enrichment cultures, an inoculum from a natural habitat, in which the presence of *Lamprocystis* cells and cell aggregates was established microscopically, should be used. The culture medium and incubation conditions are the same as described for the genus *Chromatium*. Low sulfide concentrations (1–2 mM) and low light intensity (100–300 lux) with diurnal light and dark periods (e.g., 18 h light, 6 h dark) are employed at a room temperature of about 20°C. The bottles are incubated in a lying position to avoid accumulation of cells in the nonilluminated area under the screw cap. After two or three supplementations of the enrichment culture with neutralized sulfide solution, the well-developed culture is stored in a refrigerator in an upright position. This is not done until the various types of purple sulfur bacteria have almost completely oxidized the sulfur globules inside the cells. After 1–2 weeks of storage at a temperature between 4 and 10°C, purple sulfur bacteria with gas vesicles, including *Lamprocystis* species, accumulate at the surface of the liquid medium under the screw cap. A small amount of the floating material is removed with an inoculation loop and inspected microscopically under brightfield illumination. For further enrichment, the floating cell mass is carefully pipetted from the surface and transferred to fresh medium. Alternatively, or in addition, the enriched material is used to inoculate one or two series of agar shake cultures as described for the isolation of *Chromatium* species.

MAINTENANCE PROCEDURES

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

DIFFERENTIATION OF THE GENUS *LAMPROCYSTIS* FROM OTHER GENERA

Characteristics used for differentiation of the genus *Lamprocystis* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationship of *Lamprocystis* species to other members of the *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.4 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Only a few strains of *Lamprocystis roseopersicina* have thus far been studied in pure culture. From observations in natural samples, it is apparent that cells showing the characteristics of *Lamprocystis* are quite frequent and that cells of different diameter occur. Further studies using a greater variety of pure cultures of these bacteria are needed, to show whether clusters of strains of different cell diameter represent different species. According to 16S rRNA oligonucleotide pattern analysis, *Lamprocystis roseopersicina* is distantly related to *Thiocapsa* and *Thiodictyon* species (Fowler et al., 1984). Sequence analyses of 16S rDNA place this species into the group of spherical to ovoid, nonmotile freshwater *Chromatiaceae* species, many of which contain gas vesicles (Fig. BXII.γ.4 of the chapter describing the family *Chromatiaceae*), and in close proximity to the species originally described as *Amoebobacter purpureus* (Eichler and Pfennig, 1988). In accordance with the rules of the International Code of Nomenclature of Bacteria (Lapage et al., 1992), the transfer of this species to the genus *Lamprocystis* as the new combination *Lamprocystis purpurea* comb. nov. was proposed (Imhoff, 2001b).

The genus *Amoebobacter* comprised spherical, nonmotile species containing gas vesicles (Winogradsky, 1888; Pfennig, 1989a). Two species, including the type species, were transferred to the genus *Thiocapsa* and a third species to the new genus *Thiolamprovum* (Guyoneaud et al., 1998b; see genera *Thiocapsa* and *Thiolamprovum*). Because the type species had been removed from the genus *Amoebobacter*, the names of other species of this genus had to change, according to rule 37a, and it was illegitimate to retain the name *Amoebobacter purpureus* (Guyoneaud et al., 1998b). The transfer of this species to the new genus *Pfennigia* has been proposed (Tindall, 1999). However, the high degree of similarity between 16S rDNA sequences from this bacterium and *Lamprocystis roseopersicina* demonstrated the close relationship of the two bacteria, and precluded their separation into different genera (see Fig. BXII.γ.4 of the chapter describing the family *Chromatiaceae*). Because of the priority of the genus and species name of *Lamprocystis roseopersicina*, *Pfennigia purpurea* Tindall 1999 (*Amoebobacter purpureus* Eichler and Pfennig, 1988) was transferred to *Lamprocystis purpurea* comb. nov. (Imhoff, 2001b).

Lamprocystis purpurea (*Amoebobacter purpureus*) has been described based on six isolates, which were classified into two groups according to cell size and substrate utilization (Eichler and Pfennig, 1988). The described differences between the groups may be sufficient to allow the recognition of two different species. The description of *Lamprocystis purpurea* given below includes properties of the type strain and an additional strain (ThSchm4). Strains of the second group differ from *Pfennigia purpurea* in the following characteristics: cells are 3.3–3.8 × 3.5–4.5 μm, do not utilize formate, and have a mol% G + C of 63.4–64.1 (Eichler and Pfennig, 1988).

List of species of the genus Lamprocystis

1. **Lamprocystis roseopersicina** (Kützing 1849) Schroeter 1886,151[AL] (*Protococcus roseopersicinus* Kützing 1849, 196.)
ro' se.o.per.si.ci' na. L. adj. *roseus* rosy; Gr. n. *persicus* the peach; M.L. fem. adj. *roseopersicina* rosy peach-colored.

Cells spherical to ovoid, 2.0–3.5 μm in diameter (Fig. BXII.γ.9), motile by flagella, contain gas vesicles. Color of cell suspensions pinkish violet to purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group, with lycopenal as main component (Pfennig et al., 1968).

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with sulfide and S^0 as electron donors. In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Nitrogen sources: ammonium salts.

Mesophilic freshwater bacterium with optimum growth at 20–30°C and pH 7.0-7.3.

Habitat: mud and stagnant water of ponds and lakes containing hydrogen sulfide; common planktonic purple sulfur bacterium in the sulfide-containing hypolimnion of freshwater lakes.

The mol% G + C of the DNA is: 63.8 (Bd).
Type strain: 3012, BN 4510, DSM 229.
GenBank accession number (16S rRNA): AJ006063.

2. **Lamprocystis purpurea** *comb. nov.* (Eichler and Pfennig 1988) Imhoff 2001b, 1700[VP] (*Pfennigia purpurea* (Eichler and Pfennig 1988) Tindall 1999, 1308; *Amoebobacter purpureus* Eichler and Pfennig 1988, 399.)

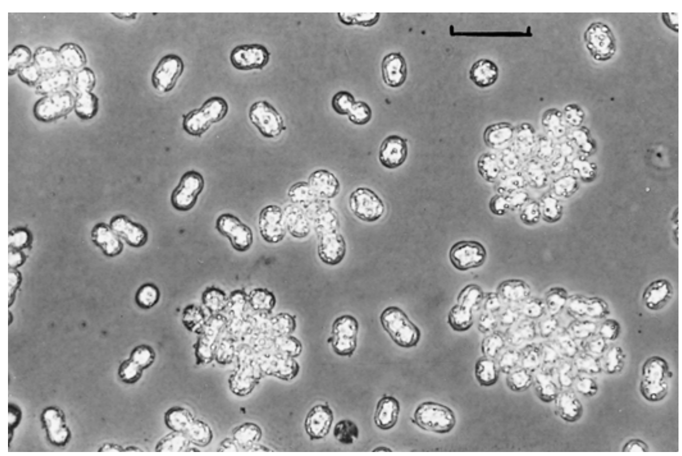

FIGURE BXII.γ.9. *Lamprocystis roseopersicina* DSM 229 cultured photoautotrophically with sulfide. Single cells and cell colonies are motile in liquid medium. The *irregular whitish areas* within the cells are the gas vacuoles. The *small spherical bodies* in the cells are the sulfur globules. Phase-contrast micrograph. Bar = 10 μm.

pur.pur′e.a. L. fem. adj. *purpurea* purple or purple-red.

Cells nearly spherical to oval, 1.9–2.3 × 2.0–3.2 μm, nonmotile, and contain gas vesicles in central parts of cells. Cells single or in irregular aggregates of up to 40 cells. Color of dense cell suspensions purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoid okenone is a major component.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide, thiosulfate, and S^0 as electron donors. In the presence of sulfide and bicarbonate, acetate, propionate, pyruvate, lactate, glucose, and formate are photoassimilated. Chemolithoautotrophic growth possible with sulfide and thiosulfate as electron donors under microoxic conditions in the dark. Assimilatory sulfate reduction is absent.

Mesophilic freshwater bacterium with optimum growth at 23–25°C and pH 7.0–7.3.

Habitat: Anoxic sulfide-containing water of stratified freshwater lakes, mud, and stagnant water of ponds and lakes, may occur as dominant bloom-forming bacterium, together with *Thiocapsa roseopersicina*, in wastewater lagoons containing degradable organic substances.

The mol% G + C of the DNA is: 63.5–63.6 (Bd).

Type strain: ThSchl2, DSM 4197.

GenBank accession number (16S rRNA): Y12366, AJ223235.

Genus VII. **Marichromatium** *Imhoff, Süling and Petri 1998b, 1140*^{VP}

JOHANNES F. IMHOFF

Ma′ri.chro.ma′ti.um. L. gen. n. *maris* of the sea; *Chromatium* a genus name; M.L. neut. n. *Marichromatium* the *Chromatium* of the sea, the truly marine *Chromatium*.

Cells straight to slightly curved rods, motile by polar flagella and multiply by binary fission. Cells single or in pairs, and may stick together and form clumps. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Grow photolithoautotrophically under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 is formed as an intermediate and stored in the form of highly refractile globules inside the cells. Final oxidation product is sulfate. Molecular hydrogen may be used as electron donor. In the presence of sulfide and bicarbonate, organic substrates can be photoassimilated. **Chemolithotrophic and chemoorganotrophic growth may be possible under microoxic conditions in the dark**.

Mesophilic bacteria with optimum growth at 25–35°C, pH 6.5–7.6, and at salt concentrations typical of marine bacteria.

Habitat: anoxic marine sediments and stagnant waters containing hydrogen sulfide and exposed to the light, marine sponges and other marine invertebrates.

The mol% G + C of the DNA is: 68.9–70.4.

Type species: **Marichromatium gracile** (Strzeszewski 1913) Imhoff, Süling and Petri 1998b, 1140 (*Chromatium gracile* Strzeszewski 1913, 321.)

ENRICHMENT AND ISOLATION PROCEDURES

The media described for *Chromatium* species can also be used for *Marichromatium* species and other marine members of the family *Chromatiaceae*, if supplemented with appropriate amounts of salt as required. The culture conditions and isolation procedures are the same as described for the genus *Chromatium*.

MAINTENANCE PROCEDURES

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

DIFFERENTIATION OF THE GENUS *MARICHROMATIUM* FROM OTHER GENERA

Marichromatium species are distinct from other members of the family *Chromatiaceae* by their specific salt requirement and the very high mol% G + C content of their DNA. Characteristics for differentiation of the genus *Marichromatium* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*.

TAXONOMIC COMMENTS

Species of this genus have previously been classified as belonging to the genus *Chromatium* (Pfennig and Trüper, 1974; Pfennig, 1989b). However, because of significant phenotypic and genetic differences to true *Chromatium* species and other members of the family *Chromatiaceae*, they have been transferred to the new genus *Marichromatium* (Imhoff et al., 1998b).

Phylogenetic relationships among the *Chromatiaceae*, their taxonomic reclassification and description of the new genera *Allochromatium*, *Halochromatium*, *Isochromatium*, *Marichromatium*, *Thiococcus*, *Thiohalocapsa*, and *Thermochromatium*. Int. J. Syst. Bacteriol. *48*: 1129–1143.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *MARICHROMATIUM*

Marichromatium species can be distinguished on the basis of cell suspension color and pigment content, differences in substrate utilization, as well as slight differences in cell size and salt response. Characteristic properties for distinguishing *Marichromatium* species are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationships of *Marichromatium* species to other members of the family *Chromatiaceae* is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

List of species of the genus Marichromatium

1. **Marichromatium gracile** (Strzeszewski 1913) Imhoff, Süling and Petri 1998b, 1140^{VP} (*Chromatium gracile* Strzeszewski 1913, 321.)

gra′ci.le. L. neut. adj. *gracile* thin, slender.

Cells are rod shaped, 1.0–1.3 × 2–6 μm. Globules of S^0 evenly distributed within cells. Single cells colorless. Color

of growing cultures orange-brown to brownish red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin group.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide, sulfur, thiosulfate, sulfite, and molecular hydrogen as electron donors. Organic substrates formate, acetate, propionate, pyruvate, fumarate, malate, succinate, lactate, propionate, butyrate, crotonate, and Casamino acids are used. Not utilized: sugars, sugar alcohols, alcohols, benzoate, citrate, and amino acids. Chemoautotrophic and mixotrophic growth under microoxic to semioxic conditions possible. Assimilatory sulfate reduction occurs (Thiele, 1968). Nitrogen sources: ammonium salts, N_2. Vitamins not required.

Habitat: brackish waters, estuaries, salt marshes, and marine habitats containing hydrogen sulfide and exposed to the light.

Mesophilic, marine bacterium with optimum growth at 2–3% NaCl, pH 7.2–7.4 (range 6.8–7.6), and a temperature range of 20–35°C.

The mol% G + C of the DNA is: 68.9–70.4 (Bd); type strain 69.9 (Bd).

Type strain: 8611, BN 5210, DSM 203.

GenBank accession number (16S rRNA): X93473.

2. **Marichromatium purpuratum** (Imhoff and Trüper 1980) Imhoff, Süling and Petri 1998b, 1140[VP] (*Chromatium purpuratum* Imhoff and Trüper 1980, 69.)

pur.pur.a'tum. L. neut. adj. *purpuratum* dressed in purple.

Cells are rod shaped, 1.2–1.7 × 3–4 μm, when grown under autotrophic conditions, motile by a single polar flagellum. Color of cell suspensions purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the okenone group.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with sulfide, sulfur, and thiosulfate as electron donors; photoorganoheterotrophic growth with acetate, propionate, butyrate, valerate, lactate, pyruvate, fumarate, malate, and succinate in the presence of bicarbonate. Fructose and casamino acids are poor substrates. Not utilized: sugars, sugar-alcohols, alcohols, higher fatty acids, benzoate, and amino acids. Nitrogen sources: ammonium salts. Vitamins not required.

Mesophilic marine bacterium that requires NaCl for growth, optimum salinity 5% NaCl, salinity range 2–7% NaCl, pH range 7.2–7.6, temperature range 25–30°C.

Habitat: anoxic and sulfidic marine sediments and waters exposed to the light, marine sponges, and other marine invertebrates, such as didemnids and copepods.

The mol% G + C of the DNA is: 68.9 (T_m).

Type strain: BN 5500, DSM 1591.

GenBank accession number (16S rRNA): AF001580, AJ224439.

Genus VIII. **Nitrosococcus** *Winogradsky1892, 127[AL] (Nom. Cons. Opin. 23 Jud. Comm. 1958b, 169)*

HANS-PETER KOOPS AND ANDREAS POMMERENING-RÖSER

Ni.tro.so.coc'cus. M.L. adj. *nitrosus* nitrous; *coccus* a grain, berry; M.L. masc. n. *Nitrosococcus* nitrous sphere.

Cells are spherical to ellipsoidal (Fig. BXII.γ.10A). Typical Gram-negative cell wall, but **some strains have additional layers composed of repeating subunits arranged in a molecular array** (Watson and Remsen, 1969, 1970). **Extensive intracytoplasmic membrane systems arranged centrally in the protoplasm** (Fig. BXII.γ.10B). Carboxysomes not observed. **Obligate salt requirement**. **Urea** can be used as ammonia source by one of the two described species. Motile cells possess **a tuft of flagella or a single flagellum**. Species are **distributed in oceans and in salt lakes**.

Type species: **Nitrosococcus nitrosus** (Migula 1900) Buchanan 1925, 402 (Nom. Cons. Opin. 23 Jud. Comm. 1958b, 169) (*Micrococcus nitrosus* Migula 1900, 194.)

TAXONOMIC COMMENTS

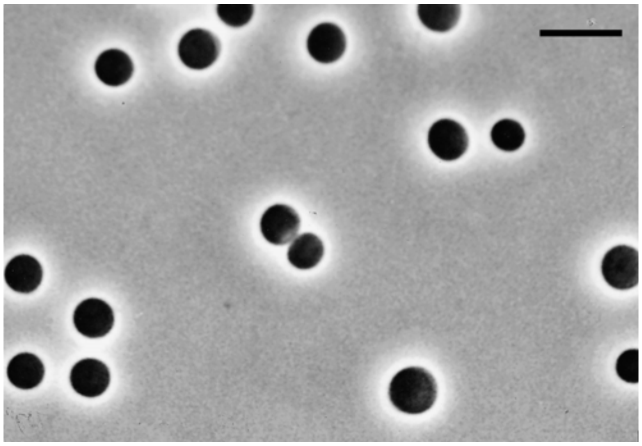
Isolates of coccoid ammonia-oxidizers were first described by Winogradsky (1892, 1904). One of these strains has been named *Nitrosococcus nitrosus* by Migula (1900). However, this type species of the genus *Nitrosococcus* was not preserved in culture. Only data on the cell shape and size are available from the original description (Winogradsky, 1892). Since this species cannot be identified with certainty, it is a candidate for placement on the list of rejected names.

Another coccoid ammonia-oxidizer, originally placed in *Nitrosococcus* as *N. mobilis* (Koops et al., 1976), has been proved via phylogenetic analyses to be a member of the genus *Nitrosomonas* (Woese et al., 1984b; Head et al., 1993; Teske et al., 1994).

The remaining two described species of the genus *Nitrosococcus*, *N. oceani* and *"N. halophilus"*, are both members of the *Gammaproteobacteria.* They are closely related to each other, as demonstrated by DNA–DNA hybridizations. Using the S_1 nuclease technique, a DNA similarity of 9–10% was estimated (Pommerening-Röser, 1993).

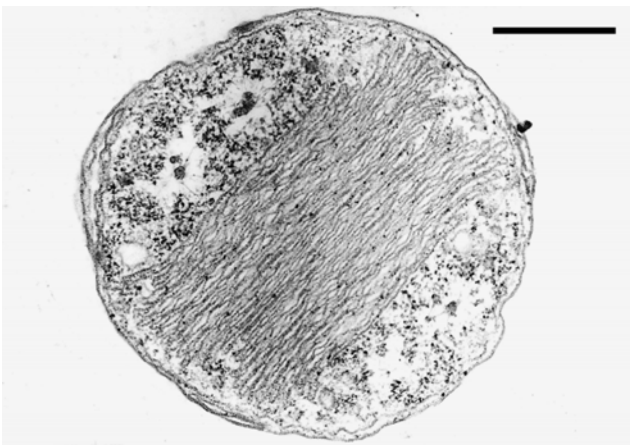
In the future, the taxonomically revised genus *Nitrosococcus* should be reserved for representatives of ammonia-oxidizing bacteria belonging to the *Gammaproteobacteria* and being closely related to the grouping of *N. oceani* and *"N. halophilus"*.

List of species of the genus Nitrosococcus



1. **Nitrosococcus nitrosus** (Migula 1900) Buchanan 1925, 402[AL] (Nom. Cons. Opin. 23 Jud. Comm. 1958b, 169) (*Micrococcus nitrosus* Migula 1900, 194.)

ni.tro'sus. M.L. adj. *nitrosus* nitrous.



Cells are spheres 1.5–1.7 μm in diameter. No further phenotypic characteristics are available.

The mol% G + C of the DNA is: unavailable.

Type strain: no longer in culture.

A

B

FIGURE BXII.γ.10. (*A*) Phase contrast micrograph of a thin section of cells of *Nitrosococcus oceani*. Bar = 5 µm. (*B*) Electron micrograph of a thin section of cells of *N. oceani*. Bar = 0.5 µm.

2. **Nitrosococcus oceani** (Watson 1965) Watson 1971, 267[AL] (*"Nitrosocystis oceanus"* Watson 1965, R279.)
o.ce.a′ nus. M.L. gen. n. *oceani* of the ocean.

The cells are spherical to ellipsoidal, 1.8–2.2 µm in diameter. Cells generally occur singly or in pairs, but sometimes aggregates are formed via production of exopolymeric substances. Motile cells possess 1–20 flagella. Cells have a typical Gram-negative envelope, with two additional cell wall layers composed of subunits arranged in rectilinear and hexagonal arrays. Cells possess an extensive intracytoplasmic membrane system, arranged as a centrally located stack of parallel, flattened vesicles. Cells have an obligate salt requirement, with optimum NaCl concentrations for growth of 400–500 mM. The maximum concentration of ammonium salts is around 1000 mM at pH 7.8. Urease positive. All strains have been isolated from marine environments.

The mol% G + C of the DNA is: 50.5 (T_m, Bd).
Type strain: C-107, ATCC 19707.
GenBank accession number (16S rRNA): M96395.

3. **"Nitrosococcus halophilus"** Koops, Böttcher, Möller, Pommerening-Röser and Stehr 1990, 247.
ha.lo′ phi.lus. Gr. n. *halos* salt; Gr. adj. *philos* loving; M.L. adj. *halophilus* salt loving.

Cells are spherical to ellipsoidal, 1.8–2.5 µm in diameter. Gram-negative cell wall. Additional outer layers, as demonstrated for *N. oceani*, may exist, but have not been reported. Motile cells have a tuft of flagella. Intracytoplasmic membranes are arranged as a stack of centrally located flattened vesicles. Cells are obligately halophilic, optimum NaCl concentrations for growth are 600–800 mM, up to 1600 mM is tolerated. Ammonium compounds are tolerated up to concentrations around 600 mM. Urease negative. Isolates originate from salt lagoons and salt lakes.

The mol% G + C of the DNA is: 50.5 (T_m).
Deposited strain: Nc 4.

Genus IX. Pfennigia *Tindall 1999, 1308*[VP]*

BRIAN J. TINDALL

Pfen.nig′ ia. M.L. *ia* ending; M.L. fem. n. *Pfennigia* named after Norbert Pfennig, in recognition of his contribution to the biology and taxonomy of anoxygenic phototrophic bacteria.

Oval to spherical cells, 1.9–3.8 × 2.0–4.5 µm. May form large aggregates (up to 40 cells). Gas vacuoles occur in the central part of the cytoplasm. The intracytoplasmic membrane system is of the vesicular type. **Nonmotile.** Gram negative. **Photolithotrophic under anaerobic conditions in the light**; chemoautotrophic under microaerobic conditions in the dark. **Hydrogen sulfide, thiosulfate, and S^0 serve as electron donors. Globules of S^0 appear in cells during oxidation of sulfide or thiosulfate to sulfate. Major photosynthetic pigments are bacteriochlorophyll *a* and the carotenoid okenone.** Isolated from the chemocline of freshwater lakes.

The mol% G + C of the DNA is: 63.4–64.1.
Type species: **Pfennigia purpurea** (Eichler and Pfennig 1988) Tindall 1999, 1308 (*Amoebobacter purpureus* Eichler and Pfennig 1988, 399.)

TAXONOMIC COMMENTS

The trend towards the use of 16S rDNA sequences in the taxonomy of anoxygenic phototrophic bacteria has indicated that many genera, such as *Chromatium*, *Thiocapsa*, and *Amoebobacter*, which are phenotypically relatively heterogeneous are also phylogenetically heterogeneous. However, this has also led to a tendency to rely heavily on the 16S rDNA sequences and to reduce many phenotypic parameters to being "unreliable". 16S rDNA sequence analysis of the type strain of *Pfennigia purpurea* (DSM 4197) indicates that this strain has a high degree of sequence similarity to *Lamprocystis roseopersicina* DSM 229. However, two 16S rDNA sequences have been deposited as AJ223235 and Y12366, both being from the type strain of *Pfennigia purpurea* DSM 4197, although they are sufficiently different to infer that they come from different species. Thus, while *Pfennigia purpurea* (DSM 4197;

Editorial Note: The type species of *Pfennigia*, *P. purpurea*, has been transferred to the genus *Lamprocystis* as *L. purpurea* (Eichler and Pfennig 1988) Imhoff 2001b comb. nov.

GenBank accession no. AJ223235) shows less than 1% 16S rDNA sequence divergence from *Lamprocystis roseopersicina* (DSM 229; GenBank accession no. AJ006063), the degree of sequence divergence between the latter and *Pfennigia purpurea* (DSM 4197; GenBank accession no. Y12366) may be more than 3%. In the first case, it would be appropriate to examine the possibility that *Pfennigia purpurea* (DSM 4197; Y12366) and *Lamprocystis roseopersicina* (DSM 229; AJ006063) are members of the same species, whereas in the latter case their membership in the same genus is questionable. These two possibilities cannot be decided based on currently available sequence data. It should be pointed out that it is implicit in the evaluations of Guyoneaud et al. (1998b), Imhoff et al. (1998b), or Puchkova et al. (2000) that species sharing 5% or less 16S rDNA sequence divergence belong in the same genus. However, this is usually without adequate supporting data or in the light of other phenotypic data being "unreliable". In other genera, sequence similarities may be higher than 95% and rely on supporting phenotypic data (see, for example, Lincoln et al., 1999).

List of species of the genus Pfennigia

1. **Pfennigia purpurea** (Eichler and Pfennig 1988) Tindall 1999, 1308^{VP} (*Amoebobacter purpureus* Eichler and Pfennig 1988, 399.)
   pur.pur′ea. L. fem. adj. *purpurea* purple or purple-red.
   The characteristics are as given for the genus.
   The mol% G + C of the DNA is: 63.4–64.1
   Type strain: ThSch12, DSM 4197.
   GenBank accession number (16S rRNA): AJ223235, Y12366.

Genus X. **Rhabdochromatium** *Dilling, Liesack and Pfennig 1996, 362^{VP} (Effective publication: Dilling, Liesack and Pfennig 1995, 130)*

Johannes F. Imhoff

Rhab′do.chro.ma′tium. Gr. n. *rhabdos* a rod; Gr. n. *chromatium* color, paint; M.L. neut. n. *Rhabdochromatium* colored rod.

Cells straight or slightly bent rods, motile by a polar tuft of flagella, multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Metabolism obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with hydrogen, sulfide, S^0, and thiosulfate as electron donors. During oxidation of sulfide, globules of sulfur are stored inside the cells as intermediary product. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated.

Mesophilic marine bacteria that require NaCl for growth, optimum growth at neutral pH and 20–35°C.

The mol% G + C of the DNA is: 60.4.

Type species: **Rhabdochromatium marinum** Dilling, Liesack and Pfennig 1996, 362 (Effective publication: Dilling, Liesack and Pfennig 1995, 130.)

Enrichment and Isolation Procedures

The media described for *Chromatium* species can also be used for *Rhabdochromatium* and other marine members of the family *Chromatiaceae*, if supplemented with 2–3% NaCl as required. The culture conditions and isolation procedures are the same as described for the genus *Chromatium*.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are as described for the genus *Chromatium*.

Differentiation of the genus *Rhabdochromatium* from other genera

Characteristics for differentiation of the genus *Rhabdochromatium* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The genetic relationship of *Rhabdochromatium marinum* to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

The genus *Rhabdochromatium* was established by Winogradsky (1888) for long, rod- or spindle-shaped, red sulfur bacteria observed in samples from natural habitats. From microscopic observations of reddish cells containing sulfur globules, he described three species that were distinguished by cell size: *R. roseum*, *R. minus*, and *R. fusiforme*. Two more species were described later (see Bavendamm, 1924). Since none of the described species has so far been isolated in pure culture or observed again in samples from nature and enrichment cultures, the genus was not included in the Approved Lists of Bacterial Names. Indeed, this genus was included in the genus *Chromatium* (Pfennig and Trüper, 1974), because long and irregularly swollen cells have been observed in pure cultures of *Chromatium okenii*, *Chromatium weissei*, *Isochromatium buderi*, and *Allochromatium warmingii*, when the mineral salts concentrations of the culture media were inappropriate. The name *Rhabdochromatium* was revived, according to Rule 33c of the International Code of Nomenclature of Bacteria (Lapage et al., 1992), for a long, rod-shaped, red sulfur bacterium, the morphology of which has proven to be stable in pure culture for several years. Only one species is currently known. *Rhabdochromatium marinum* belongs to the cluster of truly marine species of the family *Chromatiaceae*.

Dilling, W., Liesack, W. and Pfennig, N. 1995. *Rhabdochromatium marinum* gen. nom. rev., sp. nov., a purple sulfur bacterium from a salt marsh microbial mat. Arch. Microbiol. *164*: 125–131.

List of species of the genus Rhabdochromatium

1. **Rhabdochromatium marinum** Dilling, Liesack and Pfennig 1996, 362[VP] (Effective publication: Dilling, Liesack and Pfennig 1995, 130.)
   ma.ri′ num. L. neut. adj. *marinum* marine.

   Cells straight rods with slightly conical ends, sometimes slightly bent, 1.5–1.7 × 16–32 μm, motile by a polar tuft of flagella of about 10–20 bipolar fibrils, may be flagellated at both ends. Color of cell suspension beige to orange-brown. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids with lycopene as major component.

   Obligately phototrophic and strictly anaerobic. Hydrogen, sulfide, S^0, and thiosulfate used as electron donors for photolithoautotrophic growth. In the presence of sulfide and bicarbonate, acetate, propionate, and pyruvate are photoassimilated. Growth factors not required.

   Mesophilic marine bacterium requiring NaCl for growth: optimum growth at 1.5–5% NaCl, no growth below 1% and above 6.5%, optimum pH 7.2–7.3, optimum temperature 30°C, no growth below 8°C and above 35°C.

   Habitat: laminated microbial mat at Great Sippewissett Salt Marsh, Cape Cod, USA.

   The mol% G + C of the DNA is: 60.4 (Bd).

   Type strain: 8315, DSM 5261.

   GenBank accession number (16S rRNA): X84316.

Genus XI. Thermochromatium *Imhoff, Süling and Petri 1998b, 1140[VP]*

Johannes F. Imhoff and Michael T. Madigan

Ther′ mo.chro.ma′ ti.um. Gr. adj. *thermos* hot; *Chromatium* a genus name; M.L. neut. n. *Thermochromatium* the hot *Chromatium*.

Cells straight to slightly curved rods, multiply by binary fission, **motile**, most likely by polar flagella. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Strictly anaerobic, obligately phototrophic, and require sulfide-reduced media. **Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors**. During oxidation of sulfide, S^0 is transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. In the presence of sulfide and bicarbonate, organic substrates can be photoassimilated.

Thermophilic freshwater bacteria with optimum growth at temperatures higher than 40°C, at neutral pH 7.0, and without a requirement for salt.

Habitat: sulfide-containing hot springs of neutral to alkaline pH having temperatures between 35 and 60°C.

The mol% G + C of the DNA is: 60–63.

Type species: **Thermochromatium tepidum** (Madigan 1986) Imhoff, Süling and Petri 1998b, 1140 (*Chromatium tepidum* Madigan 1986, 226.)

Enrichment and Isolation Procedures

Media and culture conditions are the same as described for *Chromatium* species. Enrichment cultures with conditions suitable for *Chromatiaceae* species in general, in the presence of sulfide and acetate, and incubated at 45–55°C and neutral pH, give rise to the development of *Thermochromatium tepidum*, if present in the inoculum.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thermochromatium* from other genera

According to the results of 16S rDNA sequence analyses, the genus *Thermochromatium* belongs to the branch of the family *Chromatiaceae* containing motile freshwater bacteria, characterized by high temperature optima, above 40°C (*T. tepidum* at 48–50°C) and lack of capability for chemotrophic growth. The type strain of *T. tepidum* has an unusual and quite characteristic absorption spectrum. Intact cells and photosynthetic membrane preparations show a near-infrared absorption peak at 920 nm (Garcia et al., 1986). This absorption is due to a novel light-harvesting complex, and is the longest wavelength-absorbing band observed for a photosynthetic light-harvesting complex containing bacteriochlorophyll *a*. Whether this unusual complex is related to the thermophilic lifestyle of *T. tepidum* is unknown.

Morphological and physiological characteristics for the differentiation of *Thermochromatium* species from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationship of *Thermochromatium tepidum* to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

The temperature range for growth of *Thermochromatium tepidum* restricts development of this bacterium to hot springs and other thermal environments with sulfide and light (Madigan, 1984; Castenholz and Pierson, 1995). The successful adaptation to growth at high temperatures was regarded as a taxonomically relevant property of *Thermochromatium tepidum*, which is also phylogenetically distinct from mesophilic freshwater *Chromatiaceae* species. Therefore, *Chromatium tepidum* was transferred to the new genus *Thermochromatium* (Imhoff et al., 1998b).

Madigan, M.T. 1986. *Chromatium tepidum* sp. nov., a thermophilic photosynthetic bacterium of the family *Chromatiaceae*. Int. J. Syst. Bacteriol. *36*: 222–227.

List of species of the genus Thermochromatium

1. **Thermochromatium tepidum** (Madigan 1986) Imhoff, Süling and Petri 1998b, 1140[VP] (*Chromatium tepidum* Madigan 1986, 226.)
te′pi.dum. L. neut. adj. *tepidum* lukewarm.

Cells are rod shaped, 1–2 × 2.8–3.2 μm, occasionally motile by flagella. Photosynthetic pigments are bacteriochlorophyll *a*, esterified with phytol, and carotenoids of the normal spirilloxanthin group, with rhodovibrin and spirilloxanthin as predominant components.

Strictly anaerobic and obligately phototrophic. Growth occurs photolithoautotrophically in mineral media supplemented with sulfide as electron donor. Hydrogen and thiosulfate not utilized as electron donors. Acetate and pyruvate photoassimilated in the presence of sulfide. Citric acid cycle intermediates, other than acetate, fatty acids, and sugars not utilized. Ammonia, urea, and glutamine serve as nitrogen sources. No growth factors required. Poly-β-hydroxybutyrate is a storage material.

Thermophilic freshwater bacterium with optimum growth at 48–50°C, no growth below 34°C or above 57°C. Optimum pH is 7.0. NaCl is not required for growth and is inhibitory at concentrations above 1% (w/v).

Habitat: Sulfide-containing hot springs of neutral to alkaline pH at temperatures from 35 to 60°C.

The mol% G + C of the DNA is: 61.5 (T_m).

Type strain: MC, ATCC 43061, DSM 3771.

GenBank accession number (16S rRNA): M59150.

Genus XII. Thioalkalicoccus *Bryantseva, Gorlenko, Kompantseva and Imhoff 2000b, 2161[VP]*

Johannes F. Imhoff

Thi.o.al′ka.li.coc′cus. Gr. n. *thios* sulfur; Arab n. *al kali* potash, soda; L. masc. n. *coccus* sphere; M.L.masc. n. *Thioalkalicoccus* sulfur sphere from soda.

Cells are spherical or oval, typically form diplococcus-shaped cells during cell division, multiply by binary fission, and are Gram negative. Internal membranes are of the tubular type. **Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids with absorption properties similar to tetrahydrospirilloxanthin.** The metabolism is strictly anaerobic and obligately phototrophic. During photolithoautotrophic growth with sulfide as electron donor, globules of S^0 are accumulated inside the cytoplasm. The final oxidation product is sulfate. In the presence of sulfide and bicarbonate, organic substrates are photoassimilated. **Mesophilic, obligate alkaliphilic bacterium** with optimum growth at 20–25°C. Optimal development is dependent on sodium salts in low concentrations and on alkaline conditions.

Habitat: Surface of sediments rich in organic matter, and microbial mats of soda lakes containing hydrogen sulfide and exposed to the light.

The mol% G + C of the DNA is: 63.6–64.8.

Type species: **Thioalkalicoccus limnaeus** Bryantseva, Gorlenko, Kompantseva and Imhoff 2000b, 2162.

Differentiation of the genus *Thioalkalicoccus* from other genera

According to the results of 16S rDNA sequence analyses (Fig. BXII.γ.3) of the chapter describing the family *Chromatiaceae*, the genus *Thioalkalicoccus* belongs to the branch of the family *Chromatiaceae* that characteristically contains marine and halophilic species. Characteristics for differentiation from other phototrophic *Chromatiaceae* species are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae. Thioalkalicoccus limnaeus* is one of the very few species (in addition to *Thiococcus pfennigii* and *Thioflavicoccus mobilis*) that contain tubular internal photosynthetic membranes. The phylogenetic relationships of *Thioalkalicoccus* species to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, are shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae.*

List of species of the genus Thioalkalicoccus

1. **Thioalkalicoccus limnaeus** Bryantseva, Gorlenko, Kompantseva and Imhoff 2000b, 2162[VP]
lim.nae′us. Gr. fem. n. *limne* lake, pond, swamp; Gr. adj. *limnaios* pertaining to, living in lakes, swamps; M.L. masc. adj. *limnaeus* living in lakes and swamps.

Cells are spherical or oval in shape, multiply by binary fission, and are Gram negative. Internal membranes are of the tubular type. Cells are cocci of 1.3–1.8 μm diameter, usually nonmotile, and surrounded by a thin capsule. Occasionally cells with a single flagellum are observed. Internal photosynthetic membranes of tubular type are formed by invagination of the cell membrane and fill most of the cytoplasm. Color of cell suspensions is yellowish to orange-brown. The absorption spectrum of intact cells exhibits maxima at 410, 462, 492, 530, and 1030 nm, with shoulders at 602 and 835 nm. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids with absorption properties similar to tetrahydrospirilloxanthin.

The metabolism is strictly anaerobic. Photolithoautotrophic growth occurs in the light with hydrogen sulfide and S^0 as electron donors. Thiosulfate was not used for phototrophic growth. During growth with sulfide as electron donor, globules of S^0 are accumulated inside the cells. The final oxidation product is sulfate. In the presence of sulfide and sodium bicarbonate, acetate, yeast extract, malate, propionate, pyruvate, succinate, and fumarate were used as organic substrates for phototrophic growth. Growth factors were not required.

Mesophilic, obligate alkaliphilic bacterium with optimum growth at pH 8.8–9.5 (range from 8–10) and 20–25°C. Development is dependent on sodium salts in low concentrations, and good growth occurs over a broad range of salt concentrations without exhibiting a strong optimum, up to 6% NaCl (in the presence of 0.5% sodium carbonates) and up to 8.5% sodium carbonates (in the presence of 0.05% NaCl).

Habitat: Surface of sediments rich in organic matter, and microbial mats of soda lakes containing hydrogen sulfide and exposed to the light.

The mol% G + C of the DNA is: 64.0–64.5 (T_m).
Type strain: A26, ATCC BAA32.
GenBank accession number (16S rRNA): AJ277023.

Genus XIII. **Thiocapsa** *Winogradsky 1888, 84[AL] emend Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 962*

JOHANNES F. IMHOFF AND PIERRE CAUMETTE

Thi.o.cap' sa. Gr. n. *thios* sulfur; L. n. *capsa* box; M.L. fem. n. *Thiocapsa* sulfur box.

Cells spherical, 1.0–3.0 µm in diameter, diplococci before multiplication by binary fission, **nonmotile**. Tetrads may be formed after consecutive division in two perpendicular planes. Individual cells surrounded by a strong slime capsule and may contain gas vesicles. Gram negative, belong to the *Gammaproteobacteria*, and have internal **photosynthetic membranes of vesicular type** containing the photosynthetic pigments bacteriochlorophyll *a* and carotenoids.

Photolithotrophic growth under anoxic conditions in the light possible with sulfide, thiosulfate, and sulfur as electron donors. Hydrogen may also be used. During oxidation of sulfide, S^0 is transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. In the presence of sulfide and bicarbonate, simple organic substrates can be photoassimilated. **Some species may grow chemoautotrophically or chemoheterotrophically under microoxic to oxic conditions in the dark**. Storage materials: polysaccharides, poly-β-hydroxybutyrate, S^0, polyphosphates. Vitamin B_{12} may be required.

The mol% G + C of the DNA is: 63.3–66.3.

Type species: **Thiocapsa roseopersicina** Winogradsky 1888, 84.

FURTHER DESCRIPTIVE INFORMATION

Under unfavorable growth conditions, *Thiocapsa* species may form aggregates of cells embedded in slime, similar to species of *Thiocystis*, *Allochromatium*, and *Marichromatium*. Depending on culture conditions, the cell diameter of *Thiocapsa* species may vary considerably. Two of the presently known species, *Thiocapsa rosea* and *Thiocapsa pendens*, contain gas vesicles; *Thiocapsa roseopersicina* does not.

Thiocapsa roseopersicina has been found in freshwater, brackish water, and marine habitats, and a characteristic of this species may be the rather indifferent response to low salt concentrations, allowing development and successful competition in freshwater, brackish water, and marine environments. However, comparative sequence analyses indicate that a number of strains isolated from the marine environment and tentatively assigned to this species, could possibly be distinguished at the species level (Guyoneaud et al., 1998b). These bacteria behave indifferently to low salt concentrations and may be regarded as halotolerant, but not halophilic.

ENRICHMENT AND ISOLATION PROCEDURES

The methods are the same as those described for the genus *Chromatium*. *Thiocapsa roseopersicina* is one of the most common purple sulfur bacteria in nature. It is particularly abundant in ponds, pools, or lagoons receiving sewage or wastewater rich in organic matter. Since this species is the least fastidious purple sulfur bacterium known, its isolation presents no problems. The other species of *Thiocapsa*, *Thiocapsa pendens* and *Thiocapsa rosea*, can be isolated directly from samples collected in nature by agar shake dilution cultures, as described for the *Chromatium* species. The color of colonies in agar is characteristically pinkish. Because of their gas vesicle content, colonies of *Thiocapsa pendens* and *Thiocapsa rosea* maintain a chalky appearance, even if the cells are free of S^0.

MAINTENANCE PROCEDURES

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

DIFFERENTIATION OF THE GENUS *THIOCAPSA* FROM OTHER GENERA

Characteristics for differentiation of the genus *Thiocapsa* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*. *Thiocapsa* cells may form tetrads, and therefore can be mistaken for *Thiopedia rosea* or *Thiolamprovum pedioforme*. The cells of these latter species are, however, readily distinguishable from *Thiocapsa* by the formation of platelets, which usually consist of 8, 16, or more regularly arranged cells. Other differential phenotypic traits of these genera are listed in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationship of *Thiocapsa* species to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.4 of the chapter describing the family *Chromatiaceae*.

TAXONOMIC COMMENTS

Previously, nonmotile, spherical, purple sulfur bacteria without gas vesicles have been united within the genus *Thiocapsa*. However, the results of genetic analyses indicate that two of the three species placed in this genus (the former *Thiocapsa halophila* and *Thiocapsa pfennigii*) were phylogenetically quite distant from the type species, *Thiocapsa roseopersicina*. Both species belong to the cluster containing truly marine *Chromatiaceae* species Figs. BXII.γ.3 and BXII.γ.4 of the chapter describing the family *Chromatiaceae*). Consequently, they were removed from the genus *Thiocapsa* and transferred to *Thiococcus* and *Thiohalocapsa* as *Thiococcus pfennigii* and *Thiohalocapsa halophila*, respectively (Imhoff et al., 1998b).

Furthermore, *Thiocapsa rosea* and *Thiocapsa pendens*, previously known as *Amoebobacter roseus* and *Amoebobacter pendens* (Pfennig and Trüper, 1971b; Pfennig, 1989a), are closely related genetically to *Thiocapsa roseopersicina* and were included in the genus *Thiocapsa* (Guyoneaud et al., 1998b).

The type species of the genera *Amoebobacter* and *Thiocapsa* were united and therefore a decision concerning the genus name had to be made. Because both genera and their type strains were included in the Approved List and had been legitimately published at the same date (Winogradsky, 1888), none of the genera and species had priority according to the rules of Nomenclature

(rules 23a and 24b). *Thiocapsa* is the better-known genus and the more appropriate name, and *Thiocapsa roseopersicina* one of the best-studied species of purple sulfur bacteria. Therefore, according to rule 42 and recommendation 42 of the International Code of Nomenclature of Bacteria (Lapage et al., 1992), the two bacteria were united within the genus *Thiocapsa*, and *Thiocapsa roseopersicina* retained as the type species (Guyoneaud et al., 1998b). Because the nomenclatural type had been removed from the genus *Amoebobacter*, the names of other *Amoebobacter* species were changed, according to rule 37a (see also genera *Thiolamprovum* and *Lamprocystis*).

Differentiation of the species of the genus *Thiocapsa*

I. Cells without gas vesicles, capable of assimilatory sulfate reduction, able to use hydrogen as electron donor.
Thiocapsa roseopersicina

II. Cells with gas vesicles, not capable of assimilatory sulfate reduction, not able to use hydrogen as electron donor.

A. Able to grow under microoxic conditions in the dark, not able to use glucose.
Thiocapsa rosea

B. Not able to grow under microoxic conditions, strict anaerobe, able to use glucose.
Thiocapsa pendens

List of species of the genus Thiocapsa

1. **Thiocapsa roseopersicina** Winogradsky 1888, 84[AL]

ro.se.o.per.si.ci′ na. L. adj. *roseus* rosy; Gr. n. *persicus* the peach; M.L. fem. adj. *roseopersicina* rosy peach-colored.

Cells spherical, 1.2–3.0 µm, usually 1.5 µm in diameter (Fig. BXII.γ.11), and surrounded by a strong slime capsule. Aggregates of two, four, or more cells common; irregular clumps of cells usually surrounded by slime. Gas vesicles absent. Individual cells colorless, color of cell suspensions pink to rose-red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin group (Schmidt et al., 1965).

Photolithoautotrophic growth under anoxic conditions in the light with hydrogen, sulfide, thiosulfate, and sulfur as electron donors. Acetate, pyruvate, fumarate, malate, succinate, glycerol, and fructose are photoassimilated. Not utilized: lactate, propionate, butyrate, tartrate, α-oxoglutarate, citrate, benzoate, and alcohols. Chemoautotrophic or chemoheterotrophic growth under microoxic to oxic conditions in the dark is possible. Most strains capable of assimilatory sulfate reduction. Nitrogen sources: ammonium salts. Nitrogenase activity present. Growth factors not required.

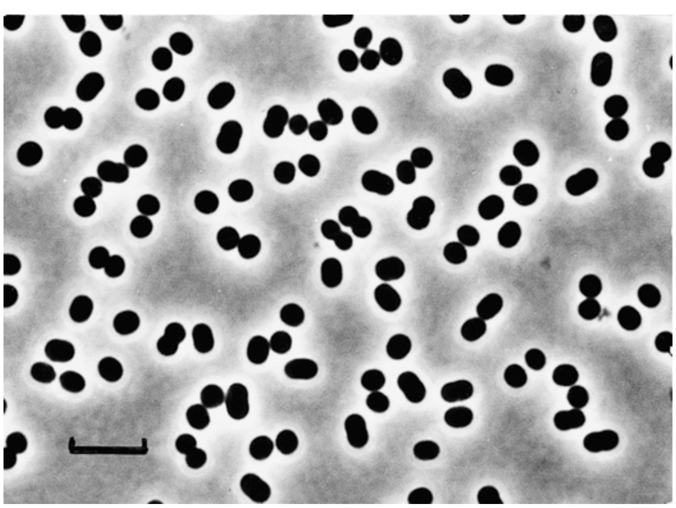

FIGURE BXII.γ.11. *Thiocapsa roseopersicina* DSM 219 cultured photoautotrophically with sulfide. Phase-contrast micrograph. Bar = 5 µm.

Mesophilic bacterium with optimum growth at 20–35°C and pH 7.3 (pH range 6.5–7.5).

Habitat: stagnant water and mud of ponds, pools, or wastewater lagoons containing degradable organic substances and hydrogen sulfide. Also common in estuaries and salt marshes.

The mol% G + C of the DNA is: 63.3–66.3 (Bd); type strain: 65.3 (Bd).

Type strain: 1711, BN 4210, DSM 217.

GenBank accession number (16S rRNA): Y12364.

2. **Thiocapsa litoralis** Puchkova, Imhoff and Gorlenko 2000, 1446[VP]

li.to.ra′ lis. L. adj. *litoralis* from the shore.

Cells are spherical and nonmotile, 1.5–2.5 µm in diameter and organized in regular platelets of 4, 8, 16, or more cells. Photosynthetic membranes are of vesicular type. Color of cell suspensions is pink to rose-red. Bacteriochlorophyll *a* and, most probably, pigments of the spirilloxanthin series are present as photosynthetic pigments.

Phototrophic growth occurs under anoxic conditions in the light and chemoautotrophic growth is possible under microoxic conditions in the dark. Electron donors used for photoautotrophic growth are hydrogen sulfide, elemental sulfur, thiosulfate, and sulfite. Globules of elemental sulfur are stored inside the cells as an intermediary product. In the presence of sulfide and bicarbonate, acetate, propionate, butyrate, valerate, pyruvate, lactate, malate, succinate, fumarate, fructose, glucose, Casamino acids, and yeast extract are photoassimilated. Caprylate, tartrate, formate, ascorbate, asparaginate, benzoate, malonate, citrate, maltose, galactose, mannitol, sorbitol, glycerol, methanol, and ethanol not utilized. Assimilatory sulfate reduction occurs. Chemolithoautotrophic growth occurs with hydrogen sulfide and thiosulfate as electron donors. Vitamin B_{12} is required as growth factor. Storage materials are poly-β-hydroxybutyrate and polyphosphates. Mesophilic bacterium with optimum growth at pH 6.5, 30°C, and 1% NaCl.

Habitat: Microbial mat communities of the White Sea littoral shore.

The mol% G + C of the DNA is: 64.0 (T_m).

Type strain: BM5, ATCC 700894.

GenBank accession number (16S rRNA): AJ24772.

3. **Thiocapsa pendens** (Molisch 1906) Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 962^{VP} (*Amoebobacter pendens* (Molisch 1906) Pfennig and Trüper 1971b, 13; *Rhodothece pendens* Molisch 1906, 230 .)
pen' dens. L. part. adj. *pendens* hanging.

Cells spherical, 1.5–2.0 μm in diameter, sometimes up to 2.5 μm in diameter. Individual cells surrounded by slime capsules, which give rise to irregular cell aggregates of different size. Because of copious slime formation, the culture medium becomes viscous. Gas vesicles present. Individual cells colorless, color of cell suspensions pink to rose-red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin group, with spirilloxanthin as the dominant component.

Strictly anaerobic and obligately phototrophic. No growth under microoxic to oxic conditions in the dark. Photolithoautotrophic growth under anoxic conditions in the light occurs with sulfide, thiosulfate, sulfite, and sulfur as electron donors. Acetate, pyruvate, propionate, lactate, malate, and glucose are the only organic substrates photoassimilated. Assimilatory sulfate reduction is absent. Nitrogen sources: ammonium salts. Vitamin B_{12} required for growth.

Mesophilic freshwater bacterium with optimum growth at 20–35°C, pH range 6.7–7.5.

Habitat: stagnant freshwater and mud containing sulfide and exposed to the light.

The mol% G + C of the DNA is: 65.3 (Bd).

Type strain: DSM 236 (neotype strain).

GenBank accession number (16S rRNA): AJ002797.

4. **Thiocapsa rosea** (Winogradsky 1888) Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 962^{VP} (*Amoebobacter roseus* Winogradsky 1888, 77.)
ro' se.a. L. fem. adj. *rosea* rosy, rose-colored, pink.

Cells spherical, 2.0–3.0 μm in diameter. Individual cells and irregular cell aggregates surrounded by slime. Gas vesicles present. Individual cells colorless, color of cell suspensions pink to rose-red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin group, with spirilloxanthin as the major component.

Photolithoautotrophic growth under anoxic conditions in the light occurs with sulfide, thiosulfate, and sulfur as electron donors. Acetate, pyruvate, propionate, lactate, malate, fructose, and Casamino acids are photoassimilated. Not utilized: other sugars, alcohols, other fatty acids, succinate, tartrate, benzoate, or citrate. Chemoautotrophic or mixotrophic growth under microoxic to oxic conditions in the dark is possible. Assimilatory sulfate reduction does not occur. Nitrogen source, ammonia. Vitamin B_{12} required.

Mesophilic freshwater bacterium with optimum growth at 20–35°C, pH range 6.7–7.5.

The mol% G + C of the DNA is: 64.3 (Bd).

Type strain: DSM 235.

GenBank accession number (16S rRNA): AJ002798, AJ006062.

Genus XIV. **Thiococcus** *Imhoff, Süling and Petri 1998b, 1139^{VP}*

Johannes F. Imhoff

Thi.o.coc' cus. Gr. n. *thios* sulfur; L. masc. n. *coccus* sphere; M.L. masc. n. *Thiococcus* sphere with sulfur.

Cells spherical, with diplococcus-shaped division stages, **nonmotile**, multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes consisting of bundles of ribbon-like branched tubes** continuous with the cytoplasmic membrane. Individual cells colorless, color of cell suspensions is yellowish to orange-brown. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 transiently stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates photoassimilated.

Mesophilic bacteria with optimum growth at 20–35°C and neutral pH (pH range 6.5–7.5). May require salt for optimum growth.

The mol% G + C of the DNA is: 69.4–69.9.

Type species: **Thiococcus pfennigii** (Eimhjellen 1970) Imhoff, Süling and Petri 1998b, 1139 (*Thiocapsa pfennigii* Eimhjellen 1970, 193.)

Enrichment and Isolation Procedures

Thiococcus pfennigii is the only species of the family *Chromatiaceae* that contains bacteriochlorophyll *b* described so far. Owing to the presence of this bacteriochlorophyll, the bacterium has an *in vivo* absorption maximum in the infrared region of the spectrum, between 1020 nm and 1030 nm. By use of selective filters, this specific absorption has been successfully applied for the selective enrichment culture of *Thiococcus* species (Eimhjellen et al., 1967; Eimhjellen, 1970). Otherwise, the culture conditions and isolation procedures are the same as described for the genus *Chromatium*. The media described for *Chromatium* species can also be used for *Thiococcus* species, if supplemented with 1–3% NaCl as required.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thiococcus* from other genera

Characteristics for differentiation of the genus *Thiococcus* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The phylogenetic relatedness of *Thiococcus pfennigii* to other members of the family *Chromatiaceae*, based on 16S rDNA analysis, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

The genus name *Thiococcus* was proposed for this bacterium by Eimhjellen et al. (1967). However, this name was never validly published and later the bacterium was validly named *Thiocapsa pfennigii* (Eimhjellen, 1970; Approved List of Bacterial Names, Skerman et al., 1980). Because of the striking genetic and phenotypic difference between *Thiococcus pfennigii* and members of the genus *Thiocapsa*, it was transferred to a new genus and the name *Thiococcus* was revived (Imhoff et al., 1998b). A possible candidate for the neotype strain of *Thiococcus pfennigii* (strain DSM 226, Trüper 8013, Imhoff 4250) belongs to the cluster of truly marine species of the family *Chromatiaceae* (Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*) and requires at least 1% NaCl for growth. The salt dependence and natural distribution of this species are poorly understood. The original type strain was isolated from a freshwater source (river water), but unfortunately was lost. Additional strains were isolated later from freshwater and marine sources. However, chemotaxonomic and genetic analyses have not been performed on these strains. In addition, salt dependence has not yet been determined for all of the isolates.

List of species of the genus Thiococcus

1. **Thiococcus pfennigii** (Eimhjellen 1970) Imhoff, Süling and Petri 1998b, 1139^{VP} (*Thiocapsa pfennigii* Eimhjellen 1970, 193.)

pfen.nig′i.i. M.L. gen. n. *pfennigii* of Pfennig, named after N. Pfennig, a German microbiologist.

Cells spherical, 1.2–1.5 µm in diameter; diplococcus-shaped division stages about 2.5 µm long; stationary phase cells 0.8–1.0 µm in diameter. Internal photosynthetic membranes are bundles of ribbon-like branched tubes continuous with the cytoplasmic membrane. Individual cells colorless, color of cell suspensions yellowish to orange-brown. Photosynthetic pigments are bacteriochlorophyll *b* and the carotenoid 3,4,3′,4′-tetrahydrospirilloxanthin (Eimhjellen et al., 1967).

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with sulfide and S^0 as electron donors. In the presence of sulfide and bicarbonate, acetate, pyruvate, propionate, lactate, fumarate, succinate, malate, and fructose are photoassimilated. Not utilized: thiosulfate and butyrate. Nitrogen sources: ammonium salts and N_2.

Mesophilic bacterium with optimum growth at 0.5–2% NaCl, 20-35°C, and pH 7.0 (range 6.5–7.5).

Habitat: freshwater, brackish, and marine waters and sediments with hydrogen sulfide and exposed to the light.

The mol% G + C of the DNA is: 69.4–69.9 (Bd).

Type strain: DSM 1375 (RG3, Nidelven) is lost; no neotype strain is designated.

GenBank accession number (16S rRNA): Y12373 (strain DSM 226).

Additional Remarks: The GenBank accession number for strain BN 4254 (Pfennig 8320) is AJ010125.

Genus XV. **Thiocystis** *Winogradsky 1888, 60^{AL} emend. Imhoff, Süling and Petri 1998b, 1138*

Johannes F. Imhoff

Thi.o.cys′tis. Gr. n. *thios* sulfur; Gr. n. *cystis* the bladder, a bag; M.L. fem. n. *Thiocystis* sulfur bag.

Cells are rod shaped or ovoid to spherical, before cell division often diplococcus-shaped, **motile by flagella**, occurring singly or in pairs; may grow in irregular aggregates surrounded by slime, multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Photolithotrophic growth occurs under anoxic conditions in the light with sulfide and S^0 as electron donors. Thiosulfate and hydrogen may also be used. During oxidation of sulfide, S^0 is transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. In the presence of sulfide and bicarbonate, simple organic substrates can be photoassimilated. **Some species grow chemoautotrophically or chemoorganotrophically under microoxic to oxic conditions in the dark**. Storage materials: polysaccharides, poly-β-hydroxybutyrate, S^0, and polyphosphates.

Ubiquitous, mesophilic bacteria with optimum growth at 25–35°C and pH 6.5–7.6, that can be isolated from freshwater, brackish water, and marine environments.

Habitat: anoxic sulfide-containing water and mud of freshwater ponds and lakes, as well as brackish water and marine environments exposed to light.

The mol% G + C of the DNA is: 61.3–67.9.

Type species: **Thiocystis violacea** Winogradsky 1888, 65.

Further descriptive information

Species of the genus *Thiocystis* are frequently found in the same natural habitats as *Allochromatium* species. Bacteria of both genera share many physiological properties. This is true not only for the phototrophic metabolism of reduced sulfur compounds and organic substrates, but also for facultatively chemoautotrophic or chemoorganotrophic metabolism under microoxic to oxic conditions in the dark (Kämpf and Pfennig, 1980), which occurs in some species of this genus.

Enrichment and Isolation Procedures

Media and culture conditions are the same as described for *Chromatium* species.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thiocystis* from other genera

According to the results of 16S rDNA sequence analyses, the genus *Thiocystis* belongs to the branch of the family *Chromatiaceae* characterized by motile freshwater species. Characteristics for differentiation of *Thiocystis* species from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*. The phylogenetic relationship of *Thiocystis* species to other *Chromatiaceae* species, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Previously, the genus *Thiocystis* was distinguished from other genera of the family *Chromatiaceae* based on its spherical morphology, flagellar motility, and lack of gas vesicles (Pfennig and Trüper, 1989). Winogradsky (1888) distinguished *Thiothece* from *Thiocystis* as a second genus of spherical, motile, purple sulfur bacteria, based on the location of the intracellular sulfur globules. In the monotypic genus *Thiothece*, the sulfur globules were located at the inner periphery of the cells, whereas in *Thiocystis* the globules were distributed at random in the cell (Winogradsky, 1888). Pfennig and Trüper (1971b) included *Thiothece gelatinosa* Winogradsky 1888 in the genus *Thiocystis* because they considered the maintenance of *Thiothece*, in addition to *Thiocystis*, unjustified.

Similarity studies on the 16S rRNA oligonucleotide catalogs of *Chromatiaceae* species (Fowler et al., 1984) and complete 16S rDNA sequence analyses (Imhoff et al., 1998b) not only substantiated the close relationship of *Thiocystis gelatinosa* and *Thiocystis violacea* (see Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*), but also revealed a high degree of genetic relatedness between these species and *Thiocystis minor* (formerly *Chromatium minus*) and *Thiocystis violascens* (formerly *Chromatium violascens*) (Imhoff et al., 1998b).

Differentiation of the species of the genus *Thiocystis*

Characteristics for diagnosis of *Thiocystis* species are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*.

I. Cells spherical.
- A. Sulfur globules appear randomly distributed within the cell, cells contain carotenoids of the rhodopinal group, and cultures are purple-violet.
  Thiocystis violacea
- B. Sulfur globules occur only at the inner periphery of the cell, cells contain carotenoids of the okenone group, and cultures are purple-red.
  Thiocystis gelatinosa

II. Cells rod shaped.
- A. Carotenoids of the okenone group are present; only acetate, pyruvate, and glucose are utilized.
  Thiocystis minor
- B. Carotenoids of the rhodopinal group are present; hydrogen, but no sugars are utilized.
  Thiocystis violascens

List of species of the genus Thiocystis

1. **Thiocystis violacea** Winogradsky 1888, 65[AL]
vi.o.la' ce.a. L. fem. adj. *violacea* violet-colored.

Cells spherical and about 2.5–3 μm in diameter. Depending on the culture conditions, larger individual cells may occur. Irregular cell aggregates surrounded by slime are formed under unfavorable conditions. Sulfur globules appear randomly distributed within the cell (Fig. BXII.γ.12). Color of individual cells grayish, color of cell suspensions purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group (Schmidt et al., 1965).

Photoautotrophic growth occurs under anoxic conditions in the light with sulfide, sulfur, thiosulfate, sulfite (used by some strains), and molecular hydrogen as electron donors. In the presence of sulfide and bicarbonate, acetate, pyruvate, and fumarate are photoassimilated. In addition, some strains use propionate, succinate, oxoglutarate, glucose, fructose, propanol, or glycerol. Chemoautotrophic or mixotrophic growth possible under microoxic to oxic conditions in the dark. Some strains capable of assimilatory sulfate reduction. Nitrogen sources: ammonium salts, urea, and N_2.

Mesophilic bacterium with optimum growth at 25–35°C and pH 7.0–7.3 (range 6.5–7.6). Marine isolates may tolerate or require low concentrations of NaCl.

Habitat: ponds and lakes with stagnant freshwater, brackish water, or seawater containing hydrogen sulfide; sewage lagoons, estuaries, salt marshes, and sulfur springs.

The mol% G + C of the DNA is: 62.8–67.9 (Bd); type strain 63.1 (Bd).

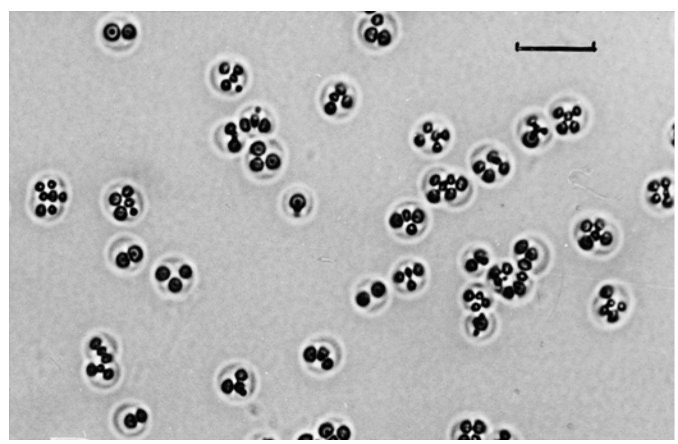

FIGURE BXII.γ.12. *Thiocystis violacea* DSM 207 cultured photoautotrophically with sulfide. The cells contain sulfur globules. Brightfield micrograph. Bar = 5 μm.

Type strain: 2711, BN 4340, DSM 207.
GenBank accession number (16S rRNA): Y11315.

2. **Thiocystis gelatinosa** (Winogradsky 1888) Pfennig and Trüper 1971b, 11[AL] (*Thiothece gelatinosa* Winogradsky 1888, 82.)
ge.la.ti.no' sa. L. part. adj. *gelatus* frozen, stiffened; M.L. n. *gelatinum* that which stiffens; M.L. fem. adj. *gelatinosa* gelatinous.

Cells spherical and about 3 μm in diameter. Under unfavorable conditions, elongated ovoid cells may occur. At

high sulfide concentration (4–6 mM) and light intensity (>1000 lux), cells become immobile, growing in irregular aggregates surrounded by slime. Under optimum growth conditions, globules of S^0 occur only in the peripheral part of the cytoplasm (Fig. BXII.γ.13). Color of individual cells slightly pink, color of cell suspensions purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the okenone group (Pfennig et al., 1968).

Photolithoautotrophic growth under anoxic conditions in the light with sulfide and sulfur as electron donors. In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Chemoautotrophic or mixotrophic growth is possible under microoxic to semioxic conditions. Nitrogen sources: ammonium salts.

Mesophilic bacterium with optimum growth at 30°C and pH 7.0–7.3 (range 6.5–7.6). The type strain requires 1% NaCl.

Habitat: stagnant water containing hydrogen sulfide, hypolimnion of meromictic lakes.

The mol% G + C of the DNA is: 61.3 (Bd).

Type strain: 2611, BN 4310, DSM 215.

GenBank accession number (16S rRNA): Y11317.

3. **Thiocystis minor** (Winogradsky 1888) Imhoff, Süling and Petri 1998b, 1139[VP] (*Chromatium minus* Winogradsky 1888, 99.)

mi' nor. L. fem. comp. adj. *minor* less, smaller.

Cells are rod shaped, ~2 × 2.5–6 μm, with polar flagella.

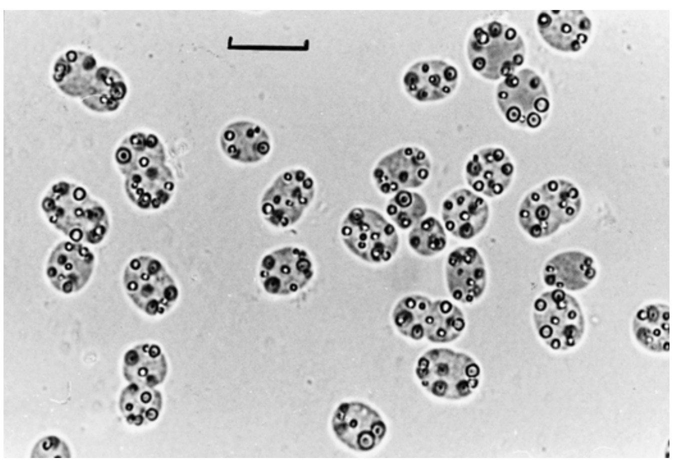

FIGURE BXII.γ.13. *Thiocystis gelatinosa* DSM 215 cultured photoautotrophically with sulfide. The peripheral deposition of the sulfur globules is clearly visible in some of the cells. Brightfield micrograph. Bar = 5 μm.

Globules of S^0 appear evenly distributed within the cell. Single cells colorless to pinkish, color of cell suspensions purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoid okenone.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide, thiosulfate, and sulfur as electron donors. In the presence of sulfide and bicarbonate, acetate, pyruvate, and glucose are photoassimilated. Not utilized: sugar-alcohols, alcohols, higher fatty acids, amino acids, benzoate, formate, and most intermediates of the tricarboxylic acid cycle (Thiele, 1968). Chemoautotrophic or mixotrophic growth possible under microoxic to semioxic conditions (Kämpf and Pfennig, 1980). Assimilatory sulfate reduction is absent. Nitrogen sources: ammonium salts and N_2.

Mesophilic freshwater bacterium with optimum growth at 30°C and pH 7.0–7.3 (pH range 6.5–7.6).

Habitat: freshwater ponds and lakes containing hydrogen sulfide and exposed to light.

The mol% G + C of the DNA is: 62.2 (Bd).

Type strain: 1711, BN 5710, DSM 178.

GenBank accession number (16S rRNA): Y12372.

4. **Thiocystis violascens** (Perty 1852) Imhoff, Süling and Petri 1998b, 1139[VP] (*Chromatium violascens* Perty 1852, 174.)

vi.o.la' scens. L. part. *violascens* becoming violet.

Cells are rod shaped, ~2 × 2.5–6.0 μm, occasionally longer. Color of cell suspensions purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group.

Phototrophic growth under anoxic conditions in the light with sulfide, sulfur, thiosulfate, sulfite, H_2, formate, acetate, propionate, and pyruvate as electron donors. Some strains utilize butyrate. Not utilized: sugars, sugar alcohols, alcohols, benzoate, citrate, and amino acids. Chemoautotrophic or mixotrophic growth is possible under microoxic to semioxic conditions (Kämpf and Pfennig, 1980). Assimilatory sulfate reduction present (Thiele, 1968). Nitrogen sources: ammonium salts and N_2.

Mesophilic bacterium with optimum growth at 25–35°C and pH 7.0–7.3 (range 6.5–7.6). Marine isolates may require up to 2% NaCl.

Habitat: ponds and lakes with stagnant freshwater, sewage lagoons, brackish waters, estuaries, salt marshes, and marine habitats containing hydrogen sulfide and exposed to the light.

The mol% G + C of the DNA is: 61.8–64.3 (Bd); type strain: 62.2 (Bd).

Type strain: 6111, BN 5410, ATCC 17096, DSM 198.

GenBank accession number (16S rRNA): AJ224438.

Genus XVI. **Thiodictyon** *Winogradsky 1888, 80*[AL]

Johannes F. Imhoff

Thi' o.dic' ty.on. Gr. n. *thios* sulfur; Gr. n. *dictyon* a net; M.L. neut. n. *Thiodictyon* sulfur net.

Cells are rod shaped with rounded ends, sometimes appearing spindle-shaped, multiply by binary fission, **nonmotile under all conditions**, may form aggregates in which the cells are arranged end-to-end in an irregular netlike structure, the shape of which is variable. May also form clumps that are more compact or break up into individual cells. Contain large, **irregularly shaped gas vesicles** in the central part of the cell. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth under anoxic conditions in the light with sulfide

and S^0 as electron donors. During oxidation of sulfide, S^0 is transiently stored in the peripheral part of the cell that is free of gas vesicles. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated.

Habitat: mud and stagnant water of ponds and lakes containing hydrogen sulfide; common as planktonic bacterium in the sulfide-containing hypolimnion of freshwater lakes.

The mol% G + C of the DNA is: 65.3–66.3.

Type species: **Thiodictyon elegans** Winogradsky 1888, 82.

Enrichment and Isolation Procedures

Media and culture conditions are the same as described for *Chromatium* species. Prerequisite for the successful enrichment and isolation of *Thiodictyon* from anoxic water or mud samples is the microscopic detection of the bacterium in the particular sample. Since in its natural habitats *Thiodictyon elegans* usually grows in the form of readily recognizable netlike cell aggregates, recognition of this bacterium is relatively easy.

For the isolation of pure cultures, it is advisable to prepare both liquid enrichment cultures and agar shake dilution cultures that are directly inoculated from the sample of the natural habitat. In liquid enrichment cultures, *Thiodictyon* may be outgrown by other purple sulfur bacteria containing gas vesicles. The culture medium and incubation conditions are the same as those described for *Lamprocystis* species.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thiodictyon* from other genera

Characteristics used for differentiation of the genus *Thiodictyon* from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

The genus *Thiodictyon* presently comprises two species: *T. elegans*, the type species of the genus, and *T. bacillosum*. The latter species was originally described by Winogradsky (1888) as *Amoebobacter bacillosus*. Pfennig and Trüper (1971b) transferred *Amoebobacter bacillosus* to the genus *Thiodictyon*, because the rod-shaped cells are very similar to those of *Thiodictyon elegans*. In addition, according to the original description of the type species of the genus *Amoebobacter* (*Amoebobacter roseus* Winogradsky 1888), this genus should comprise only spherical, nonmotile species with gas vesicles. According to 16S rRNA oligonucleotide pattern analysis, *Thiodictyon elegans* is related to *Thiocapsa* species, including *Thiocapsa pendens* and *Thiocapsa rosea* (Fowler et al., 1984). Studies on 16S rDNA sequence similarities of *Thiodictyon* species are expected to confirm this relationship. Because of the lack of genetic sequence information, *Thiodictyon* species have not been included in a recent reclassification of *Chromatiaceae* species (Guyoneaud et al., 1998b; Imhoff et al., 1998b).

Differentiation of the species of the genus *Thiodictyon*

I. Cells able to grow in form of typical netlike aggregates under certain culture conditions.
Thiodictyon elegans

II. Cells that do not form netlike aggregates, usually growing in the form of free single cells.
Thiodictyon bacillosum

List of species of the genus Thiodictyon

1. **Thiodictyon elegans** Winogradsky 1888, 82[AL]
e′le.gans. L. adj. *elegans* choice, elegant.

Cells are rod shaped, 1.5–2.0 × 3–8 μm, grow in the form of irregular netlike aggregates, dependent on the sulfide concentration and light intensity (Fig. BXII.γ.14). In cultures of higher population densities, cell chains break apart and the cultures contain predominantly single cells (Fig. BXII.γ.15). Color of single cells grayish, color of cell suspensions light violet to purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group, with rhodopinal and rhodopin as major components (Pfennig et al., 1968).

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 is transiently stored in the peripheral part of the cell that is free of gas vesicles. In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Nitrogen sources: ammonium salts.

Mesophilic freshwater bacterium with optimum growth at 20–25°C, pH range 6.7–7.3.

The mol% G + C of the DNA is: 65.3–66.3 (Bd); type strain 65.4 (Bd).

Type strain: 3011, DSM 232.

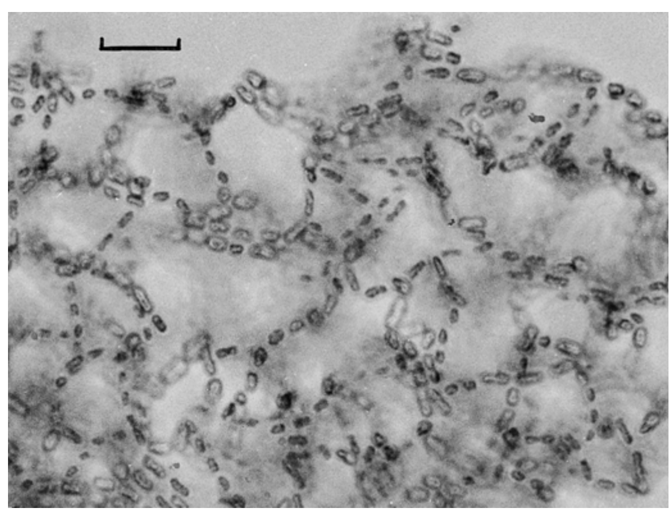

FIGURE BXII.γ.14. *Thiodictyon elegans* DSM 232 showing the typical, somewhat irregular netlike arrangement of the cells. Brightfield micrograph. Bar = 12 μm.

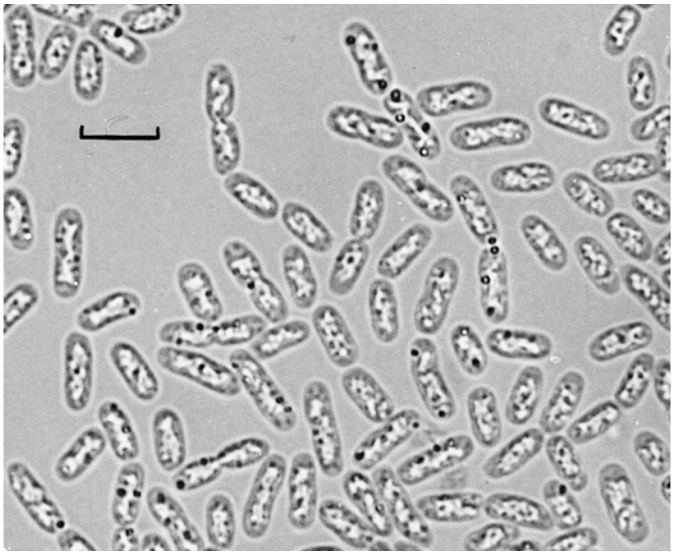

FIGURE BXII.γ.15. *Thiodictyon elegans* DSM 232 cultured photoautotrophically with sulfide. The *irregular whitish areas* within the cells are the gas vacuoles. The cells also contain small, blackish-appearing globules of S^0. Brightfield micrograph. Bar = 5 μm.

2. **Thiodictyon bacillosum** (Winogradsky 1888) Pfennig and Trüper 1971b, 12[AL] (*Amoebobacter bacillosus* Winogradsky 1888, 78.)
ba.cil.lo′sum. L. dim. n. *bacillus* a small rod; M.L. neut. adj. *bacillosum* full of or made up of small rods.

Cells are rod shaped, 1.5–2.0 × 3–6 μm, may grow in irregular clumps surrounded by slime. Netlike aggregates not formed. Color of cell suspensions light violet to purple-violet. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal group, with rhodopinal as major component (Schmidt et al., 1965).

In the presence of sulfide and bicarbonate, acetate and pyruvate are photoassimilated. Nitrogen sources: ammonium salts.

Mesophilic freshwater bacterium with optimum growth at 20–30°C, pH range 6.7–7.3.

The mol% G + C of the DNA is: 66.3 (Bd).

Type strain: 1814, DSM 234.

Genus XVII. Thioflavicoccus *Imhoff and Pfennig 2001, 109*[VP]

Johannes F. Imhoff

Th.io.fla′ vi.coc′ cus. Gr. n. *thios* sulfur; L. masc. adj. *flavus* golden-yellow, beige; L. masc. n. *coccus* sphere; M.L. masc. n. *Thioflavicoccus* beige-yellow coccus with sulfur.

Cells are spherical with diplococcus-shaped division stages, motile by flagella, multiply by binary fission. Gram negative; belong to the *Gammaproteobacteria*. Contain internal photosynthetic membranes of tubular shape. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth under anoxic conditions in the light with sulfide and elemental sulfur as electron donors. During oxidation of sulfide, elemental sulfur transiently stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates photoassimilated.

Mesophilic bacteria growing well at 20–30°C and neutral pH (pH range 6.5–7.5) and **requiring sodium chloride for optimum growth**.

The mol% G + C of the DNA is: 66.5.

Type species: **Thioflavicoccus mobilis** Imhoff and Pfennig 2001, 109.

Differentiation of the genus *Thioflavicoccus* from other genera

According to the results of 16S rDNA sequence analyses (Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*), the genus *Thioflavicoccus* belongs to the branch of the family *Chromatiaceae* that characteristically contains marine and halophilic species. Characteristics for differentiation from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. *Thioflavicoccus mobilis* is one of the very few species (in addition to *Thiococcus pfennigii* and *Thioalkalicoccus limnaeus*) that contain tubular internal photosynthetic membranes. The phylogenetic relationship of the *Thioflavicoccus* species to other *Chromatiaceae* species, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

List of species of the genus Thioflavicoccus

1. **Thioflavicoccus mobilis** Imhoff and Pfennig 2001, 109[VP]
mo′ bi.lis. L. adj. *mobilis* mobile.

Cells are coccoid, short, rod-shaped to diplococcus-shaped before cell division. Cocci 0.8–1.0 μm in diameter. Motile by monopolar monotrichous flagella. Internal photosynthetic membrane system of tubular type. Color of cell suspensions is yellowish beige to orange-brown. The absorption spectrum of living cell suspensions exhibits maxima at 410, 462, 492, 530, and 1025 nm, with shoulders at 602 and 835 nm. Photosynthetic pigments are bacteriochlorophyll *b* and 3,4,3′,4′-tetrahydro-spirilloxanthin as the main carotenoid. The metabolism is obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth occurs in the light with hydrogen sulfide as electron donor. Globules of elemental sulfur are accumulated inside the cells. The final oxidation product is sulfate. Thiosulfate is not used. In the presence of sulfide and bicarbonate, acetate, pyruvate, and ascorbate are used as organic substrates. Growth factors are not required. Sodium chloride is required for growth. Good growth occurs at 25–30°C, pH

7.2–7.4, with 1–3% NaCl (optimum is at 2%), and at 500 lux light intensity from a tungsten lamp. Habitat: laminated microbial mats of salt marshes.

The mol% G + C of the DNA is: 66.5 (Bd).
Type strain: 8321, ATCC 700959.
GenBank accession number (16S rRNA): AJ010126.

Genus XVIII. **Thiohalocapsa** *Imhoff, Süling and Petri 1998b, 1139*[VP]

Johannes F. Imhoff and Pierre Caumette

Thi'o.ha.lo.cap'sa. Gr. n. *thios* sulfur; Gr. gen. n. *halos* of the salt; L. fem. n. *capsa* capsule; M.L. fem. n. *Thiohalocapsa* the sulfur capsule of the salt.

Cells spherical, nonmotile, multiply by binary fission. Individual cells surrounded by a strong slime capsule and cell aggregates formed. Gram negative, belong to the *Gammaproteobacteria*, and contain internal **photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide, S^0, and possibly other electron donors. During oxidation of sulfide, S^0 transiently stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. **Chemolithotrophic or chemoorganotrophic growth is possible under microoxic to oxic conditions in the dark**.

Mesophilic bacteria with optimum growth at 20–30°C and pH 6.5–7.5. Elevated concentrations of sodium chloride required for growth.

Habitat: Sulfide-containing waters and sediments of saltern and other coastal habitats with elevated salt concentrations and exposed to the light.

The mol% G + C of the DNA is: 65.9–66.6.

Type species: **Thiohalocapsa halophila** (Caumette, Baulaigue and Matheron 1991) Imhoff, Süling and Petri 1998b, 1139 (*Thiocapsa halophila* Caumette, Baulaigue and Matheron 1991, 175.)

Enrichment and Isolation Procedures

Methods for enrichment and isolation are the same as those described for the genus *Chromatium*. *Thiohalocapsa* species often form dense purple layers in microbial mats of hypersaline environments with shallow waters at salinities from 10 to 20%, such as salterns, shallow salt lakes, and evaporitic lagoons. They are also found at the surface of sediments below top layers of salt deposits. *Thiohalocapsa* species can be enriched from samples of the natural environment using media composed of natural brines, as described by Caumette et al. (1991). They can be purified by repeated deep-agar dilution series. After achievement of pure cultures, a single colony is transferred into synthetic media containing 7–10% NaCl (Caumette et al., 1991).

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*. Maintenance is easier in media composed of natural brine than in synthetic media.

Differentiation of the genus *Thiohalocapsa* from other genera

Characteristics for differentiation of the genus *Thiohalocapsa* from other members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The genetic relationship of *Thiohalocapsa halophila* to other *Chromatiaceae* species, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Thiohalocapsa halophila was originally described as a *Thiocapsa* species (Caumette et al., 1991), because its phenotypic properties were in agreement with this genus classification, according to Pfennig and Trüper (1989). Cells are spherical and nonmotile purple sulfur bacteria. Because phylogenetic relationships and salt response clearly distinguish *Thiohalocapsa halophila* from species of the genus *Thiocapsa* (Guyoneaud et al., 1998b; Imhoff et al., 1998b), this bacterium was transferred to the new genus *Thiohalocapsa* (Imhoff et al., 1998b).

List of species of the genus Thiohalocapsa

1. **Thiohalocapsa halophila** (Caumette, Baulaigue and Matheron 1991) Imhoff, Süling and Petri 1998b, 1139[VP] (*Thiocapsa halophila* Caumette, Baulaigue and Matheron 1991, 175.)

ha.lo'phi.la. Gr. n. *hals* salt; Gr. adj. *philos* loving; M.L. fem. adj. *halophila* salt-loving.

Cells spherical, 1.5–2.5 μm in diameter, form aggregates of 2, 4, or more cells, nonmotile. Color of cell suspensions purple-red. Photosynthetic pigments are bacteriochlorophyll *a* and okenone.

Photolithoautotrophic growth occurs with hydrogen, sulfide, S^0, sulfite, and thiosulfate as electron donors. In presence of sulfide and bicarbonate, acetate, pyruvate, lactate, and fructose are photoassimilated. Glycerol and glucose poorly used. Chemolithotrophic or chemoorganotrophic growth is possible under microoxic conditions in the dark. Assimilatory sulfate reduction is absent. Vitamin B_{12} required.

Mesophilic and halophilic bacterium with optimum

growth at 20–30°C, pH 7.0 (pH range 6.0–8.0), and at 4–8% NaCl (salinity range 3–20% NaCl).

Habitat: Reduced sediments in coastal saltern with salt deposits exposed to light.

The mol% G + C of the DNA is: 65.9–66.6 (T_m).

Type strain: SG3202, ATCC 49740, DSM 6210.

GenBank accession number (16S rRNA): AJ002796.

Genus XIX. **Thiolamprovum** *Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 963*[VP]

Pierre Caumette, Rémi Guyoneaud and Johannes F. Imhoff

Thi'o.lam.pro' vum. Gr. n. *thios* sulfur; Gr. n. *lampros* bright, brilliant; L. n. *ovum* egg; M.L. neut. n. *Thiolamprovum* bright egg with sulfur.

Cells nearly spherical to oval, 2 × 2–3 μm, may occur in regular platelets of 4–16 cells, **nonmotile**, and multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, and have internal photosynthetic membranes of vesicular type containing the photosynthetic pigments bacteriochlorophyll *a* and carotenoids.

Photolithoautotrophic growth under anoxic conditions in the light occurs with sulfide, thiosulfate, and sulfur as electron donors. During oxidation of sulfide, S^0 transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. In the presence of sulfide and bicarbonate, simple organic substrates can be photoassimilated. **Chemoautotrophic or mixotrophic growth under microoxic to oxic conditions in the dark is possible**.

The mol% G + C of the DNA is: 64.5–66.5 (Bd).

Type species: **Thiolamprovum pedioforme** (Eichler and Pfennig 1986) Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 963 (*Amoebobacter pedioformis* Eichler and Pfennig 1986, 300.)

Enrichment and Isolation Procedures

Media and culture conditions are the same as described for *Chromatium* species. No specific enrichment or isolation procedures are applicable for *Thiolamprovum* species. Inoculation of agar shake dilution cultures directly from samples collected in nature is recommended as described for the *Chromatium* species.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thiolamprovum* from other genera

Characteristics for differentiation of *Thiolamprovum* species from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*. *Thiolamprovum* is characterized by the formation of platelets of 8–16 or more regularly arranged cells, similar to *Thiopedia rosea*. These bacteria can be distinguished by their different carotenoid content and color of cultures and colonies. *Thiolamprovum* cells contain carotenoids of the spirilloxanthin group with a pinkish color of the colonies, whereas *Thiopedia rosea* cells contain okenone with a purple color of the colonies. The phylogenetic relationship of *Thiolamprovum pedioforme* to other *Chromatiaceae* species, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.4 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

At present, *Thiolamprovum pedioforme* is the only representative of this genus. It was previously known as *Amoebobacter pedioformis* (Eichler and Pfennig, 1986). Sequence analyses of 16S rRNA genes have shown that *Thiolamprovum pedioforme* is genetically distant from *Lamprocystis* and *Thiocapsa* species (Guyoneaud et al., 1998b). Therefore, it has been transferred to *Thiolamprovum pedioforme* (Guyoneaud et al., 1998b).

Further Reading

List of species of the genus Thiolamprovum

1. **Thiolamprovum pedioforme** (Eichler and Pfennig 1986) Guyoneaud, Süling, Petri, Matheron, Caumette, Pfennig and Imhoff 1998b, 963[VP] (*Amoebobacter pedioformis* Eichler and Pfennig 1986, 300.)

pe' di.o.for' me. Gr. n. *pedion* a plain, a flat area; L. n. *forma* shape; M.L. neut. adj. *pedioforme* flat shaped.

Spherical to oval cells occur singly or in regular platelets of 4–16 cells. Individual cells 2 × 2–3 μm, nonmotile, and contain gas vesicles in peripheral parts of the cell. Color of cell suspensions pinkish red. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoids spirilloxanthin, anhydrorhodovibrin, rhodopin, and OH-spirilloxanthin.

Photolithoautotrophic growth with sulfide, thiosulfate, and S^0 as electron donors. In the presence of sulfide and bicarbonate, acetate, lactate, and pyruvate photoassimilated. Chemolithoautotrophic growth under microoxic conditions in the dark is possible with sulfide and thiosulfate as electron donors. Assimilatory sulfate reduction does not occur.

Mesophilic freshwater bacterium with optimum growth at 37°C and pH 7.4–7.6.

Habitat. freshwater and waste water ponds, type strain originates from a wastewater pond of a sugar factory.

The mol% G + C of the DNA is: 65.5 (Bd).

Type strain: Strain CML2, DSM 3802.

GenBank accession number (16S rRNA): Y12297.

Genus XX. **Thiopedia** *Winogradsky 1888, 85[AL]*

JOHANNES F. IMHOFF

Thi.o.pe' di.a. G. n. *thios* sulfur; Gr. n. *pedium* a plain, a flat area; M.L. fem. n. *Thiopedia* sulfur plain.

Cells spherical to ovoid, nonmotile, and multiply by binary fission. Rectangular platelets formed with 4, 8, 16, 32, or more regularly arranged cells (up to 128 or 256 cells may stick together). Gram negative, **contain irregularly shaped gas vesicles in the central part of the cell and internal photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 transiently stored in the peripheral part of the cell in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. Reduced sulfur compounds required as sulfur source.

Habitat: mud and stagnant water of ponds and lakes containing hydrogen sulfide, common planktonic bacterium in the sulfide-containing hypolimnion of freshwater lakes.

The mol% G + C of the DNA is: 62.5–63.5.

Type species: **Thiopedia rosea** Winogradsky 1888, 85.

ENRICHMENT AND ISOLATION PROCEDURES

A prerequisite for the successful enrichment and isolation of *Thiopedia* species is the use of an inoculum from anoxic water or mud samples in which the characteristic *Thiopedia* platelets were microscopically detected. For the isolation of pure cultures, it is advisable to prepare enrichment cultures in liquid media, as well as agar shake dilution cultures that are directly inoculated from the sample of the natural habitat. In liquid media, *Thiopedia* may be outgrown by other purple sulfur bacteria containing gas vesicles.

The culture medium and incubation conditions are similar to those described for *Chromatium* species. Not more than 1.5 mM sulfide and 3 mM acetate should be used for growth of *Thiopedia*, and the trace element solution must not contain a chelating agent (e.g., EDTA). Growth is enhanced by the addition of 100 μM dithionite to the medium. Incubation is carried out at a temperature of 20–25°C and a light intensity of 100–200 lux. *Thiopedia* species grow in the form of individual cells, or platelets with 4–128 cells. Colonies and cell suspensions of *Thiopedia rosea* exhibit a unique bright purple-red color and can, therefore, be differentiated readily from other purple sulfur bacteria.

MAINTENANCE PROCEDURES

Stock cultures may be maintained in liquid medium in tightly closed 100-ml screw-capped bottles at 4–8°C. Such cultures should be transferred every 2 months. For long-term preservation, vials of cell suspensions in anoxic culture medium containing 5% (v/v) DMSO are stored in liquid nitrogen.

DIFFERENTIATION OF THE GENUS *THIOPEDIA* FROM OTHER GENERA

Characteristics that differentiate *Thiopedia* species from other phototrophic members of the family *Chromatiaceae* are: i) the arrangement of the cells in rectangular platelets, ii) possession of gas vesicles, and iii) the purple-red color of cultures and colonies, which is due to the carotenoid okenone. Platelets similar to those of *Thiopedia* species are formed by *Thiolamprovum pedioforme*. Characteristics for differentiation of *Thiopedia* species from other spherical and nonmotile purple sulfur bacteria and from other phototrophic *Chromatiaceae* species are shown in Table BXII.γ.6 of the chapter describing the family *Chromatiaceae*.

TAXONOMIC COMMENTS

Purple sulfur bacteria having the morphology first described by Winogradsky for *Thiopedia rosea* are widely distributed in sulfide-containing ponds and lakes (Utermöhl, 1925; Eichler and Pfennig, 1991). Fine-structure studies of *Thiopedia*-like cell material collected from a purple bacteria bloom in a small forest pond (Michigan, USA) revealed the presence of at least two cell types with different internal membrane systems (Hirsch, 1973). One type contained a vesicular membrane system, while the other type contained a membrane system that consisted of stacks of disk-shaped lamellae. Thin section micrographs of the type strain of *Thiopedia rosea*, showing a vesicular membrane system, were published by Remsen (1978).

The description of *T. rosea* given here is based on information from five strains described by Eichler and Pfennig (1991). Little information on this species was previously available. It should be noted, however, that the properties of the five isolates differ in some aspects from earlier descriptions. Winogradsky (1888) indicated a cell diameter of 1–2 μm and Pfennig (1989c) reported cells being 1.2–1.6 × 1.5–2.0 μm and requiring vitamin B_{12}. The latter property was not substantiated by Eichler and Pfennig (1991) and cells were reported to be 2.0–2.5 × 2.5–3.0 μm by these authors.

Unfortunately, the ability of *Thiopedia* to multiply in rectangular platelets, as characteristically observed in many natural habitats, is gradually lost over periods of months or years in pure culture. Therefore, it is not a taxonomically reliable character. Because the formation of rectangular platelets was considered a genus-specific property, distinguishing *Thiopedia* from other *Chromatiaceae* species (Pfennig and Trüper, 1989), recognition of the taxonomic unreliability of this property raises questions about the existence of the genus *Thiopedia*. Further studies are needed to show whether *Thiopedia rosea* is a close relative of *Thiolamprovum pedioforme*, which also forms rectangular platelets (Eichler and Pfennig, 1986), or *Thiocapsa* species, that do not form large platelets, but may form tetrads of cells.

List of species of the genus Thiopedia

1. **Thiopedia rosea** Winogradsky 1888, 85[AL]
ro′se.a. L. adj. *rosea* rose-colored, pink.

Cells spherical to ovoid, 2.0–2.5 × 2.5–3.0 μm, with regular arrangements in rectangular platelets of up to 64 or more cells (Fig. BXII.γ.16). Nonmotile and contain gas vesicles in the central part of the cells. Individual cells colorless, color of cell suspensions bright purple-red. Internal photosynthetic membranes of vesicular type. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids with okenone as major component.

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with sulfide and S^0 as electron donors. Sulfide concentrations above 0.6 mM are growth inhibitory. In the presence of sulfide and bicarbonate, the following substrates are photoassimilated: acetate, pyruvate, butyrate, valerate (not more than 0.03% (w/v) of each to be added), and glucose. Some strains also utilize succinate, fumarate, malate, and fructose (0.05%). Ammonium salts serve as nitrogen source. Reduced sulfur compounds required as sulfur source. Assimilatory sulfate reduction does not occur. Growth enhanced by the addition of 100 μM dithionite to growth media.

Mesophilic planktonic freshwater bacterium with optimum growth at 23°C and pH 7.3–7.5.

Habitat: anoxic and sulfidic water of stratified freshwater lakes.

The mol% G + C of the DNA is: 62.5–63.5 (Bd).

Type strain: 4711, DSM 1236 (neotype strain; no type strain available).

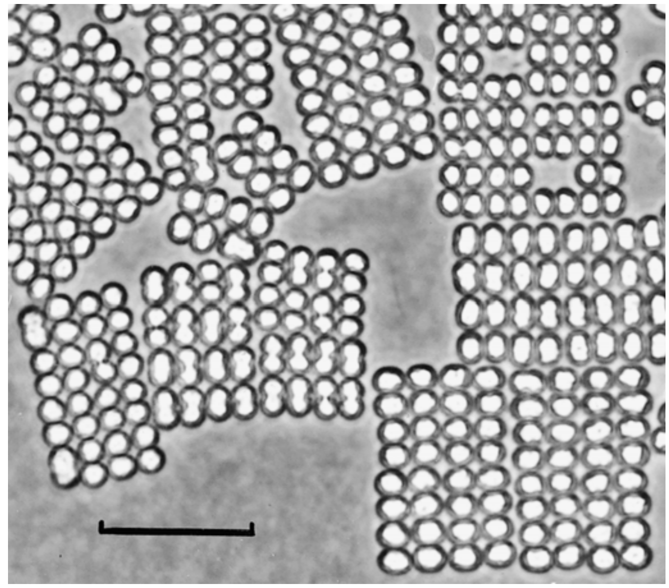

FIGURE BXII.γ.16. *Thiopedia rosea* strain 4211 cultured photoautotrophically with sulfide and acetate. The *light areas* inside the cells are the gas vacuoles. In some of the platelets, synchronously dividing cells can be recognized. Phase-contrast micrograph. Bar = 10 μm.

Genus XXI. Thiorhodococcus *Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1998a, 328*[VP] *(Effective publication: Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1997, 22)*

Rémi Guyoneaud, Pierre Caumette and Johannes F. Imhoff

Thi′o.rho.do.co′ccus. Gr. n. *thios* sulfur; Gr. n. *rhodon* the rose; L. n. *coccus* sphere; M.L. masc. n. *Thiorhodococcus* rose sphere with sulfur.

Cells spherical to slightly ovoid, diplococcus-shaped before cell division, motile by flagella. Cells single or in pairs but may form irregular aggregates, multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, **and contain internal photosynthetic membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 transiently stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. Chemotrophic growth is possible under microoxic conditions in the dark.

Habitat: water and sediment of marine and brackish environments containing hydrogen sulfide.

The mol% G + C of the DNA is: 66.8–67.0.

Type species: **Thiorhodococcus minor** Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1998a, 328 (Effective publication: Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1997, 22.)

Enrichment and Isolation Procedures

The media described for *Chromatium* species can also be used for *Thiorhodococcus* and other marine *Chromatiaceae* species, if supplemented with 2–3% NaCl as required. The culture conditions and isolation procedures are the same as described for the genus *Chromatium*.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*. Long term preservation by freezing at −80°C in 40% glycerol is also possible.

Differentiation of the genus *Thiorhodococcus* from other genera

The genus *Thiorhodococcus* is distinguished from other members of the family *Chromatiaceae* by phenotypic and genetic traits. The spherical, motile, purple sulfur bacteria of the genus *Thiorhodo-*

coccus are morphologically similar to *Thiocystis* species, but differ from them by their salt requirement and 16S rDNA sequence composition. *Thiorhodococcus minor* forms a separate lineage not specifically affiliated with other *Chromatiaceae* species (Imhoff et al., 1998b; see Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*). Characteristics useful for the differentiation of the genus *Thiorhodococcus* from other members of the family *Chromatiaceae* are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*.

List of species of the genus Thiorhodococcus

1. **Thiorhodococcus minor** Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1998a, 328[VP] (Effective publication: Guyoneaud, Matheron, Liesack, Imhoff and Caumette 1997, 22.)
mi' nor. L. masc. adj. *minor* small.

Cells spherical to slightly ovoid, 1.0–2.0 µm in diameter, highly motile by flagella, divide by binary fission, and form diplococcus-shaped division stages (Fig. BXII.γ.17). Color of individual cells grayish, color of cell suspensions brown-orange. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin group, with rhodopin as major pigment.

Photolithoautotrophic growth under anoxic conditions in the light with hydrogen, sulfide, thiosulfate, and S^0 as electron donors. In the presence of sulfide and hydrogen carbonate, acetate, propionate, lactate, glycolate, pyruvate, malate, fumarate, succinate, fructose, sucrose, ethanol, and propanol are photoassimilated. Chemolithotrophic growth with sulfide and thiosulfate, and chemoorganotrophic growth with acetate and fructose are possible under microoxic conditions in the dark. Some strains (but not the type strain) assimilate sulfate. Nitrogen sources: ammonium salts and N_2.

Mesophilic marine bacterium requiring NaCl for growth. Optimal growth at 2% NaCl (salinity range 0.5–9% NaCl), pH 7.0–7.2 (pH range 6.0–8.0), and 30–35°C.

Habitat: anoxic sediments from coastal lagoons and marine environments rich in sulfide.

The mol% G + C of the DNA is: 66.9 (HPLC).
Type strain: CE2203, ATCC 700259, DSM 11518.
GenBank accession number (16S rRNA): Y11316.

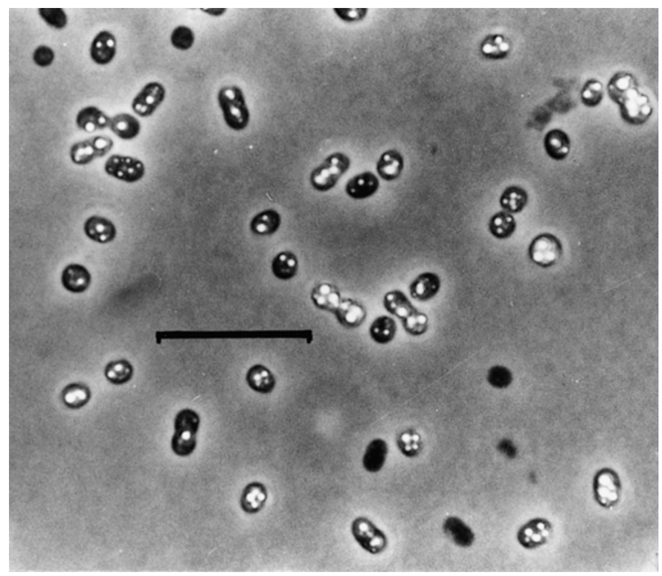

FIGURE BXII.γ.17. *Thiorhodococcus minor* DSM 11518[T] grown photolithoautotrophically with sulfide. Phase-contrast microphotograph. Bar = 10 µm.

Genus XXII. **Thiorhodovibrio** *Overmann, Fischer and Pfennig 1993, 188[VP] (Effective publication: Overmann, Fischer and Pfennig 1992, 334)*

Johannes F. Imhoff and Jörg Overmann

Thi' o.rho.do.vi' brio. Gr. n. *thios* sulfur; Gr. n. *rhodon* the rose; L. v. *vibrio* vibrate; M.L. masc. n. *vibrio* that which vibrates; *Thiorhodovibrio* rose vibrio with sulfur.

Individual **cells vibrioid to spirilloid, motile by a single polar flagellum**, multiply by binary fission. Gram negative, belong to the *Gammaproteobacteria*, and contain **internal membranes of vesicular type** with bacteriochlorophyll *a* and carotenoids as photosynthetic pigments.

Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors. During oxidation of sulfide, S^0 stored inside the cells in the form of highly refractile globules. Final oxidation product is sulfate. In the presence of sulfide and bicarbonate, simple organic substrates are photoassimilated. Chemotrophic growth at reduced oxygen partial pressure.

Habitat: surface layers of marine and salt lake sediments and microbial mats containing hydrogen sulfide.

The mol% G + C of the DNA is: 61–63.

Type species: **Thiorhodovibrio winogradskyi** Overmann, Fischer and Pfennig 1993, 188 (Effective publication: Overmann, Fischer and Pfennig 1992, 334.)

Enrichment and Isolation Procedures

The media described for *Chromatium* species can also be used for *Thiorhodovibrio* and other marine members of the family *Chromatiaceae*, if supplemented with 2–3% NaCl as required. The culture conditions and isolation procedures are the same as described for the genus *Chromatium*.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*.

Differentiation of the genus *Thiorhodovibrio* from other genera

Characteristics for differentiation of the genus *Thiorhodovibrio* from other phototrophic *Chromatiaceae* species are shown in Table BXII.γ.5 of the chapter describing the family *Chromatiaceae*. The genetic relationship of *Thiorhodovibrio winogradskyi* to other members of the family *Chromatiaceae*, based on 16S rDNA sequence comparison, is shown in Fig. BXII.γ.3 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

Thiorhodovibrio winogradskyi was described based on two isolates that show significant phenotypic differences (Overmann et al., 1992). Both strains may be considered different species, and the description of *Thiorhodovibrio winogradskyi* given here is that of the type strain (DSM 6702, SSP1). The following properties distinguish strain 06511 from the type strain of *Thiorhodovibrio winogradskyi*: Cells are spirilloid, 0.7–0.9 × 2.5–3.9 μm. Thiosulfate is used as photosynthetic electron donor and the mol% G + C content of the DNA is 62.4. Propionate does not support growth of strain 06511. However, in addition to the substrates used by the type strain, succinate, fumarate, malate, tartrate, malonate, glycerol, and peptone stimulate growth slightly (Overmann et al., 1992) for strain O6511.

Overmann, J., Fischer, U. and Pfennig, N. 1992. A new purple sulfur bacterium from saline littoral sediments, *Thiorhodovibrio winogradsky* gen. nov. and sp. nov. Arch. Microbiol. *157*: 329–335.

List of species of the genus Thiorhodovibrio

1. **Thiorhodovibrio winogradskyi** Overmann, Fischer and Pfennig 1993, 188[VP] (Effective publication: Overmann, Fischer and Pfennig 1992, 334.)
wi.no.grad′ sky.i. M.L. gen. n. *winogradskyi* of Winogradsky, named for S.N. Winogradsky, a Russian microbiologist, who did the first comprehensive studies on the purple sulfur bacteria.

Cells vibrioid, 1.2–1.6 × 2.6–4.0 μm, motile by a single polar flagellum. Gram negative and belong to the *Gammaproteobacteria*. Anaerobically grown cultures pink to light pinkish purple. Living cell suspensions have absorption maxima at 370–372, 483–484, 510, 590–591, 794–795, and 867 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin group, with rhodopin as the major component, and spirilloxanthin, lycopene, anhydrorhodovibrin, and rhodovibrin.

Photolithoautotrophic growth with sulfide and S^0 as photosynthetic electron donors. When growing on sulfide, up to ten small sulfur globules are formed inside the cell, often in a row along its long axis. High growth rates are obtained with S^0 as electron donor. In the presence of sulfide and hydrogen carbonate, acetate, pyruvate, and propionate are photoassimilated. Chemotrophic growth possible under mixotrophic conditions at reduced oxygen partial pressure (~1% O_2). No vitamins required.

Mesophilic marine bacterium requiring NaCl, with optimum growth at 2.2–3.2% NaCl (range 0.2–7.2% NaCl), pH 7.0–7.4 and 33°C (temperature range 14–37°C).

Habitat: sulfide-containing surface layers of salt lake sediments and marine microbial mats.

The mol% G + C of the DNA is: 61.0 (HPLC).

Type strain: SSP1, DSM 6702.

GenBank accession number (16S rRNA): AB016986, AJ006214, Y12368.

Genus XXIII. **Thiospirillum** *Winogradsky 1888, 104*[AL]

Johannes F. Imhoff

Thi′ o.spi.ril′ lum. Gr. n. *thios* sulfur; M.L. dim. neut. n. *Spirillum* a bacterial genus; M.L. neut. n. *Thiospirillum* sulfur *Spirillum*.

Cells **curved rods or spirals** (sigmoid), dividing by binary fission, **motile by (multitrichous) polar flagella**. Cells may be immobile and grow in irregular aggregates surrounded by slime. Gram negative, belong to the *Gammaproteobacteria*, and contain **internal photosynthetic membranes of vesicular type** in which the photosynthetic pigments bacteriochlorophyll *a* and carotenoids are located.

Obligately phototrophic and strictly anaerobic. **Photolithoautotrophic growth under anoxic conditions in the light with sulfide and S^0 as electron donors**. During oxidation of sulfide, S^0 transiently stored inside the cells in the form of highly refractile globules. Sulfate is the final oxidation product. Storage materials are polysaccharides, poly-β-hydroxybutyrate, S^0, and polyphosphate.

The mol% G + C of the DNA is: 45.5.

Type species: **Thiospirillum jenense** (Ehrenberg 1838) Migula 1900, 1050 (*Ophidomonas jenensis* Ehrenberg 1838, 44.)

Further descriptive information

Thiospirillum jenense is the only species of this genus studied in pure culture so far. *T. jenense* is a typical freshwater bacterium. Information obtained from rRNA oligonucleotide patterns (Fowler et al., 1984) indicates that *T. jenense* belongs to the family *Chromatiaceae* and is distantly related to *Chromatium* and *Allochromatium* species. Complete sequences of the 16S rDNA of this bacterium are not yet available.

Enrichment and Isolation Procedures

Conditions for enrichment and cultivation of *Thiospirillum jenense* are essentially the same as those described for *Chromatium* species. The large cells of *T. jenense* (generally 30–40 µm in length) grow only in agar shake cultures, when the final concentration of thoroughly washed agar is below 0.6–0.8% (w/v). In such agar cultures, colonies of *Thiospirillum* appear irregular and wisp-shaped. Individual cells can be recognized by using a low power, binocular microscope. Cultures containing not more than 1–2 mM sulfide should be incubated at low light intensity (200–500 lux). Colonies from agar shake cultures grow well in liquid medium, provided culture vessels of small volume are used first, e.g., screw-capped test tubes of 10–15-ml volume.

Maintenance Procedures

Maintenance of strains in liquid culture medium and long-term preservation in liquid nitrogen are carried out as described for the genus *Chromatium*. *Thiospirillum* species cannot be preserved by lyophilization.

Differentiation of the genus *Thiospirillum* from other genera

Characteristics used for the differentiation of *Thiospirillum* species from other phototrophic members of the family *Chromatiaceae* are shown in Table BXII.γ.4 of the chapter describing the family *Chromatiaceae*.

Taxonomic Comments

In addition to *Thiospirillum jenense*, two other species of *Thiospirillum*, *"Thiospirillum sanguineum"* and *"Thiospirillum rosenbergii"*, have been described from observations of water and mud samples collected in nature. The former species was described as having the same size and morphology as *Thiospirillum jenense*, with which it could have been confused. More recent reports of the existence of *"Thiospirillum rosenbergii"* are lacking. Winogradsky (1888) originally designated *Thiospirillum sanguineum* as the type species of this genus. However, because this species, in contrast to *Thiospirillum jenense*, has never been obtained in pure culture, *Thiospirillum jenense* was later recognized as the type species (Pfennig, 1989d). Further studies of strains obtained in pure culture and 16S rDNA sequence analyses are required to determine the relatedness of *Thiospirillum* species with each other and with other members of the family *Chromatiaceae*. According to 16S rRNA oligonucleotide catalogs, *Thiospirillum jenense* is not similar to *Chromatium* and *Allochromatium* species (Fowler et al., 1984), though it may be distantly related to these bacteria and belong to the corresponding group of motile freshwater *Chromatiaceae* species.

List of species of the genus Thiospirillum

1. **Thiospirillum jenense** (Ehrenberg 1838) Migula 1900, 1050[AL] (*Ophidomonas jenensis* Ehrenberg 1838, 44.)
je.nen′se. M.L. neut. adj. *jenense* jenense pertaining to Jena, Germany, the city where Ehrenberg discovered this organism.

Cells curved rods, sigmoid or spiral-shaped, 2.5–4.0 µm wide. Sigmoid cells usually 30–40 µm long, spiral cells up to 100 µm long. Complete turns may measure 15–40 µm and have a coil depth of 3–7 µm. Motile by a polar tuft of flagella, which is usually 10–12 µm long and visible by brightfield or phase-contrast microscopy (Fig. BXII.γ.18). Cells rarely tufted at both ends. Color of individual cells is pale yellow, color of cell suspensions yellowish to orange-brown. Photosynthetic pigments are bacteriochlorophyll *a* and the carotenoids lycopene and rhodopin (Schmidt et al., 1965).

Obligately phototrophic and strictly anaerobic. Photolithoautotrophic growth with sulfide and S^0 as electron donors. Thiosulfate not utilized. In the presence of sulfide and bicarbonate, acetate is photoassimilated. Nitrogen sources: ammonium salts. Vitamin B_{12} required for growth.

Mesophilic freshwater bacterium with optimum growth at 20–25°C and pH 7.0 (range 6.5–7.5).

Habitat: mud and stagnant water of ditches and freshwater ponds containing hydrogen sulfide.

The mol% G + C of the DNA is: 45.5 (Bd).

Type strain: 1112, DSM 216.

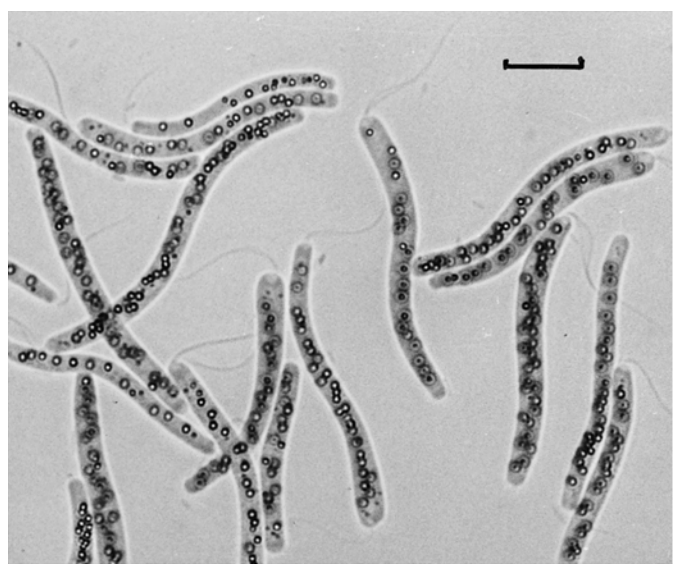

FIGURE BXII.γ.18. *Thiospirillum jenense* DSM 216 cultured photoautotrophically with sulfide. Note the intracellular sulfur globules and the short, slightly sigmoidal tufts of polar flagella. Brightfield micrograph. Bar = 10 µm.

Family II. **Ectothiorhodospiraceae** Imhoff 1984b, 339[VP]

JOHANNES F. IMHOFF

Ec' to.thi' o.rho' do.spi.ra' ce.ae. M.L. fem. n. *Ectothiorhodospira* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Ectothiorhodospiraceae* the *Ectothiorhodospira* family.

This family contains **phototrophic purple sulfur bacteria** that perform **anoxygenic photosynthesis with bacteriochlorophylls and carotenoids as photosynthetic pigments and strictly chemotrophic bacteria**. Cells spiral, vibrioid, or rod-shaped, motile by means of polar flagella, divide by binary fission, with or without gas vesicles. **Gram negative** and **belong to the *Gammaproteobacteria***. Phototrophic representatives preferably grow anaerobically in the light using reduced sulfur compounds as electron donors, **oxidize sulfide to S^0, which is deposited outside the cells, and eventually in the peripheral periplasmic space of the cell body**, forming sulfate as the final oxidation product. **Phototrophic *Ectothiorhodospiraceae* are found in marine to extremely saline environments containing sulfide and having an alkaline to extremely alkaline pH**. Species of this family are the most halophilic eubacteria.

The mol% G + C of the DNA is: 50.5–69.7.

Type genus: **Ectothiorhodospira** Pelsh 1936, 120.

TAXONOMIC COMMENTS

The taxonomic position of bacteria now classified as *Ectothiorhodospiraceae* has been disputed since their discovery by Pelsh (1936). He distinguished these bacteria, which he called *"Ectothiorhodaceae"*, from those phototrophic purple bacteria with elemental sulfur inside their cells, which he called *"Endothiorhodaceae"* (Pelsh, 1937). Pelsh's isolates were poorly characterized and were lost soon after their isolation. Trüper (1968) reisolated *Ectothiorhodospira mobilis*, and Pfennig and Trüper (1971a) included *Ectothiorhodospira* as an exceptional genus into the *Chromatiaceae* because of its ability to perform an oxidative dissimilatory sulfur metabolism similar to that of other phototrophic purple sulfur bacteria. Because bacteria known at that time as *Ectothiorhodospira* species were significantly different from all other genera of the *Chromatiaceae*, and because representatives of the purple nonsulfur bacteria had been found to oxidize sulfide to extracellular elemental sulfur, Pfennig (1977) suggested the removal of *Ectothiorhodospira* from the *Chromatiaceae* and its placement in the purple nonsulfur bacteria. However, on the basis of significant differences in their polar lipid composition, three major groups of phototrophic purple bacteria were distinguished by Imhoff et al. (1982a): *Chromatiaceae*, the bacteria known at that time as *Ectothiorhodospira*, and the purple nonsulfur bacteria (see also Imhoff and Bias-Imhoff, 1995). A clear differentiation of *Ectothiorhodospira* species from *Chromatiaceae* was later demonstrated by the oligonucleotide patterns of 16S rRNA molecules (Stackebrandt et al., 1984). With the support of this information, it was proposed that the *Ectothiorhodospiraceae* be separated as a family distinct from the *Chromatiaceae* (Imhoff, 1984b). The separation of two groups of species within the family had been recognized not only based on physiological properties and lipid composition (Tindall, 1980; Imhoff et al., 1982a; Imhoff, 1984a), but also by similarities of rRNA oligonucleotide patterns (Stackebrandt et al., 1984). However, a formal separation into genera was not proposed until later. The complete sequence analysis of the 16S rDNA from a large number of strains, including all available type strains of *Ectothiorhodospiraceae*, not only supported their separation from the *Chromatiaceae*, but also the divergence of the two groups within this family (Imhoff and Süling, 1996). Because of the large phylogenetic distance between these two groups, which is also reflected in a number of distinctive phenotypic properties, the extremely halophilic species were transferred to the new genus *Halorhodospira* (Imhoff and Süling, 1996). With this taxonomic reevaluation of the *Ectothiorhodospiraceae*, their taxonomy now follows their phylogenetic relationships, based on 16S rDNA sequences.

Two new isolates have expanded our knowledge of the *Ectothiorhodospiraceae*. A new phototrophic sulfur bacterium isolated from a Siberian soda lake, *Thiorhodospira sibirica*, has been shown to be genetically related to the genus *Ectothiorhodospira*, and many of its properties resemble those of *Ectothiorhodospira* species (Bryantseva et al., 1999b). This impressively large bacterium is unique in that it forms S^0 globules outside the cells as well as inside. Sulfur globules are located in the cells only in the very peripheral part, which is represented by an apparently large periplasmic space; they are not located in the cell interior. Therefore, the mechanism of S^0 formation and the location of the involved enzymes appear to be the same as in other *Ectothiorhodospiraceae*. However, particular care is needed to distinguish between internal and external deposition of S^0.

Another new halophilic and strictly chemotrophic bacterium has been found to be genetically related to the *Ectothiorhodospiraceae*, in particular to *Halorhodospira* (Adkins et al., 1993; Imhoff and Süling, 1996). This bacterium, *Arhodomonas aquaeolei*, is a close, purely chemotrophic relative to the phototrophic *Ectothiorhodospiraceae*. It uses a restricted spectrum of carbon sources for growth. It is considered as a member of the *Ectothiorhodospiraceae* primarily because of its phylogenetic relationship by 16S rDNA sequence.

Differentiation of the genera of *Ectothiorhodospiraceae* Characteristics for differentiation of the genera *Ectothiorhodospira*, *Halorhodospira*, *Thiorhodospira*, and *Arhodomonas* are summarized in Table BXII.γ.7. Characteristic fatty acid compositions of *Halorhodospira* and *Ectothiorhodospira* species are shown in Table BXII.γ.8. The genetic relationships of *Ectothiorhodospiraceae* based on 16S rDNA sequences are presented in Fig. BXII.γ.19.

Key to the genera of the Ectothiorhodospiraceae

I. Halophilic *Gammaproteobacteria* that require >10% total salts for optimum growth.
   A. Cells contain photosynthetic pigments typical of phototrophic purple bacteria, perform a strictly phototrophic metabolism, and require alkaline pH for optimum growth.
      Genus *Halorhodospira*
   B. Cells without photosynthetic pigments and with a strictly chemotrophic metabolism.
      Genus *Arhodomonas*

II. Halophilic phototrophic purple sulfur bacteria that require alkaline pH and salt concentrations below 10% total salts for optimum growth.
   A. S^0 globules deposited exclusively outside the cells.
      Genus *Ectothiorhodospira*
   B. S^0 globules deposited both outside and inside the cells.
      Genus *Thiorhodospira*

III. Halophilic chemolithotrophic bacteria that require a pH range of 6.8–8.0 and carry out aerobic oxidation of nitrate to nitrite.
      Genus *Nitrococcus*

Acknowledgments

Sequence alignments and the construction of the phylogenetic tree by Dr. J. Süling (IFM Kiel, Germany) are gratefully acknowledged.

[a]nd, not determined.

[b]Data from Thiemann and Imhoff (1996).

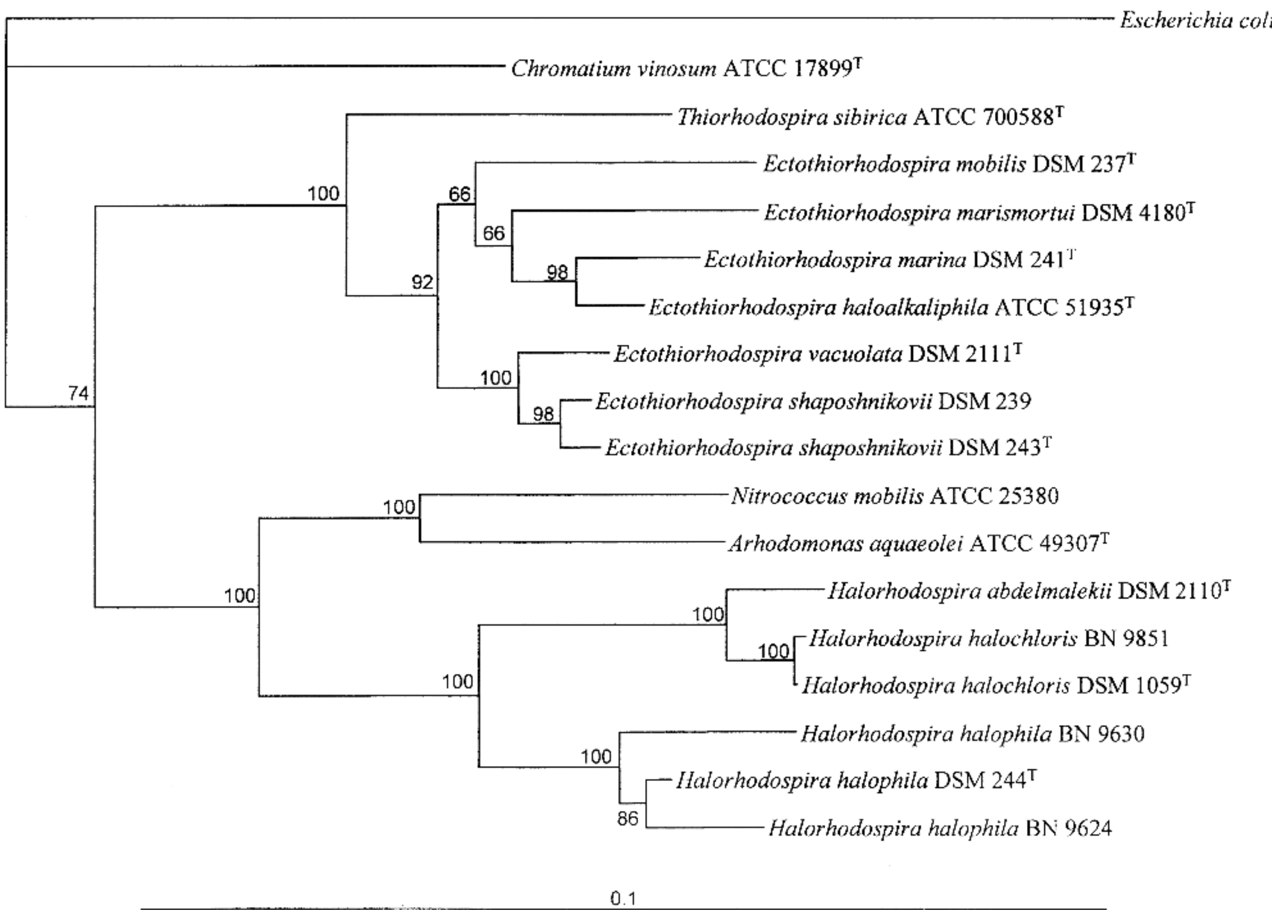

FIGURE BXII.γ.19. 16S rDNA-derived phylogenetic tree of the family *Ectothiorhodospiraceae* including species of *Ectothiorhodospira*, *Halorhodospira*, *Thiorhodospira* and *Arhodomonas*. Sequence data used were published previously (Imhoff and Süling, 1996). In addition, 16S rDNA sequences of *Arhodomonas aquaeolei* (M26631) and *Thiorhodospira sibirica* (AJ006530) were used. Sequence alignments, calculation of distance data and tree construction were performed as described earlier (Petri and Imhoff, 2000).

Stackebrandt, E., V.J. Fowler, W. Schubert and J.F. Imhoff. 1984. Towards a phylogeny of phototrophic purple sulfur bacteria: the genus *Ectothiorhodospira*. Arch. Microbiol. *137*: 366–370.

Thiemann, B. and J.F. Imhoff. 1996. Differentiation of *Ectothiorhodospiraceae* based on their fatty acid composition. Syst. Appl. Microbiol. *19*: 223–230.

Genus I. **Ectothiorhodospira** *Pelsh 1936, 120*[AL]

Johannes F. Imhoff

Ec' to.thi' o.rho' do.spi' ra. Gr. prep. *ectos* outside; Gr. n. *thios* sulfur; Gr. n. *rhodon* the rose; Gr. n. *spira* the spiral; M.L. fem. n. *Ectothiorhodospira* spiral rose with sulfur outside.

Cells rod-shaped or vibrioid, also appearing as true spirals, 0.7–1.5 μm in diameter, **motile by a polar tuft of flagella**, multiply by binary fission, and may contain gas vesicles. **Gram-negative and belong to the** *Gammaproteobacteria.* **Internal photosynthetic membranes are lamellar stacks** that are continuous with the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids.

Grow photoautotrophically under anoxic conditions with reduced sulfur compounds or hydrogen as electron donors, or photoheterotrophically with a limited number of organic compounds. **Sulfide oxidized to sulfate, with S^0, which is deposited outside the cells, as an intermediary product.** Some species grow microaerobically to aerobically in the dark. **Sodium chloride is required for growth**, which is dependent on saline and alkaline conditions. Compatible solutes include glycine betaine, sucrose, and *N*-carbamoyl-L-glutamine amide. Growth factors are not required, but vitamin B_{12} enhances growth of some strains. Storage products are polysaccharides, poly-β-hydroxybutyrate, and polyphosphate.

Most species live in marine and saline environments that contain sulfide, have slightly to extremely alkaline pH, and are exposed to light, such as estuaries, salt flats, salt lakes, and soda lakes. Occasionally found in soil.

The mol% G + C of the DNA is: 61.4–68.4.

Type species: **Ectothiorhodospira mobilis** Pelsh 1936, 120.

Further descriptive information

Cell morphology of the *Ectothiorhodospira* species varies with the growth conditions, in particular with pH and salinity. Cells of *Ectothiorhodospira mobilis* are spirals under optimum growth conditions, but tend to form vibrioid cells or bent rods. *Ectothiorhodospira shaposhnikovii* and *Ectothiorhodospira vacuolata* form straight or slightly bent rods under suitable growth conditions. Carotenoids are of the normal spirilloxanthin series with spirilloxanthin as the predominant component (Schmidt and Trüper, 1971). The *in vivo* absorption spectra of *Ectothiorhodospira* species are characterized by long wavelength absorption bands at 798, 822–827, 851–855, and 892–895 nm. The band at ~850 nm is the absolute maximum; the band at ~890 nm is mostly recognized as a shoulder, sometimes as a maximum of similar strength to that at 850 nm; and the one at ~820–830 nm can be seen only in second derivative spectra (Imhoff, unpublished results).

All species grow well under anoxic conditions in the light with reduced sulfur compounds as photosynthetic electron donors and in the presence of organic carbon sources and inorganic carbonate. *Ectothiorhodospira mobilis*, *Ectothiorhodospira shaposhnikovii*, and *Ectothiorhodospira haloalkaliphila* also grow microaerobically in the dark if sulfide is present. During phototrophic growth with sulfide as electron donor, the oxidation of sulfide and S^0 strictly follow each other, as has been shown for *E. mobilis* (see Trüper, 1978). Under the alkaline growth conditions, which are optimal for *Ectothiorhodospira* species, polysulfides are stable intermediates in sulfide oxidation. As a result, polysulfides are the first measurable oxidation products, and the medium becomes translucent yellow at this stage. After sulfide depletion, S^0 droplets are formed rather rapidly, and the medium becomes opaque and whitish. Upon further growth, cultures become pinkish and finally red, if S^0 disappears. The knowledge of enzymes involved in the oxidation of reduced sulfur compounds by *Ectothiorhodospira* species has been summarized by Trüper and Fischer (1982).

The fixation of carbon dioxide via the Calvin cycle is apparently the major route of carbon assimilation in *Ectothiorhodospira* species under autotrophic growth conditions. High activities of ribulosebisphosphate carboxylase have been found in *E. shaposhnikovii* (Firsov et al., 1974) and *E. mobilis* (Sahl and Trüper, 1977). However, the assimilation of several organic carbon sources, such as acetate and propionate, depends on the presence of carbon dioxide and proceeds via several carboxylation reactions (Firsov and Ivanovskii, 1974, 1975). Under these conditions, a considerable proportion of the cellular carbon is therefore derived from carbon dioxide, which is not assimilated via the ribulosebisphosphate pathway. Phosphoenolpyruvate carboxylase, ferredoxin-dependent pyruvate synthase and oxoglutarate synthase have been found in *E. shaposhnikovii* (Firsov et al., 1974); phosphoenolpyruvate carboxylase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase have been found in *E. mobilis* (Sahl and Trüper, 1977). All enzymes of the glycolytic pathway and the tricarboxylic acid cycle, with the exception of oxoglutarate dehydrogenase, are present in *E. shaposhnikovii* (Krasil'nikova, 1975). Cells grown on acetate demonstrate increased activities of isocitrate lyase, which indicates activity of the glyoxylic acid pathway. The major reserve material formed from acetate and butyrate in the absence of carbon dioxide is poly-β-hydroxybutyric acid. In the presence of carbon dioxide and from other organic carbon sources, carbohydrates are formed instead (Novikova, 1971).

Ammonia and glutamine are suitable nitrogen sources for all species. Dinitrogen fixation has been demonstrated for some species and is probably a property inherent to the genus as a whole. Glutamate dehydrogenase (NADH-dependent) and glutamine synthetase/glutamate synthase (NADH-dependent) have been found in *E. mobilis* (Bast, 1977). Nitrate can be used as a nitrogen source by *E. shaposhnikovii*, and its reduction is catalyzed by a ferredoxin-dependent nitrate reductase, which is associated with or bound to the membranes and induced during growth with nitrate (Malofeeva et al., 1975).

In regard to their salt responses and the salt concentrations required for optimum growth, *Ectothiorhodospira* species are slightly halophilic or marine. Based on the salt concentration at which optimum growth occurs, species are grouped as nonhalophilic bacteria (<0.1 M NaCl), brackish water bacteria (~0.1–0.35 M NaCl), marine or slightly halophilic bacteria (~0.35–1.2 M NaCl), moderately halophilic bacteria (~1.2–2.5 M NaCl), and extremely halophilic bacteria (>2.5 M NaCl) (see Imhoff, 1993, 2001d). Bacteria of each of these groups may show up with different degrees of salt tolerance. Even nonhalophilic bacteria may exhibit extreme salt tolerances and grow at very high concentration, though at a suboptimal level. In this respect, *Ectothiorhodospira* species have salt optima at the upper border of marine bacteria, and some, in particular *E. haloalkaliphila*, are moderately halotolerant. Because of its extended salt tolerance, this species may successfully compete with *Halorhodospira* species in moderately saline soda lakes. To cope with the salt and osmotic stress, *Ectothiorhodospira* species (*E. haloalkaliphila*, *E. marismortui*) accumulate glycine betaine, sucrose, and a third component (α-*N*-carbamoyl-L-glutamine amide) as osmotica (Oren et al., 1991; Severin et al., 1992; Imhoff, 1993; Imhoff and Riedel, unpublished results), but not ectoine and trehalose, which along with glycine betaine have been found as major components in *Halorhodospira* species (Galinski et al., 1985; Severin et al., 1992).

Enrichment and Isolation Procedures

Ectothiorhodospira species can be selectively enriched under photoautotrophic conditions with sulfide as the electron donor in saline and alkaline media (3% NaCl and pH 7.6–8.5), even when high proportions of *Chromatiaceae* species occur in the natural sample. Using Pfennig's medium for purple sulfur bacteria with the addition of appropriate concentrations of NaCl and adjusted to an alkaline pH (Trüper, 1970) and alternatively with a medium based on the mineral composition of the soda lakes of the Wadi Natrun (Jannasch, 1957; Imhoff and Trüper, 1977; Imhoff et al., 1979) or modifications thereof, *Ectothiorhodospira* strains have been isolated from marine sources, hypersaline ponds, salt swamps, and salt lakes from many parts of the world. From such sources, isolation can be achieved in agar dilution series with natural samples without prior enrichment. A recipe of the medium specifically designed for species from alkaline lakes containing 5% (and 20%) salts is given below (see Imhoff, 1988a).[1]

1. The medium is prepared as a basal solution with (final content per liter medium): KH_2PO_4, 0.8 g; trace element solution SLA (see below), 1 ml; 1 M sodium carbonate buffer pH 9.0, 200 ml; and NaCl, 30 g. This basal solution is sterilized in an autoclave. Solutions of 20% NH_4Cl (4 ml/l), 1% $CaCl_2 \cdot 2H_2O$ (5ml/l), 2% $MgCl_2 \cdot 6H_2O$ (5 ml/l), and 5% $Na_2S \cdot 9H_2O$ (5–10 ml/l) are sterilized separately and added after cooling to room temperature. Sodium thiosulfate (1.0 g/l), if used as electron donor, and sodium acetate (1–2 g/l) may be added to the basal solution before sterilization. The final salinity is adjusted by changing the concentrations of sodium chloride, keeping under consideration the constant level of carbonate buffer, which is equivalent to ~2% total salts. The amounts yield a medium with 5% total salts. Part of the sodium chloride (10% of the total final salt content by weight) may be replaced by sodium sulfate. In order to adjust the salinity to a total

The recipe of the standard medium according to Pfennig is given in the description of the genus *Chromatium*.

Maintenance Procedures

Cultures can be maintained at the lab bench in dim light for several months. They can be stored in agar deeps kept in the dark at 4–10°C for up to a year. For long-term preservation, storage in liquid nitrogen is recommended. In this case, cell suspensions of well-grown cultures supplemented with DMSO to a final concentration of 5% are dispensed in plastic ampules, sealed, and frozen at the temperature of liquid nitrogen.

Differentiation of the genus *Ectothiorhodospira* from other genera

Species of the genus *Ectothiorhodospira* are differentiated from other purple sulfur bacteria of the *Chromatiaceae* family by the deposition of elemental sulfur outside their cells, when grown with sulfide as the photosynthetic electron donor. Differentiation of *Ectothiorhodospira* and *Halorhodospira* species is possible based on both molecular and physiological properties (Table BXII.γ.7). *Ectothiorhodospira* species contain MK-7 and either Q-7 or Q-8 as major components, whereas *Halorhodospira* species lack significant proportions of homologs with 7 isoprenoid units, but instead have MK-8, Q-8, and a short chain MK component as major components (Imhoff, 1984a; Ventura et al., 1993). Both genera form separate groups according to their fatty acid compositions (Thiemann and Imhoff, 1996; Table BXII.γ.8). They differ significantly according to their 16S rDNA sequences, as can be seen by a number of signature sequences and sequence similarities of 87.2–89.9% (Table BXII.γ.7). In contrast to *Ectothiorhodospira* species that form sulfur globules outside their cells, *Thiorhodospira* also forms sulfur globules enclosed by the outer membrane (Bryantseva et al., 1999b).

Metabolic properties such as utilization of carbon, sulfur, and nitrogen sources are very similar among the species of both genera. Whereas several species of the genus *Ectothiorhodospira* are able to grow under chemotrophic conditions in the dark, *Halorhodospira* species are obligately phototrophic. *Ectothiorhodospira* species have growth optima under conditions of 1–8% total salts, whereas *Halorhodospira* species do not grow below 10% total salts.

Taxonomic Comments

After reevaluation of the taxonomy of *Ectothiorhodospiraceae* on the basis of complete 16S rDNA sequences, the extremely halophilic species were removed from *Ectothiorhodospira* and reassigned to the new genus *Halorhodospira* (Imhoff and Süling, 1996). Analyses of 16S rDNA sequences and fatty acid compositions supported the identification and species assignments of some strains, but demonstrated the misclassification of others (Imhoff and Süling, 1996; Thiemann and Imhoff, 1996). A number of strains have been tentatively assigned to *E. mobilis*. Strains 8112 (DSMZ 237), 8113 (DSMZ 238), and 8815 (DSMZ 240, Trüper, 1970; Mandel et al., 1971) were confirmed as strains of *E. mobilis*. Strain 8115 (DSMZ 239, Trüper, 1970; Mandel et al., 1971) was recognized as belonging to *E. shaposhnikovii*. Strains 51/7 (BN 9903, ATCC 51935) and C (BN 9902, Imhoff et al., 1978) were recognized as belonging to a new species, *E. haloalkaliphila*. Strain BA 1010 (DSMZ 241, Matheron and Baulaigue, 1972) was found to represent the new species *E. marina*, and strain BA 1011 (Matheron and Baulaigue, 1972) was found to be most closely related to strain BA 1010. The recognition of strain DSMZ 239 as belonging to *E. shaposhnikovii*, the close relationship between *E. shaposhnikovii* and *E. vacuolata*, and that between *E. mobilis* and *E. marismortui* are supported by the DNA–DNA hybridization studies of Ivanova et al. (1985) and DNA restriction pattern analysis by Ventura et al. (1993). These results were substantiated by DNA–DNA reassociation studies by Ventura et al. (2000); these authors proposed the transfer of *E. vacuolata* to *E. shaposhnikovii* and *E. marismortui* to *E. mobilis*. Given the present state of knowledge, we do not follow this proposal here because of clearly distinctive phenotypic properties and ribotyping patterns. In addition, strain BN 9903 (ATCC 51935) has been intensively studied and, though it is known from the literature as *E. mobilis* (Stackebrandt et al., 1984; Imhoff et al., 1982a; Imhoff, 1984a; Imhoff and Riedel, 1989; Imhoff and Thiemann, 1991; Imhoff et al., 1991; Zahr et al., 1992; Ventura et al., 1993), recent studies have led to the definition of this strain as the type strain of *E. haloalkaliphila* (Imhoff and Süling, 1996).

Differentiation of the species of the genus *Ectothiorhodospira*

Characteristic differential properties of *Ectothiorhodospira* species are summarized in Table BXII.γ.9. The genetic relationship of *Ectothiorhodospira* species based on 16S rDNA sequences is shown in Fig. BXII.γ.19 of the chapter describing the family *Ectothiorhodospiraceae*.

List of species of the genus Ectothiorhodospira

1. **Ectothiorhodospira mobilis** Pelsh 1936, 120[AL] emend. Ventura, Viti, Pastorelli and Giovannetti 2000, 589.
   mo′ bi.lis. L. adj. *mobilis* mobile.

   Cells vibrioid, curved in a short spiral or slightly bent rods, 0.7–1.0 × 2.0–2.6 μm (Fig. BXII.γ.20). Motile by means of a polar tuft of flagella. Color of cell suspensions free of polysulfides and S^0 is red. Absorption spectra of living cells show maxima at 378, 488, 516, 550, 590, 798, and 854 nm, with a shoulder at 892 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

   Obligately phototrophic and strictly anaerobic. Grow under anoxic conditions in the light with reduced sulfur compounds or organic carbon sources as electron donors. Photoautotrophic growth occurs with sulfide, thiosulfate, S^0, sulfite and hydrogen. Acetate, pyruvate, malate, succinate, and fumarate used as organic carbon sources and electron donors. Some strains also use fructose, glucose, lactate, butyrate, and propionate. Nitrogen sources are ammonia, glu-

---

of 20% salts, either 180 g NaCl or 20 g Na_2SO_4 and 160 g NaCl are added to a final volume of 1 liter medium. The medium is dispensed into tightly closed screw-capped bottles that are completely filled and stored until use. Prior to inoculation, it is necessary to preincubate the bottles, after removal of an appropriate small volume, at the incubation temperature in order to achieve volume expansion.

The trace element solution SLA has the following composition: $FeCl_2 \cdot 4H_2O$, 1.8 g; $CoCl_2 \cdot 6H_2O$, 250 mg; $NiCl_2 \cdot 6H_2O$, 10 mg; $CuCl_2 \cdot 5H_2O$, 10 mg; $MnCl_2 \cdot 4H_2O$, 70 mg; $ZnCl_2$, 100 mg; H_3BO_3, 500 mg; $Na_2MoO_4 \cdot 2H_2O$, 30 mg; and $Na_2SeO_3 \cdot 5H_2O$, 10 mg. These components are dissolved in 1 liter of doubly distilled water. The pH of the solution is adjusted with HCl to 2–3.

[a]Symbols: +, characteristic positive or substrate utilized by most strains; ±, characteristic positive or substrate utilized by some strains; −, characteristic negative or substrate not utilized by most strains; U, unknown—no data available; (+) weak activity or growth.

[b]None of the species uses formate, methanol, ethanol, propanol, citrate, or benzoate.

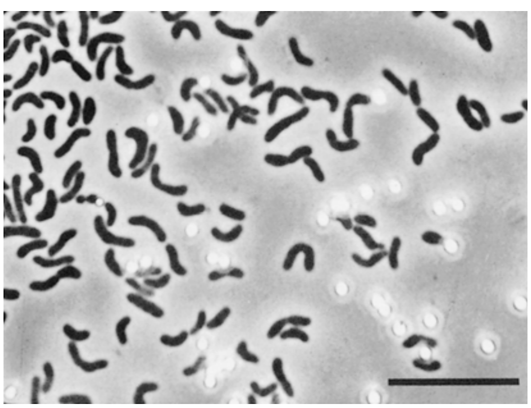

FIGURE BXII.γ.20. *Ectothiorhodospira mobilis* DSMZ 237. Note extracellular sulfur globules. Phase-contrast micrograph. Bar = 10 μm. (Reproduced with permission from H.G. Trüper and J.F. Imhoff. 1977. *In* Starr, Stolp, Trüper, Balows and Schlegel (Editors), The Prokaryotes. A Handbook on Habitats, Isolation, and Identification of Bacteria. Springer-Verlag, Berlin, p. 277.)

tamine, and some other amino acids. Sulfate is assimilated as sole sulfur source. Growth of some strains is enhanced by vitamin B_{12}.

Sodium chloride required for growth. Optimal development is at salt concentrations of 2–3% (salinity range 1–7%), pH 7.6–8.0, and 25–30°C.

Habitat: Salt marshes, marine coastal sediments containing sulfide and exposed to the light.

Major quinone components are MK-7 and Q-8.

The mol% G + C of the DNA is: 67.3–68.4 (Bd); type strain 67.3 (Bd).

Type strain: DSMZ 237.

GenBank accession number (16S rRNA): BN 9911, X93481.

2. **Ectothiorhodospira haloalkaliphila** Imhoff and Süling 1997,915[VP] (Effective publication: Imhoff and Süling 1996, 112.)

ha'lo.al.ka.li'phi.la. Gr. n. *hals* salt; Arabic n. *al kali* potash; Gr. adj. *philos* loving; M.L. fem. adj. *haloalkaliphila* loving salt and alkaline conditions.

Cells are vibrios or curved in a short spiral, 0.7–1.2 × 2.0–3.0 μm. Motile by means of a polar tuft of flagella. Color of cell suspensions free of polysulfides and S^0 is red. Absorption spectra of living cells show maxima at 379, 488, 513, 552, 593, 798, and 851 nm, with a shoulder at 892 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Grow preferably anaerobically in the light with reduced sulfur compounds or organic carbon sources as electron donors. Photoautotrophic growth occurs with sulfide, thio-

sulfate, and S^0. Chemoautotrophic and chemoheterotrophic growth is possible under microoxic conditions in the presence of sulfide. Organic carbon sources and electron donors used are acetate, pyruvate, malate, succinate, and fumarate. Nitrogen sources are ammonia and some amino acids. Sulfate is assimilated as the sole sulfur source.

Sodium chloride required for growth. Optimal development is at salt concentrations of 5% (range 2.5–15%), pH 8.5–10, and 26–40°C. Habitat: alkaline salt and soda lakes containing sulfide and exposed to the light.

Major quinone components are MK-7 and Q-8.

The mol% G + C of the DNA is: 63.5 (T_m).

Type strain: ATCC 51935, BN 9903.

GenBank accession number (16S rRNA): X93479.

3. **Ectothiorhodospira marina** Imhoff and Süling 1997, 915[VP] (Effective publication: Imhoff and Süling 1996, 112.)
ma.ri′na. L. fem. adj. *marina* marine.

Cells curved, sometimes slightly bent rods, 0.8–1.2 × 1.5–4.0 µm. Motile by means of a polar tuft of flagella. Color of cell suspensions that are free of polysulfides and S^0 is red. Absorption spectra of living cells show characteristic absorption bands at 379, 483, 513, 552, 593, 798, and 853 nm, with a shoulder at 893 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Grow preferably anaerobically in the light under photoautotrophic and photoheterotrophic conditions. Reduced sulfur compounds or organic carbon sources serve as electron donors. Photoautotrophic growth is possible with sulfide, thiosulfate, S^0, and sulfite. Acetate, pyruvate, lactate, propionate, malate, succinate, and fumarate used as organic carbon sources and electron donors. Oxoglutarate and peptone also support growth. Nitrogen sources are ammonia, dinitrogen, and glutamine. Sulfate is assimilated as sole sulfur source.

Sodium chloride required for growth. Optimal development is at salt concentrations of 2–6% (salinity range 0.5–10%), pH 7.5–8.5, and 30–40°C. Habitat: Coastal marine sediments containing sulfide and exposed to the light.

Major quinone components are MK-7 and Q-8.

The mol% G + C of the DNA is: 62.8 (Bd).

Type strain: BA 1010, BN 9914, DSMZ 241.

GenBank accession number (16S rRNA): X93476.

4. **Ectothiorhodospira marismortui*** Oren, Kessel and Stackebrandt 1990, 105[VP] (Effective publication: Oren, Kessel and Stackebrandt 1989, 529.)
ma′ris.mor′tu.i. L. gen. n. *maris* of the sea; L. adj. *mortuus* dead; M.L. gen. n. *marismortui* of the Dead Sea.

Pleomorphic irregular short rods, often curved, 0.9–1.3 × 1.5–3.3 µm. Motile by means of a polar tuft of flagella. Color of liquid cultures is red to purple. *In vivo* absorption spectra show distinct maxima at 486, 515, 550, 591, 796, and 856 nm, with a shoulder at 885 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Strictly phototrophic and obligately anaerobic. Grow photoautotrophically with sulfide and S^0 as electron donors, or photoheterotrophically with simple organic substrates. Carbon sources used are acetate, succinate, fumarate, malate, and pyruvate; poor substrates are lactate, glycerol, propionate, and yeast extract. Not utilized: methanol, ethanol, *n*-propanol, isopropanol, *n*-butanol, hydrogen, formate, butyrate, isobutyrate, citrate, benzoate, glycine, L-alanine, L-glutamate, glucose, fructose, mannitol, and sorbitol. Ammonia and dinitrogen can serve as nitrogen sources. Assimilatory sulfate reduction absent. No growth factors required, but small concentrations of yeast extract stimulate growth.

Sodium chloride required for growth. Optimum development is at salt concentrations of 3–8% (salinity range 1–20%), pH 7–8, and 35–45°C.

Habitat: Microbial mats of hypersaline sulfur springs.

Major quinone components are MK-7 and Q-8.

The mol% G + C of the DNA is: 65.0 (T_m).

Type strain: EG-1, BN 9410, DSMZ 4180.

GenBank accession number (16S rRNA): X93482.

5. **Ectothiorhodospira shaposhnikovii** Cherni, Solovieva, Fedorova and Kondratieva 1969, 483[AL] emend. Ventura, Viti, Pastorelli and Giovannetti 2000, 589.
sha′posh′ni.kov′i.i. M.L. gen. n. *shaposhnikovii* of Shaposhnikov, named for D. I. Shaposhnikov, a Russian microbiologist.

Cells rod-shaped, usually slightly bent vibrios or short spirilla. 0.8–0.9 × 1.5–2.5 µm when grown on propionate as carbon source. Motile by means of a polar tuft of flagella. Color of cell suspensions in the absence of polysulfides and S^0 is red. Absorption spectra of living cells show maxima at 378, 481, 513, 556, 593, 798, and 854 nm, with a shoulder at 892 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Cells preferably grow under anoxic conditions in the light. Photoautotrophic growth occurs with reduced sulfur compounds or molecular hydrogen as the electron donor. Chemoautotrophic and chemoheterotrophic growth possible under microoxic conditions in the dark. Photosynthetic electron donors are sulfide, S^0, thiosulfate, sulfite, molecular hydrogen, acetate, propionate, butyrate, lactate, pyruvate, malate, succinate, fumarate, and fructose. Not used: formate, methanol, ethanol, propanol, glycerol, citrate, and benzoate. Ammonia, dinitrogen, nitrate, and some amino acids used as nitrogen sources. Sulfate is assimilated as the sole sulfur source under photoheterotrophic conditions. Growth factors are not required.

Optimal development is at salt concentrations of 3% (salinity range 0–7%), pH 8.0-9.0, and 30–35°C.

Habitat: Marine sediments containing sulfide and exposed to the light.

Major quinone components are MK-7 and Q-7.

The mol% G + C of the DNA is: 62.3 (Bd), 64.0 (chem. anal.), and 62.0 (T_m).

Type strain: BN 9711, DSMZ 243, KMMGU N1.

GenBank accession number (16S rRNA): M59151.

6. **Ectothiorhodospira vacuolata*** Imhoff, Tindall, Grant and Trüper 1982b, 266[VP] (Effective publication: Imhoff, Tindall, Grant and Trüper 1981, 240.)
va.cu.o.la′ta. L. fem. adj. *vacuolata* containing vacuoles.

**Editorial Note:* Ventura et al. (2000) consider *E. marismortui* a junior heterotypic synonym of *E. mobilis.*

Cells rod-shaped, sometimes slightly bent, 1.5 × 2–4 µm. Motile by means of a polar tuft of flagella. Motile forms often develop gas vesicles and later become immotile and float to the top because of the gas vesicles. At low sulfide concentrations and low light intensities, motile cells without gas vesicles predominate. Stationary-phase cells generally become immotile and form gas vesicles. Color of cell suspensions is pink to red. Absorption spectra of living cells show maxima at 378, 486, 513, 555, 593, 798, and 855 nm, with a shoulder at 893 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the major component.

Grow under anoxic conditions in the light. Photoautotrophic growth occurs with sulfide, thiosulfate, or S^0. Organic carbon sources and electron donors used are acetate, propionate, pyruvate, malate, succinate, and fumarate. Nitrogen sources are ammonia and dinitrogen. Cysteine, but not sulfate or methionine, serves as the sulfur source under photoheterotrophic growth conditions. Growth factors are not required.

Sodium chloride required for growth. Optimal development is at salt concentrations of 1–6% (salinity range 0.5–10%), pH 7.5–9.5, and 30–40°C.

Habitat: Salt flats and salt lakes containing sulfide and exposed to the light.

Major quinone components are MK-7 and Q-7.

The mol% G + C of the DNA is: 61.4–63.6 (T_m), type strain 63.6 (T_m).

Type strain: ATCC 43036, BN 9512, DSMZ 2111.

GenBank accession number (16S rRNA): X93478.

Genus II. **Arhodomonas** *Adkins, Madigan, Mandelco, Woese and Tanner 1993, 518*[VP]

Ralph S. Tanner and Johannes F. Imhoff

A.rho.do.mo′nas. Gr. pref. *a* not; Gr. n. *rhodon* the rose, also the color or odor of the rose; Gr. n. *monas* lonely, alone; M.L. n. *Arhodomonas* the *monas* that is not rose colored.

Cells are **rods that occur singly or in pairs, are motile by means of flagella**, and multiply by binary fission. Gram negative. Members of the *Ectothiorhodospiraceae* of the *Gammaproteobacteria*. **Gas vesicles and endospores are not formed**.

Growth occurs under chemoorganotrophic conditions with oxygen or nitrate as the electron acceptor. **Phototrophic growth is not possible and photosynthetic pigments are not produced**. Catalase and oxidase positive.

Mesophilic and halophilic bacteria that require sodium for growth.

The mol% G + C of the DNA is: 67 (T_m).

Type species: **Arhodomonas aquaeolei** Adkins, Madigan, Mandelco, Woese and Tanner 1993, 518.

Further descriptive information

Arhodomonas aquaeolei is one of the few purely chemotrophic bacteria known that is phylogenetically related to the phototrophic purple sulfur bacteria of the *Gammaproteobacteria* and that belongs to the phylogenetic rather coherent group of the *Ectothiorhodospiraceae*. According to its 16S rDNA sequence, it is genetically most similar to *Halorhodospira* species but is sufficiently different so as to be recognized as a separate genus (Fig. BXII.γ.19of the chapter describing the family *Ectothiorhodospiraceae* Imhoff and Süling, 1996). The characteristic loop at position 420 (UGCG) and the addition of C in the loop covering position 1361 are also present in the sequence of *Arhodomonas aquaeolei* (Adkins et al., 1993). *Arhodomonas* shares both the requirement for high salt concentrations and the restricted spectrum of carbon sources used with *Halorhodospira* and *Ectothiorhodospira* species (Imhoff, 1989). Most carbohydrates do not support growth, but other simple organic compounds are used instead. *Arhodomonas* does not have the ability to perform a phototrophic type of metabolism.

Enrichment and Isolation Procedures

Arhodomonas aquaeolei was found in a subterranean brine produced from a petroleum reservoir, a habitat that has been without sunlight for very long time periods. It was isolated from this brine by direct plating on plate broth count agar (Difco) containing 15% NaCl and subsequent incubation under aerobic conditions at 23°C. Current information is based on a single isolate.

Maintenance Procedures

Cultures can be preserved by conventional freeze-drying.

Differentiation of the genus *Arhodomonas* from other genera

The 16S rDNA sequence similarity shows that *A. aquaeolei* is related to *Ectothiorhodospiraceae* and is most similar to *Halorhodospira* (Fig. BXII.γ.19 of the chapter describing the family *Ectothiorhodospiraceae*; Imhoff and Süling, 1996). It is clearly distinguished from these phototrophic bacteria by its strictly chemotrophic metabolism, its inability to grow phototrophically, and its lack of photosynthetic pigments. It shares the requirement for high salt concentrations with *Halorhodospira* species and in addition has a restricted spectrum of carbon sources, similar to those of its phototrophic relatives (Imhoff, 1989, 1992). Some properties of *A. aquaeolei* that differentiate it from other genera of the *Ectothiorhodospiraceae* are shown in Table BXII.γ.7 of the chapter describing the family *Ectothiorhodospiraceae*.

List of species of the genus Arhodomonas

1. **Arhodomonas aquaeolei** Adkins, Madigan, Mandelco, Woese and Tanner 1993, 518[VP]
a.quae.o′ le.i. L. gen. n. *aquae* of the water; L. gen. n. *olei* of the oil; M.L. gen. n. *aquaeolei* from water of oil.

Cells are straight, short rods, 0.8–1.0 × 2.0–2.5 μm and motile by means of a single polar flagellum. Metabolism is strictly chemotrophic. Simple organic compounds such as acetate, propionate, lactate, butyrate, valerate, isovalerate, ethanol, glycerol, glutamic acid, glutamine, and xylose are used as substrates for aerobic chemotrophic growth. Glucose, fructose, sucrose, mannose, maltose, lactose, citrate, alanine, aspartic acid, asparagine, histidine, arginine, serine, and tryptophan are not used. Nitrate, but not nitrite, is reduced. Oxidase, catalase, and urease are present, but arginine, lysine, and ornithine decarboxylases are absent. Hydrolysis of Tween 80 is positive, while casein, DNA, esculin, gelatin, and starch are not hydrolysed. Cells are sensitive to chloramphenicol, penicillin, and tetracycline.

Mesophilic and extremely halophilic bacterium with optimum growth at 15% NaCl (range: 6–20%).

Habitat: oil field brine.

The mol% G + C of the DNA is: 67 (T_m).

Type strain: HA-1, ATCC 49307.

GenBank accession number (16S rRNA): M26631.

Genus III. **Halorhodospira** *Imhoff and Süling 1997, 915*[VP] *(Effective publication: Imhoff and Süling 1996, 112.)*

Johannes F. Imhoff

Ha′ lo.rho′ do.spi′ ra. Gr. gen. n. *halos* of the salt; Gr. n. *rhodon* the rose; Gr. n. *spira* the spiral; M.L. fem. n. *Halorhodospira* the spiral rose from salt lakes.

Cells spirals or rods, 0.5–1.2 μm in diameter, motile by means of bipolar flagella, multiply by binary fission. **Gram negative and belong to the** ***Gammaproteobacteria*****. Internal photosynthetic membranes appear as lamellar stacks** that are continuous with the cytoplasmic membrane. **Photosynthetic pigments are bacteriochlorophyll** ***a*** **or** ***b*** **and carotenoids.**

Grow **photoautotrophically** under anoxic conditions with reduced sulfur compounds as electron donors, or photoheterotrophically with a limited number of simple organic compounds. **Sulfide oxidized to S^0, which is deposited outside the cells** and may be further oxidized to sulfate.

Growth dependent on highly saline and alkaline conditions. Greater than 10% (w/v) total salt concentration required by all known species, some of which grow in saturated salt solutions. **Glycine betaine, ectoine, and trehalose accumulated as compatible solutes in response to salt and osmotic stress.** Growth factors not required. Storage products are polysaccharides, poly-β-hydroxybutyrate, and polyphosphate.

Halorhodospira **species are found in hypersaline and extremely saline environments** with slightly to extremely alkaline pH (up to pH 11–12) that contain sulfide and are exposed to light, such as salt flats, salt lakes, and soda lakes.

The mol% G + C of the DNA is: 50.5–69.7.

Type species: **Halorhodospira halophila** (Raymond and Sistrom 1969) Imhoff and Süling 1997, 915 (Effective publication: Imhoff and Süling 1996, 110) (*Ectothiorhodospira halophila* Raymond and Sistrom 1969, 125.)

Further descriptive information

Cells of *Halorhodospira* species are spirals, but under severe osmotic stress, i.e., at low salt concentrations, they tend to become vibrioid to rod-shaped and increase in volume. The photosynthetic membranes of *Halorhodospira halochloris* have been intensively studied. In negatively stained preparations under the electron microscope, a regularly granulated structure is observed (Imhoff and Trüper, 1977). More detailed work, including image analysis, has demonstrated that the photosynthetic complexes are arranged in a regular hexagonal array in *Halorhodospira halochloris* and *Halorhodospira abdelmalekii* (as well as in other bacteria containing bacteriochlorophyll *b*) (Engelhardt et al., 1983). Bacteriochlorophyll *b* of *H. halochloris* and *H. abdelmalekii* is esterified with Δ-2,10-phytadienol, not with phytol as is bacteriochlorophyll *a* of *H. halophila* (Steiner et al., 1981; R. Steiner, personal communication). Carotenoids of the normal spirilloxanthin series are present in *H. halophila* with spirilloxanthin as predominant component and negligible amounts of rhodopin (Schmidt and Trüper, 1971). The content of carotenoids in *H. halochloris* and *H. abdelmalekii* is low. Major components were methoxy-hydroxylycopene glucoside (methoxy-rhodopin glucoside), hydroxylycopene glucoside (rhodopin glucoside), and dihydroxylycopene diglucoside (Takaichi et al., 2001). Substantial amonuts of dihydroxylycopene diglucoside diester were also found.

Halorhodospira species are among the most halophilic eubacteria known (Imhoff, 1988a, b). With regard to their salt responses and the salt concentrations required for optimum growth, *Halorhodospira* species are extremely halophilic (see Genus *Ectothiorhodospira* in this volume and Imhoff, 1993). In alkaline and highly hypersaline salt and soda lakes, they commonly develop massive blooms that cause red or green coloration of the water or sediment horizons (Jannasch, 1957; Imhoff et al., 1979). To adapt to high concentrations of salts and to cope with the high external osmotic pressure, bacteria and other unicellular microorganisms have to accumulate osmotically active molecules that are compatible with the molecular cell structures and metabolic processes; these are called compatible solutes or osmotica (see Imhoff, 1986, 1993). In contrast to halophilic algae and archaebacteria that selectively accumulate glycerol and potassium ions, respectively, *Halorhodospira* species accumulate glycine betaine, ectoine, and trehalose. In *H. halochloris*, glycine betaine was initially reported as the main osmotic active cytoplasmic component (Galinski and Trüper, 1982). More recently, a novel component that is active as an osmoprotectant and accumulates in high concentrations in cells of *H. halochloris* and other *Halorhodospira* species has been identified as 1,4,5,6-tetra-

hydro-2-methyl-4-pyrimidinecarboxylic acid (Galinski et al., 1985). The trivial name ectoine has been given to this component because of its first discovery in an *Ectothiorhodospiraceae* (at that time *Ectothiorhodospira*) species. This compound was later found to be widely distributed among the halophilic eubacteria (Severin et al., 1992). Unlike the *Halorhodospira* species, ectoine and trehalose have not been found as osmotica in *Ectothiorhodospira* species (*E. haloalkaliphila* and *E. marismortui*) that characteristically accumulate glycine betaine, sucrose, and an unidentified component (Oren et al., 1991; Imhoff and Riedel, unpublished. results).

Enrichment and Isolation Procedures

Halorhodospira species have been isolated from various hypersaline environments, such as salt and soda lakes, from many parts of the world. Alkaline soda lakes show a natural abundance of *Ectothiorhodospira* species, which can be taken as proof of their successful adaptation to these environments. From such sources, isolation can be achieved by agar dilution series using natural samples without prior enrichment. The tolerance of and dependence on high salinity and alkalinity are strong selective conditions for the enrichment of *Halorhodospira* species.

A medium based on the mineral composition of the soda lakes of the Wadi Natrun (Jannasch, 1957; Imhoff and Trüper, 1977; Imhoff et al., 1979) is appropriate for the cultivation of all currently known *Halorhodospira* species. A recipe for this medium containing 20% total salts is given with the description of the genus *Ectothiorhodospira* (see also Imhoff, 1988a).

Maintenance Procedures

Most cultures can be maintained at the lab bench in dim light for several months; they can be stored for up to a year in agar deeps kept in the dark. Species that have bacteriochlorophyll *b* are more sensitive to prolonged storage, particularly with respect to oxygen and light. These should be transferred more frequently than *H. halophila*. For long-term preservation, storage in liquid nitrogen is recommended as the standard maintenance procedure.

Differentiation of the genus *Halorhodospira* from other genera

Halorhodospira species represent the most halophilic species known in the phototrophic purple sulfur bacteria, and they are well adapted to form massive blooms in hypersaline environments and in alkaline soda lakes. *Halorhodospira* species are extremely halophilic bacteria and do not grow at total salt concentrations below 10%, whereas *Ectothiorhodospira* species have growth optima at salt concentrations below 10%.

Species of the genus *Halorhodospira* are easily differentiated from other purple sulfur bacteria of the *Chromatiaceae* by the deposition of S^0 outside their cells, when grown with sulfide as the photosynthetic electron donor. Differentiation of *Ectothiorhodospira* and *Halorhodospira* species is possible based on both molecular and physiological properties (Table BXII.γ.7 of the chapter describing the family *Ectothiorhodospiraceae*). Absorption spectra of *H. halophila* have a clear maximum at approximately 890 nm, but do not show absorbance at 830 nm. The long wavelength absorption maximum of the species having bacteriochlorophyll *b* is between 1010 and 1020 nm. Whereas several species of the genus *Ectothiorhodospira* are able to grow under chemotrophic conditions in the dark, all *Halorhodospira* species are obligately phototrophic. In contrast to *Ectothiorhodospira* species, *Halorhodospira* species do not contain significant proportions of quinone homologs with 7 isoprenoid units, but instead have MK-8, Q-8, and a short chain MK component as major components (Imhoff, 1984a; Ventura et al., 1993). Both genera also form separate groups according to their fatty acid compositions (Thiemann and Imhoff, 1996; Table BXII.γ.8 of the chapter describing the family *Ectothiorhodospiraceae*). Their 16S rDNA sequences are significantly different; this is evident from a number of signature sequences as well as sequence similarities of 87.2–89.9% (Table BXII.γ.7 of the chapter describing the family *Ectothiorhodospiraceae*).

Taxonomic Comments

After reevaluation of the taxonomy of *Ectothiorhodospiraceae* based on complete 16S rDNA sequence comparison, the extremely halophilic species were removed from *Ectothiorhodospira* and reassigned to the new genus *Halorhodospira* (Imhoff and Süling, 1996).

Two different but closely related groups of *H. halophila* strains (12 strains included in the study) have been recognized based on fatty acid composition (Thiemann and Imhoff, 1996), 16S rDNA sequences (Imhoff and Süling, 1996), and DNA restriction pattern analysis (Ventura et al., 1993). This diversity is considered to be intraspecies variation, most likely related to different salt responses. The mol% G + C content of the DNA of *H. halochloris* is surprisingly low when compared to that of the two other species of this genus. Such a difference of nearly 20% within the same genus is unusual, particularly when given the rather similar sequences of the 16S rRNA gene. However, the mol% G + C values in Table BXII.γ.9 of the chapter describing the family *Ectothiorhodospiraceae* have been confirmed by two independent analyses of a total of three strains (personal communication of H. Hippe, Braunschweig).

Differentiation of the species of the genus *Halorhodospira*

Characteristic properties for differentiation of *Halorhodospira* species are summarized in Table BXII.γ.10 of the chapter describing the family *Ectothiorhodospiraceae*. The genetic relationship of *Halorhodospira* species based on 16S rDNA sequences is shown in Fig. BXII.γ.19 of the chapter describing the family *Ectothiorhodospiraceae*.

List of species of the genus Halorhodospira

1. **Halorhodospira halophila** (Raymond and Sistrom 1969) Imhoff and Süling 1997, 915[VP] (Effective publication: Imhoff and Süling 1996, 110) (*Ectothiorhodospira halophila* Raymond and Sistrom 1969, 125.)

ha.lo′phi.la. Gr. n. *hals* salt; Gr. adj. *philos* loving; M.L. fem. adj. *halophila* salt-loving.

Cells curved in a spiral, 0.6–0.9 × 2–8 μm (Fig. BXII.γ.21). Color of cell suspensions in the absence of polysulfides and S^0 is red. Absorption spectra of living cells show maxima at 378, 488, 520, 554, 590, 799, 831-835, and 886–889 nm. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol) and carotenoids of the spirilloxanthin series with spirilloxanthin as the predominant component.

TABLE BXII.γ.10. Differential characteristics of *Halorhodospira* species[a]

Characteristic	*Halorhodospira halophila*	*Halorhodospira abdelmalekii*	*Halorhodospira halochloris*

Succinate	+	+	+
Malate	+	+	+

[a]Symbols: +, characteristic positive or substrate utilized by some strains; ±, characteristic positive or substrate utilized by some strains; −, characteristic negative or substrate not utilized by most strains; U, unknown—no data available; (+) weak activity or growth.

[b]In addition a short chain isoprenoid quinone is present in large amounts.

[c]No species uses formate, butyrate, glucose, fructose, glycerol, methanol, ethanol, or propanol.

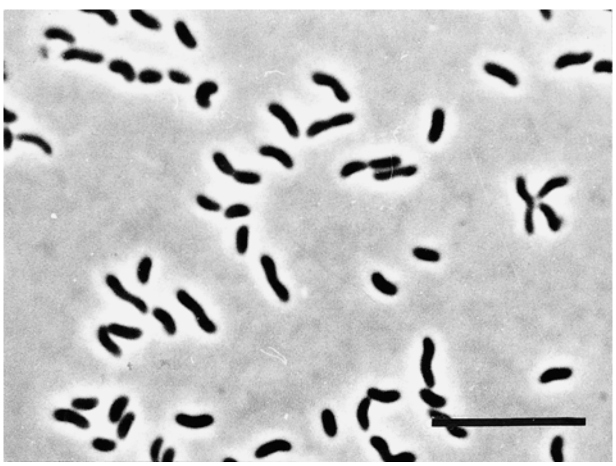

FIGURE BXII.γ.21. *Halorhodospira halophila* BN 9621. Phase-contrast micrograph. Bar = 10 μm. (Reproduced with permission from H.G. Trüper and J.F. Imhoff. 1977. *In* Starr, Stolp, Trüper, Balows and Schlegel (Editors), The Prokaryotes. A Handbook on Habitats, Isolation, and Identification of Bacteria. Springer-Verlag, Berlin, p. 277.)

Obligately phototrophic and strictly anaerobic. Photoautotrophic growth occurs with sulfide and thiosulfate as electron donors. When inorganic carbonate is present, acetate, propionate, pyruvate, malate, succinate, and fumarate are used as organic carbon sources. Ammonia, glutamate, and glutamine serve as nitrogen sources. Sulfate assimilation absent. Cysteine used as a sulfur source under photoheterotrophic growth conditions. Growth factors not required, but vitamin B_{12} enhances growth of some strains.

Extremely high concentrations of sodium chloride are required for growth. Optimal development is at 30–47°C, pH 8.5–9.0, and 11–32% salt concentration. Cells lyse at low salt concentrations (below approximately 0.5 M NaCl).

Habitat: mud and waters of highly saline and alkaline environments containing sulfide and exposed to the light, such as salt and soda lakes.

The mol% G + C of the DNA is: 66.5-69.7 (T_m), type strain 68.4 (Bd).

Type strain: SL1, BN 9610, DSMZ 244.

GenBank accession number (16S rRNA): M26630.

2. **Halorhodospira abdelmalekii** (Imhoff and Trüper 1982) Imhoff and Süling 1997, 915[VP] (Effective publication: Imhoff and Süling 1996, 111) (*Ectothiorhodospira abdelmalekii* Imhoff and Trüper 1982, 266.)
abd' el.ma.lek' i.i. M.L. gen. n. *abdelmalekii* of Abd-El-Malek, named for Yousef Abd-El-Malek, an Egyptian microbiologist.

Cells spirals or rods, 0.9–1.2 × 4–6 μm, or longer. Motile by means of bipolar, sheathed flagella. Color of cell suspensions is pale green, sometimes with a brownish tinge. Photosynthetic pigments are bacteriochlorophyll *b* (esterified with phytadienol) and small amounts of carotenoids.

Grow under strictly anoxic conditions in the presence of sulfide, inorganic carbonate, and an organic carbon source. Acetate, propionate, pyruvate, succinate, fumarate, and malate are used as carbon sources and electron donors. Growth factors are not required. Ammonia is used as nitrogen source.

Extremely high concentrations of sodium chloride are required for growth. Optimal development is at 30–44°C, pH 8.0-9.2, and 12–18% salts.

Habitat: mud and waters of highly saline and alkaline environments containing sulfide and exposed to the light, such as salt and soda lakes.

The mol% G + C of the DNA is: 63.3–63.8 (T_m), type strain 63.8 (T_m).

Type strain: BN 9840, ATCC 35917, DSMZ 2110.

GenBank accession number (16S rRNA): X93477.

3. **Halorhodospira halochloris** (Imhoff and Trüper 1979) Imhoff and Süling 1997, 915[VP] (Effective publication: Imhoff and Süling 1996, 111) (*Ectothiorhodospira halochloris* Imhoff and Trüper 1979, 79.)

ha.lo.chlo'ris. Gr. gen. n. *halos* of the salt; Gr. adj. *chloros* green; M.L. adj. *halochloris* green-colored and from salt lakes.

Cells spiral-shaped, 0.5–0.6 μm wide and, depending on the culture conditions, 2.5–8.0 μm long (Fig. BXII.γ.22). Color of cell suspensions is pale green to gooseberry-green, in dense populations with a brownish tinge. Living cells have absorption maxima at 374, 389, 598, 796, 884, and 1018 nm. Photosynthetic pigments are bacteriochlorophyll *b* (esterified with phytadienol) and small amounts of carotenoids (mainly rhodopin glucoside and its methoxy derivative).

Obligately phototrophic and strictly anaerobic. In the presence of sulfide as the photosynthetic electron donor and inorganic carbonate, acetate, propionate, pyruvate, succinate, fumarate, and malate are used. Nitrogen sources are ammonia and glutamine. Growth factors are not required.

Extremely high concentrations of sodium chloride required for growth. Optimal development is at 30–47°C, pH 8.1–9.1, and 14–27% salt concentration, no growth below approximately 10% total salts.

Habitat: mud and waters of highly saline and alkaline environments containing sulfide and exposed to the light, such as salt and soda lakes.

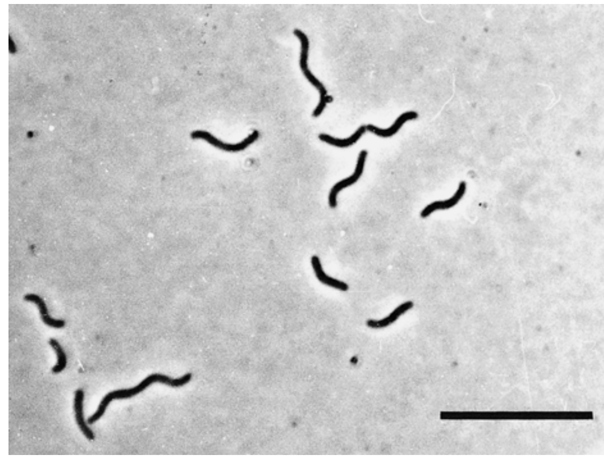

FIGURE BXII.γ.22. *Halorhodospira halochloris* DSMZ 1059. Phase-contrast micrograph. Bar = 10 μm. (Reproduced with permission from H.G. Trüper and J.F. Imhoff. 1977. *In* Starr, Stolp, Trüper, Balows and Schlegel (Editors), The Prokaryotes. A Handbook on Habitats, Isolation, and Identification of Bacteria. Springer-Verlag, Berlin, p. 277.)

The mol% G + C of the DNA is: 50.5–52.9 (T_m), type strain 52.9 (T_m).

Type strain: BN 9850, ATCC 35916, DSMZ 1059.

GenBank accession number (16S rRNA): M59152.

Genus IV. **Nitrococcus** *Watson and Waterbury 1971, 224*[AL]

EVA SPIECK AND EBERHARD BOCK

Ni.tro.coc'cus. L. n. *nitrum* nitrate; Gr. n. *coccus* a grain, berry; M.L. masc. n. *Nitrococcus* nitrate sphere.

Spherical cells 1.5 μm or more in diameter, occurring singly or in pairs. Cells reproduce by binary fission. **Intracytoplasmic membranes occur as tubes**, randomly arranged throughout the cytoplasm. Gram negative. **Motile** by 1 or 2 flagella. **Aerobic**. Energy derived from the **oxidation of nitrite to nitrate**. **Obligate lithoautotrophs**. Optimal growth in 70–100% seawater enriched with nitrite and other inorganic salts. No organic growth factors required. Isolated from marine environments.

The mol% G + C of the DNA is: 61.2.

Type species: **Nitrococcus mobilis** Watson and Waterbury 1971, 224[AL].

FURTHER DESCRIPTIVE INFORMATION

Nitrococcus mobilis belongs to the family *Ectothiorhodospiraceae* in the class *Gammaproteobacteria* (Woese et al., 1985). It is the only example of a nitrite-oxidizing bacterium that is phylogenetically related to ammonia-oxidizing bacteria (*Nitrosococcus oceani* and *"Nitrosococcus halophilus"*) in the same class. All these organisms are from marine habitats. No growth occurs in freshwater media even if NaCl is included. The temperature range for growth is 15–30°C and the pH range is 6.8–8.0. No terrestrial strains are known so far. *Ectothiorhodospira*, *Arhodomonas*, *Halorhodospira*, and *Thiorhodospira* are the closest relatives of *Nitrococcus*.

Additional details and a comparison of the biochemical properties of *Nitrococcus* to those of other nitrite-oxidizing genera can be found in the introductory chapter "Lithoautotrophic Nitrite-Oxidizing Bacteria." Detailed treatments of the ecology of nitrite-oxidizing bacteria and of the phylogeny of these organisms can be found in the introductory chapter "Nitrifying Bacteria."

Because of the presence of extensive intracytoplasmic membrane systems in both genera, Teske et al. (1994) hypothesized that *Nitrobacter* and *Nitrococcus* derived from an immediate photosynthetic ancestry. Additional features that the two genera have in common include *a*-type cytochromes, flagella, carboxysomes, and storage materials. The tubular membranes of *Nitrococcus* are quite similar to the internal photosynthetic membrane system of *Thiocapsa pfennigii* (*Thiococcus pfennigii*).

A spherical cell of *Nitrococcus* with two flagella is shown in Fig. BXII.γ.23. The tubular intracytoplasmic membranes are visible in Fig. BXII.γ.24. Cells are elongated before division (1.8 × 3.5 μm). They may occur as small clumps of cells embedded in a slime matrix. The cell wall is similar to that seen in most other Gram-negative bacteria. The tubular membrane system arises by invaginations of the cytoplasmic membrane and has a branching nature. As in *Nitrobacter*, the cytoplasmic and intracytoplasmic membranes are asymmetric, with an electron-dense layer on the inner side; the structure of the membranes becomes apparent when cells are ruptured and negatively stained. The surface of the membrane is covered with particles, which are arranged in rows (Fig. BXII.γ.24 and BXII.γ.25). Watson and Waterbury (1971) described doughnut-shaped particles 6–8 nm in diameter, which occasionally form rectilinear arrays. The particulate intracytoplasmic membranes of *Nitrococcus* were labeled with gold particles using monoclonal antibodies (MAbs) that recognize the β-

subunit of the nitrite oxidoreductase (β-NOR) of *Nitrobacter* (Fig. BXII.γ.26). The molecular mass of the β-subunit of the nitrite-oxidizing system (β-NOS) of *Nitrococcus* is in the same range as the β-NOR of *Nitrobacter* (65 KDa) (Bartosch et al., 1999). The size of this protein corresponds to that of one of the main proteins (135 and 61 KDa) found in crude extracts of *Nitrococcus* (Krause-Kupsch, personal communication). Cytochromes of the *a*- and *c*-types as well as several kinds of inclusion bodies such as carboxysomes and poly-β-hydroxybutyrate granules are present in *Nitrococcus*. Electron-dense bodies believed to be composed of glycogen are observed.

Enrichment and Isolation Procedures

Nitrite oxidizers can be isolated using a mineral medium containing nitrite; the compositions of media for lithotrophic, mixotrophic, and heterotrophic growth are given in Table BXII.γ.11. Serial dilutions of enrichment cultures must be incubated for one to several months in the dark. Since nitrite oxidizers are sensitive to high partial pressures of oxygen, cell growth on agar surfaces is limited. Nitrite oxidizers can be separated from heterotrophic contaminants by Percoll gradient centrifugation and subsequent serial dilution (Ehrich et al., 1995).

Maintenance Procedures

Nitrifying organisms can survive starvation for more than one year when kept at 17°C in liquid medium. Nevertheless, cells should be transferred to fresh media every four months. Table BXII.γ.11 lists three different growth media for nitrite oxidizers. Freezing in liquid nitrogen is a suitable technique for maintenance of stock cultures suspended in a cryoprotective buffer containing sucrose and histidine.

Differentiation of the genus *Nitrococcus* from other genera

The nitrite oxidizers are a diverse group of long or short rods, cocci, and spirillae. The genera *Nitrobacter* and *Nitrococcus* possess

[e]After sterilization pH should be 7.4–7.8.

a complex arrangement of intracytoplasmic membranes in form of flattened vesicles or tubes. *Nitrococcus* is motile by 1–2 flagella and possesses a tubular membrane system as well as carboxysomes. The taxonomic categorization is based on the work of Sergei and Helene Winogradsky (Winogradsky, 1892). Traditionally, the classification of genera is performed primarily on cell shape and arrangement of intracytoplasmic membranes. So far, four morphologically distinct genera (*Nitrobacter*, *Nitrococcus*, *Nitrospina*, and *Nitrospira*) have been described; the four genera contain a total of eight species (Watson et al., 1989; Bock and Koops, 1992; Ehrich et al., 1995; Sorokin et al., 1998). Differential traits of the four genera of nitrite-oxidizing bacteria are given in Table BXII.γ.12, further properties in Table BXII.γ.13, and fatty acid profiles in Table BXII.γ.14. Motility and carboxysomes have been observed in *Nitrobacter* and *Nitrococcus* (Tables BXII.γ.12 and BXII.γ.13).

Nitrococcus can be separated from the other genera by means of monoclonal antibodies that recognize the key enzyme (Table BXII.γ.12). Aamand et al. (1996) developed three monoclonal antibodies (MAbs) that recognize the α- and the β-subunit of the NOR of *Nitrobacter*. MAb Hyb 153-2 was specific for the α-NOR of *Nitrobacter*, whereas MAb Hyb 153-1 recognized the β-NOSs of both *Nitrobacter* and *Nitrococcus*. The MAb Hyb 153-3 recognized the β-NOSs of *Nitrobacter*, *Nitrococcus*, *Nitrospina* and *Nitrospira* (Bartosch et al., 1999). Thus, the suite of MAbs permits detection of all known nitrite oxidizers and discrimination of *Nitrobacter* and *Nitrococcus* from *Nitrospina* and *Nitrospira*.

Taxonomic Comments

Classification of *Nitrococcus* as a distinct genus of nitrite-oxidizing bacteria is based primarily on its unique morphology and ultrastructure. Sequence analysis of the 16S rRNA confirmed the separation.

List of species of the genus Nitrococcus

1. **Nitrococcus mobilis** Watson and Waterbury 1971, 224[AL]
mo' bi.lis. L. adj. *mobilis* movable, motile.

The morphological, cultural and biochemical characteristics are as described for the genus. The minimum generation time is 10 h. Optimum temperature range, 25–30°C. Optimum pH range, 7.5–8.0. The type strain was isolated from equatorial Pacific seawater.

The mol% G + C of the DNA is: 61.3 (Bd).

Type strain: ATCC 25380.

Genus V. **Thioalkalivibrio** *Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578*^{VP}

THE EDITORIAL BOARD

Thi.o.al.kal.i.vi' bri.o. Gr. n. *thios* sulfur; N.L. n. *alkali* Arabic *al* the; *qaliy* soda ash; L. v. *vibrio* vibrate; M.L. n. *Thioalkalivibrio* sulfur alkaline vibrio.

Motile Gram-negative curved rods or spirilla (0.4–0.6 × 0.8–3.0 µm). **One polar flagellum. Cell wall rippled.** Possess carboxysomes. **Obligate chemolithoautotrophs. Oxidize sulfide, thiosulfate, sulfur, and tetrathionate.** Carbon assimilation via Calvin cycle. **Halotolerant** up to 1.2–1.5 M Na^+; require at least 0.3 M Na^+.

The mol% G + C of the DNA is: 61–65.6.

Type species: **Thioalkalivibrio versutus** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579 (*Thioalkalivibrio versutus* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579.)

FURTHER DESCRIPTIVE INFORMATION

These organisms were found in the water and sediments of alkaline lakes in which sulfide is produced in the underlying sediments. Growth in the laboratory was studied in carbonate/bicarbonate buffered medium containing thiosulfate, sulfide, polysulfide, sulfur, and polythionates. All strains produce elemental sulfur from thiosulfate at the beginning of the exponential phase in batch culture; this sulfur vanishes later in growth. Tetrathionate and elemental sulfur were used by most strains. The pH optimum was 9–10. Ammonia, nitrite, and nitrate were used as nitrogen sources. Some strains reduced nitrate to nitrite under reduced O_2 levels. The type strain of *T. denitrificans*, ALJD, is a facultative anaerobe able to grow with thiosulfate and nitrous oxide as electron donor and acceptor, respectively (Sorokin et al., 2001a).

Analysis of the 16S rDNA sequence of the type strains of *T. versutus*, *T. denitrificans*, and *T. nitratis* showed that the genus *Thioalkalivibrio* belongs to the *Gammaproteobacteria*; two species of the genus *Ectothiorhodospira* (anaerobic purple sulfur bacteria) were their closest relatives (Sorokin et al., 2001a).

ENRICHMENT AND ISOLATION PROCEDURES

These bacteria were obtained by aerobic enrichment and isolation in a carbonate/bicarbonate buffered liquid salts medium containing thiosulfate. For some strains the amount of NaCl in the base medium had to be increased. Strains that reduce nitrate to nitrite can be obtained by adding 20 mM nitrate to the base medium. The single denitrifying strain was obtained using thiosulfate and N_2O in an anaerobic enrichment culture (Sorokin et al., 2001a).

MAINTENANCE PROCEDURES

Thioalkalivibrio spp. can be stored at 4°C for 2 months between transfers in liquid salts medium (pH 10) containing 5 mM $MgCl_2$ to stabilize the cell walls. They can also be stored in 10% glycerol (v/v) at –80°C (Sorokin et al., 2001a).

List of species of the genus Thioalkalivibrio

1. **Thioalkalivibrio versutus** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579 (*Thioalkalivibrio versutus* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579.)
ver.su' tus. L. adj. *versutus* versatile.

Description as for the genus with the following additional characteristic. Best growth occurs under atmospheric levels of O_2.

The mol% G + C of the DNA is: 63–65.6 (T_m).
Type strain: AL 2, DSM 13738.
GenBank accession number (16S rRNA): AF126546.

2. **Thioalkalivibrio denitrificans** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579^{VP} (*Thioalkalivibrio denitrificans* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579.)
de.ni.tri' fi.cans M.L. v. *denitrifico* denitrify; M.L. part. adj. *denitrificans* denitrifying.

Description as for the genus with the following additional characteristics. Facultatively anaerobic denitrifier. Best growth is obtained with thiosulfate and nitrous oxide under anaerobic conditions.

The mol% G + C of the DNA is: 62.3–65. 0 (T_m).
Type strain: ALJD, DSM 13742.
GenBank accession number (16S rRNA): AF126545.

3. **Thioalkalivibrio nitratis** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579^{VP} (*Thioalkalivibrio nitratis* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 579.)
ni.tra' tis. M.L. adj. *nitratis* nitrate.

Description as for the genus with the following additional characteristic. Nitrate reduced to nitrite under microaerophilic conditions.

The mol% G + C of the DNA is: 61.3–62.1 (T_m).
Type strain: ALJ 12, DSM 13741.
GenBank accession number (16S rRNA): AF126547.

Other Organisms

Sorokin et al. (2001c) described two further alkaliphilic chemoautotrophs whose 16S rDNA sequences were related to *Thioalkalivibrio* spp.: one type utilized thiocyanate as a nitrogen source while using thiosulfate as an electron donor; the other utilized thiocyanate as both a source of nitrogen and of electrons.

Genus VI. **Thiorhodospira** *Bryantseva, Gorlenko, Kompantseva, Imhoff, Süling and Mityushina 1999b, 700*[VP]

Johannes F. Imhoff and Vladimir M. Gorlenko

Thi' o.rho' do.spi' ra. Gr. n. *thios* sulfur; Gr. n. *rhodon* the rose; Gr. n. *spira* spiral; M.L. fem. n. *Thiorhodospira* the spiral rose with sulfur.

Cells vibrioid or spiral-shaped, motile by means of a monopolar flagellar tuft, multiplies by binary fission. Gram-negative and belong to the *Gammaproteobacteria*. Internal photosynthetic membranes are parallel lamellae piercing the cytoplasm lengthwise or underlying the cytoplasmic membrane. **Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids**.

Obligately phototrophic and strictly anaerobic. **During photolithoautotrophic growth with sulfide as the electron donor, globules of S^0 are formed outside the cytoplasm**, in the medium, attached to cells, or in the periplasm. The final oxidation product is sulfate. In the presence of sulfide, organic substances may be photoassimilated. Development is **dependent on sodium salts** in low concentrations and on alkaline conditions.

Habitat: surface of sediments rich in organic matter and microbial mats from brackish soda lakes that contain hydrogen sulfide.

The mol% G + C of the DNA is: 56.0–57.4 (T_m).

Type species: **Thiorhodospira sibirica** Bryantseva, Gorlenko, Kompantseva, Imhoff, Süling and Mityushina 1999b, 700.

Enrichment and Isolation Procedures

Thiorhodospira species can be selectively enriched under photoautotrophic conditions with sulfide as the electron donor and in saline and alkaline media similar to those for *Ectothiorhodospira* and *Halorhodospira* species. From suitable environmental sources, isolation can be achieved using a basal medium[1] in agar dilution series inoculated with natural samples without prior enrichment. Cultures are grown phototrophically in 50-ml screw-capped bottles at 25–30°C and a light intensity of 2000 lux.

Maintenance Procedures

For long-term preservation, storage in liquid nitrogen is recommended as the standard maintenance procedure. For this purpose, cell suspensions of well-grown cultures supplemented with DMSO to a final concentration of 5% are dispensed in plastic ampules, sealed, and frozen at the temperature of liquid nitrogen.

Differentiation of the genus *Thiorhodospira* from other genera

Thiorhodospira species may be differentiated from other purple sulfur bacteria by the deposition of S^0 both outside and inside the cells, as seen under the light microscope. Differentiation from *Ectothiorhodospira* and *Halorhodospira* species is possible on the basis of sulfur deposition both outside and inside the cells, the irregular arrangement of the membrane stacks of photosynthetic membranes, the low mol% G + C content, and some characteristic differences in the 16S rDNA sequence (Table BXII.γ.7 of the chapter describing the family *Ectothiorhodospiraceae*). The 16S rDNA sequence of *Thiorhodospira* is ~88–92% similar to those of *Ectothiorhodospira* species. Metabolic properties, such as utilization of carbon, sulfur, and nitrogen sources, are very similar to those of other *Ectothiorhodospiraceae*. *Thiorhodospira* species grow at salt concentrations between 0.5–8%, as do *Ectothiorhodospira* species.

List of species of the genus Thiorhodospira

1. **Thiorhodospira sibirica** Bryantseva, Gorlenko, Kompantseva, Imhoff, Süling and Mityushina 1999b, 700[VP]
si.bi' ri.ca. M.L. fem. n. *sibirica* related or belonging to Siberia.

Cells vibrioid or spirals, 3–4 × 7–20 µm, multiply by binary fission with formation of septa. Motile by means of a monopolar tuft of flagella, which is approximately the same length as the cells. Internal photosynthetic membranes are parallel lamellae piercing the cytoplasm lengthwise or underlying the cytoplasmic membrane. Color of cell suspensions is brownish-red to red. Suspensions of intact cells show absorption maxima at 377, 485, 509, 537-550, 591, 711, 799, 830, 858, and 901 nm. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series, with anhydrorhodovibrin, rhodopin, and spirilloxanthin as major components.

Strictly anaerobic and obligately phototrophic. Photolithoautotrophic growth occurs with sulfide and sulfur as electron donors. Thiosulfate is not oxidized. When sulfide and carbonates are present, acetate, pyruvate, malate, succinate, propionate, and fumarate are photoassimilated.

Mesophilic and alkaliphilic brackish-water bacterium with optimum growth at pH 9.0–9.5 (pH-range 7.5–10.5) and 25–30°C. Requires sodium carbonate and/or sodium chloride for growth. Salinity range is 0.5–8% sodium bicarbonate or 0–6% NaCl (in the presence of 0.5% sodium carbonate).

Habitat: Sulfide-containing surface layers of the Lake Malyi Kasytui sediment.

The mol% G + C of the DNA is: 56.0–57.4 (T_m).

Type strain: A12, ATCC 700588, BN 9312.

GenBank accession number (16S rRNA): AJ006530.

---

1. The basal medium used for isolation and cultivation of *Thiorhodospira* contains (g/l distilled water): KH_2PO_4, 0.5 g; NH_4Cl, 0.5 g; NaCl, 0.5 g; $MgCl_2 \cdot 6H_2O$, 0.2 g; $CaCl_2 \cdot 2H_2O$, 0.05 g; $NaHCO_3$, 2.5 g; Na_2CO_3, 2.5 g; Na-acetate, 0.5 g; Na-malate, 0.5 g; yeast extract, 0.1 g; $Na_2S \cdot 9H_2O$, 0.7 g; and trace element solution SL8, 1 ml. The pH is adjusted to 9.0–9.5 (Bryantseva et al., 1999b).

Family III. **Halothiobacillaceae** *fam. nov.* Kelly and Wood 2003

DONOVAN P. KELLY AND ANN P. WOOD

Hal.o.thi.o.ba.cil' la' ce.ae. M.L. neut. n. *Halothiobacillus* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Halothiobacillaceae* the *Halothiobacillus* family.

Cells are rods, motile by polar flagella, contain ubiquinone Q-8, and are obligately aerobic and chemolithotrophic. **Gram negative, belong to the *Gammaproteobacteria*, halotolerant and halophilic, obligately chemolithoautotrophic.** Aerobic chemolithoautotrophic growth is dependent on the oxidation of inorganic sulfur compounds or elemental sulfur and the fixation of carbon dioxide by the Calvin-Bassham-Benson reductive pentose phosphate cycle. In nature, members of the *Halothiobacillaceae* occur in seawater and marine mud, fresh water, salt lakes, and hydrothermal vents.

The mol% G + C of the DNA is: 56–58.

Type genus: **Halothiobacillus** Kelly and Wood 2000, 515 emend. Sievert, Heidorn and Kuever 2000, 1235.

TAXONOMIC COMMENTS

The family *Halothiobacillaceae* has been newly created to include the single genus *Halothiobacillus*, and the characteristics of the family are currently those given in the Genus *Halothiobacillus* chapter.

The four currently recognized and validly published species are physiologically and morphologically similar, and exhibit a relatively wide spread of mol% G + C content of their DNA. Their distinctive physiological properties and biochemical requirements distinguish them all other species. Analysis of nearly complete 16S rDNA sequences from all four species showed them to form a single phylogenetic cluster (Kelly et al., 1998; Kelly and Wood, 2000; Sievert et al., 2000).

Pairwise comparisons of the relative identities of their 16S rDNA sequences using BLASTN and BLAST2 (http://www.ncbi.nlm.gov) showed the type species, *H. neapolitanus*, to share 91.0–92.9% identity with the other three; *H. kellyi* showed 93.4% identity to both *H. halophilus* and *H. hydrothermalis*; and *H. halophilus* and *H. hydrothermalis* shared 98.6% identity. For comparison, 16S rDNA from *Allochromatium vinosum* ATCC 17899 (M26629) showed only 86.7% and 88.0% identity to *H. neapolitanus* and *H. halophilus*. Several other strains of *Halothiobacillus* have been identified by 16S rDNA sequencing (strains MS02, RA13, W5 and WJ18), and additional species are likely to be defined and validly published in due course.

Genus I. **Halothiobacillus** *Kelly and Wood 2000, 515^{VP} emend. Sievert, Heidorn and Kuever 2000, 1235*

DONOVAN P. KELLY AND ANN P. WOOD

Hal.o.thi.o.ba.cil' lus. Gr. n. *hals* sea, salt; Gr. n. *thios* sulfur; L. n. *bacillus* a small rod; L. masc. n. *Thiobacillus* salt-loving sulfur rodlet.

Obligately chemolithoautotrophic Gram-negative rods, 0.3–0.6 × 1.0–2.5 μm, occurring singly or in pairs. Energy for growth is obtained from the oxidation of reduced inorganic sulfur compounds (thiosulfate, tetrathionate, trithionate, sulfur, and sulfide, but not thiocyanate); unable to oxidize ferrous iron. Tolerant of high concentrations of solutes (e.g., 4 M NaCl; 0.25 M sodium thiosulfate), with some strains showing moderate halophily with a requirement for NaCl (optima 0.4–1.0 M NaCl). Optimum temperature for growth 30–42°C and optimum pH 6.5–8.0. During growth on reduced sulfur compounds, pH is changed from neutrality to pH 2.5–3.0. Contain ubiquinone Q-8. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 56–67.

Type species: **Halothiobacillus neapolitanus** (Parker 1957) Kelly and Wood 2000, 515 (*Thiobacillus neapolitanus* Parker 1957, 86.)

FURTHER DESCRIPTIVE INFORMATION

This genus was created to accommodate the neutrophilic, obligately chemolithoautotrophic, and halophilic or halotolerant species previously described as *Thiobacillus*. Characteristics of the four species of *Halothiobacillus* currently recognized are shown in Table BXII.γ.15. The properties, taxonomy, and differentiation of the genera of sulfur-oxidizing, chemolithoautotrophic, Gram-negative, rod-shaped bacteria are summarized in the tables and the figure in the chapter on the genus *Thiobacillus* which appear in Volume 2 Part C in this *Manual*.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *HALOTHIOBACILLUS*

The properties, similarity, and distinctive features of the species of *Halothiobacillus* are fully discussed elsewhere (Kelly et al., 1998; Kelly and Wood, 2000; Sievert et al., 2000).

List of species of the genus Halothiobacillus

1. **Halothiobacillus neapolitanus** (Parker 1957) Kelly and Wood 2000, 515^{VP} (*Thiobacillus neapolitanus* Parker 1957, 86.)
ne.a.po.li.ta' nus. L. adj. *neapolitanus* Neapolitan; pertaining to the seawater at Naples from which this species was probably first isolated by Nathansohn in 1902.

Small rods, 0.3–0.5 × 1.0–1.5 μm. Motile by means of a polar flagellum. Colonies grown on thiosulfate agar are small (1–2 mm), circular, convex, glistening, and whitish yellow due to precipitated sulfur. The center of old colonies becomes pink. In static culture in liquid thiosulfate medium, sulfur and polythionates may accumulate, and the medium becomes uniformly turbid with a sulfur pellicle. Aerated cultures may show transitory accumulation of tetrathionate and trithionate. pH drops to 2.8–3.3. Chemostat cultures do not accumulate intermediates and convert thiosulfate quantitatively to sulfate. This organism oxidizes sulfur, sulfide, thiosulfate, tetrathionate, and trithionate but

not thiocyanate, and uses ammonium salts or nitrates as nitrogen source. Obligately chemolithotrophic and autotrophic. Strict aerobe. Optimum temperature for growth: 28–32°C; growth range: 8–39°C. Optimum pH for growth: 6.5–6.9; growth range pH: 4.5–8.5. Isolated from seawater, canal water, and corroding concrete. Frequently, this organism is found in marine mud and in seawater. Presumably widely distributed in freshwater, soil, and marine environments. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 56 (Bd).

Type strain: ATCC 23641, DSM 15147, NCIB 8539.

GenBank accession number (16S rRNA): AF173169.

2. **Halothiobacillus halophilus** (Wood and Kelly 1991) Kelly and Wood 2000, 515[VP] (*Thiobacillus halophilus* Wood and Kelly 1991, 280.)

hal.o.phil.us. L. n. *halophil* salt-loving; M.L. adj. *halophilus* loving salt.

Cells are Gram-negative small rods. Obligately halophilic, optimum growth with 1 M NaCl and tolerating up to 4 M NaCl. Obligately chemolithoautotrophic; grows aerobically with thiosulfate, tetrathionate or sulfur; lowers the pH to 5.5–6. Also oxidizes sulfide, trithionate, and hexathionate. On thiosulfate agar, colonies are small (1–3 mm), circular, opaque, smooth, and convex, and become yellow/white with deposited sulfur. Optimum temperature for growth 30–32°C and optimum pH for growth 7.0–7.3. Nitrate reduced to nitrite but anaerobic growth with thiosulfate does not occur. Contains ubiquinone Q-8. Isolated from a salt lake in the wheat belt of Western Australia. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 64.2 (HPLC).

Type strain: DSM 6132, ATCC 49870.

GenBank accession number (16S rRNA): U58020.

3. **Halothiobacillus hydrothermalis** (Durand, Reysenbach, Prieur and Pace 1993) Kelly and Wood 2000, 515[VP] (*Thiobacillus hydrothermalis* Durand, Reysenbach, Prieur and Pace 1993, 43.)

hy.dro.ther.mal′is. M.L. *hydrothermalis* pertaining to a hydrothermal vent in the North Fiji basin.

Cells are Gram negative, motile, nonsporeforming, short rods, 0.5 × 1.0 μm. Obligately chemolithotrophic, using oxidation of thiosulfate, tetrathionate, sulfide, or sulfur for growth. Lowers the pH of thiosulfate medium to 4.8, without formation of tetrathionate. Growth occurs in the ranges pH 6–9, 11–45°C, and 0–2 M NaCl; no growth at pH 5 or 9.5, or at 8°C or 50°C. Optimum pH 7.5–8 and temperature 35–40°C; optimum salinity 0.43 M NaCl, tolerates 2 M NaCl. Contains ubiquinone Q-8. Isolated from samples taken from a depth of 2 km in an active hydrothermal vent in a rift system of the North Fiji Basin. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 67.1–67.4 (T_m, Bd, HPLC).

Type strain: ATCC 51453, DSM 7121.

GenBank accession number (16S rRNA): M90662.

4. **Halothiobacillus kellyi** Sievert, Heidorn and Kuever 2000, 1235[VP]

kel′ly.i. M.L. gen. n. *kellyi* of Kelly; named after Donovan P. Kelly, a British microbiologist who has made important contributions to research on sulfur-oxidizing bacteria and their physiology.

Cells are Gram negative, motile, and rod shaped (0.4–0.6 × 1.2–2.5 μm). The organism is strictly aerobic and grows autotrophically on thiosulfate, tetrathionate, sulfur, and sulfide, but not thiocyanate. The organism does not grow heterotrophically. When thiosulfate is used as the primary energy source, a transient formation of sulfur occurs. During growth on reduced sulfur compounds, the pH decreases from neutrality to around pH 2.8. Thiosulfate is completely oxidized to sulfate. Autotrophic growth on thiosulfate occurs between pH 3.5 and 8.5 and at a temperature of 35–49°C; optimum growth occurs at pH 6.5 and at 37–42°C. The optimal NaCl concentration for growth is 0.4–0.5 M; growth is possible between NaCl concentrations of 0–2 M. Nitrate is not used as terminal electron acceptor. The average maximum specific growth rate on thiosulfate is 0.45 h^{-1} for the type strain, Milos-BIII1. On thiosulfate agar, cells produce white to yellowish, smooth, entire colonies (diameter on 1.2% w/v agar is 1–4 mm), in which sulfur is deposited and acid is produced. Ubiquinone Q-8 is present in the respiratory chain. As determined by 16S rRNA gene sequence analysis, *Halothiobacillus kellyi* belongs to the *Gammaproteobacteria* and is most closely related to other members of the *Halothiobacillus* genus. The type strain Milos-BIII1 was isolated from a marine, shallow-water, hydrothermal vent system and is deposited at the DSM.

The mol% G + C of the DNA is: 62 (HPLC).

Type strain: Milos-BIII, DSM 13162.

GenBank accession number (16S rRNA): AF170419.

Order II. **Acidithiobacillales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

A.ci.di.thi.o.ba.cil.la′ les. M.L. masc. n. *Acidothiobacillus* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Acidithiobacillales* the *Acidithiobacillus* order.

The order *Acidithiobacillales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the order contains the families *Acidithiobacillaceae* and *Thermithiobacillaceae*.

Autotrophs utilizing reduced sulfur compounds; mesophilic or moderately thermophilic.

Type genus: **Acidithiobacillus** Kelly and Wood 2000, 513[VP].

Family I. **Acidithiobacillaceae** *fam. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

A.ci.di.thi.o.ba.cil.la′ ce.ae. M.L. masc. n. *Acidothiobacillus* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Acidithiobacillaceae* the *Acidithiobacillus* family.

The family *Acidithiobacillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the family contains the genus *Acidithiobacillus* (type genus).

Description is the same as for the genus *Acidithiobacillus*.

Type genus: **Acidithiobacillus** Kelly and Wood 2000, 513[VP].

Genus I. **Acidithiobacillus** *Kelly and Wood 2000, 513[VP]*

DONOVAN P. KELLY AND ANN P. WOOD

A.ci.di.thi.o.ba.cil′ lus. L. adj. *acidus* sour; Gr. n. *thios* sulfur; L. n. *bacillus* a small rod; M.L. masc. n. *Thiobacillus* small acid-loving sulfur rod.

Obligately acidophilic, aerobic, Gram-negative rods, 0.4 × 2.0 μm, motile by one or more flagella. Optimum growth below pH 4.0, using reduced sulfur compounds to support autotrophic growth. Some species oxidize ferrous iron or use natural and synthetic metal sulfides for energy generation; some species oxidize hydrogen. Optimum temperature 30–35°C for mesophilic species and 45°C for moderately thermophilic species. Contain ubiquinone Q-8. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 52–64.

Type species: **Acidithiobacillus thiooxidans** (Waksman and Joffe 1922) Kelly and Wood 2000, 513 (*Thiobacillus thiooxidans* Waksman and Joffe 1922, 239.)

FURTHER DESCRIPTIVE INFORMATION

The characteristics of the four current recognized species of *Acidithiobacillus* are shown in Table BXII.γ.16. The properties, taxonomy, and differentiation of the genera of sulfur-oxidizing, chemolithoautotrophic, Gram-negative, rod-shaped bacteria are summarized in the chapter on the genus *Thiobacillus* which appears in Volume 2 Part C in this *Manual*. Some species of *Acidithiobacillus* grow chemolithoautotrophically on sulfide minerals, and *A. ferrooxidans* also uses the oxidation of ferrous iron [and probably uranium (IV) and copper (I) oxidation] as the source of metabolic energy. One strain of *A. ferrooxidans* (ATCC 21834) has been shown to have a circular chromosome (2.9 Mb) and one small plasmid (8.6 kb) (Irazabal et al., 1997). Other bacteria able to oxidize sulfide minerals or iron (II) that appear superficially similar to *Acidithiobacillus*, but that are taxonomically and biochemically very different, have been described. These include the Gram-negative genus *Leptospirillum* and the Gram-positive genera *Acidimicrobium* and *Sulfobacillus* (Balashova et al., 1974; Golovacheva and Karavaiko, 1979; Harrison and Norris, 1985; Clark and Norris, 1996; Norris et al., 1996).

TAXONOMIC COMMENTS

This genus was created to accommodate the obligately acidophilic *Thiobacillus* species that were shown by 16S rRNA gene sequence analysis to fall into the *Gammaproteobacteria* (McDonald et al., 1997; Kelly and Wood, 2000).

The assignment of *T. albertis* to the new genus as *Acidithiobacillus albertensis* is very tentative. The 16S rRNA gene sequence, required for placement in a family in the *Proteobacteria*, is not yet available. Its relatively high mol% G + C value (61.5) and the possession of a tuft of flagella and a glycocalyx could indicate significant differences from the other three species included here. Unfortunately, the original isolate may have been lost from culture (B.M. Goebel, personal communication).

Since the first description of *Thiobacillus ferrooxidans* (Temple and Colmer, 1951), numerous organisms from mineral leaching environments have been described as strains of *T. ferrooxidans*, because they were extremely acidophilic, obligately chemolithoautotrophic with ferrous iron as an energy substrate, and could degrade pyrite and various other sulfide minerals. It became clear that selective culture for organisms exhibiting this growth phenotype actually resulted in the isolation of morphologically and genomically diverse strains (Harrison, 1982; Kelly and Harrison, 1989; Kondrat'eva and Karavaiko, 1997; Goebel et al., 2000). Eight different DNA homology groups of isolates described as *T. ferrooxidans* were identified by Harrison (Harrison, 1982; Kelly and Harrison, 1989). One of these groups was subsequently identified as *Leptospirillum*, and DNA–DNA hybridization values between the group containing the type strain (ATCC 23270) and the other six groups ranged from 0–19% to 58–73%. Using PCR-based techniques to assess this genomic variability, similarity coefficients between various isolates ranged from nearly 0 to >98% (Novo et al., 1996), and while several culture collection isolates were very closely related to the type strain (ATCC 23270[T]), one

strain (ATCC 33020) was not taxonomically related to the others (Selenska-Pobell et al., 1998). It is, therefore, inevitable that some strains assigned to *Acidithiobacillus ferrooxidans* will in due course be reassigned to new species or genera.

Thiobacillus concretivorus (Parker, 1945) was once listed as a distinct species in *Bergey's Manual* (Parker, 1957) and appeared in the Approved Lists of Bacterial Names (Skerman et al., 1980). It is, however, now recognized as a synonym of *T. thiooxidans* (now *Acidithiobacillus thiooxidans*) (Vishniac, 1974; Kelly and Harrison, 1989).

List of species of the genus Acidithiobacillus

1. **Acidithiobacillus thiooxidans** (Waksman and Joffe 1922) Kelly and Wood 2000, 513[VP] (*Thiobacillus thiooxidans* Waksman and Joffe 1922, 239.)
thio.ox′i.dans. Gr. n. *thios* sulfur; M.L. v. *oxido* make acid, oxidize; M.L. part adj. *thiooxidans* oxidizing sulfur.

Short rods, single, paired or in short chains, 0.5 × 1.0–2.0 μm. Motile by means of a polar flagellum (Doetsch et al., 1967). Minute colonies (0.5–1.0 mm) grown on thiosulfate agar appear transparent or whitish yellow and clear on prolonged incubation; edges appear complete. This organism grows in liquid medium on S^0, thiosulfate, or tetrathionate. Tetrathionate and sulfur may be produced transiently during growth on thiosulfate. This organism cannot oxidize iron or pyrite but has been shown to grow on sulfur from pyrite in co-culture with *"Leptospirillum ferrooxidans"*, an iron-oxidizing, non-sulfur-oxidizing vibrio. Reduces pH of sulfur media to values of 0.5–0.8.

Obligate chemolithotroph and autotroph; remarkable ability to oxidize S^0 rapidly. Strictly aerobic. Ammonium sulfate used as nitrogen source. Optimum temperature: 28–30°C; temperature range: 10–37°C. Optimum pH: 2.0–3.0; growth range pH: 0.5–5.5. Isolated from soil, sulfur springs, acid mine drainage waters, and corroding concrete and steel environments. Likely to be widely distributed in acidic habitats with elemental sulfur or soluble reduced sulfur compounds. Member of the *Gammaproteobacteria.*

The mol% G + C of the DNA is: 52 (T_m, Bd).

Type strain: ATCC 19377, NCIMB 8343.

GenBank accession number (16S rRNA): Y11596.

2. **Acidithiobacillus albertensis** (Bryant, McGroarty, Costerton and Laishley 1988) Kelly and Wood 2000, 514[VP] (*Thiobacillus albertis* Bryant, McGroarty, Costerton and Laishley 1988, 221.)
al.ber′ten.sis. M.L. adj. *albertensis* named for Alberta, Canadian province of Alberta.

Rods, 0.45 × 1.2–1.5 μm. Motile by means of a tuft of polar flagella. Condensed glycocalyx present, extending outwards from outer membrane, apparently involved in cell adhesion to surfaces such as sulfur. This organism grows on sulfur, thiosulfate, or tetrathionate; tetrathionate is accumulated transiently during growth on thiosulfate but not on sulfur. Intracellular sulfur granules have been observed in stationary phase cells. Obligate chemolithotroph and autotroph. Aerobic. Ammonium sulfate is used as nitrogen source. Optimum temperature: 28–30°C. Optimum pH: 3.5–4.0; growth range pH: 2.0–4.5. Isolated from extremely acidic soil adjacent to a sulfur stockpile. Probably occurs in other similar environments.

The mol% G + C of the DNA is: 61.5 (UV spectrum).

Type strain: ATCC 35403.

3. **Acidithiobacillus caldus** (Hallberg and Lindström 1995) Kelly and Wood 2000, 514[VP] (*Thiobacillus caldus* Hallberg and Lindström 1995, 619.)
cal′dus. M.L. adj. *caldus* warm, liking warmth.

Cells are short, motile, Gram-negative rods, 0.7–0.8 × 1.2–1.8 μm. Capable of chemolithoautotrophic growth with thiosulfate, tetrathionate, sulfide, sulfur, and molecular hydrogen; no growth with ferrous iron or sulfidic ores. Mixotrophic growth with tetrathionate and glucose or yeast extract. Colonies on tetrathionate agar are small, circular, convex, smooth, and transparent, with precipitated sulfur in their center. Growth occurs between 32 and 52°C and

pH 1–3.5, with optimum growth at 45°C and pH 2–2.5. Contains ubiquinone Q-8 and a menaquinone. No significant DNA hybridization (2–20%) with *T. ferrooxidans*, *T. thiooxidans*, *T. cuprinus*, or *T. thioparus*. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 63.1–63.9 (T_m).

Type strain: KU, ATCC 51756, DSM 8584.

GenBank accession number (16S rRNA): Z29975.

4. **Acidithiobacillus ferrooxidans** (Temple and Colmer 1951) Kelly and Wood 2000, 513[VP] (*Thiobacillus ferrooxidans* Temple and Colmer 1951, 605.)
ferro.ox'i.dans. L. n. *ferrum* iron; M.L. v. *oxido* oxidize, make acid; M.L. part. adj. *ferrooxidans* iron-oxidizing.

Rods, usually single or in pairs, 0.5 × 1.0 µm. Motile; the type strain is motile by a single polar flagellum. Small colonies (0.5–1 mm) grown on thiosulfate or tetrathionate agar are round, sometimes with irregular margins, and white with sulfur. On solid media (agar or agarose) with ferrous sulfate, microscopic colonies with low iron concentrations are formed, resulting in the appearance of an amber zone in the medium around them. With higher iron concentrations, round colonies (1 mm) that become red, brown, and hard with deposited ferric salts are produced. Liquid medium with ferrous sulfate at pH 1.6 changes from clear pale green to amber to red-brown with ferric sulfate. At pH 1.9 and above, considerable precipitation and encrustation with basic ferric sulfates (jarosite) take place.

Obligate chemolithotroph and autotroph. Oxidizes and grows on ferrous iron, pyrite, numerous sulfide minerals, sulfur, thiosulfate, or tetrathionate. Strictly aerobic. Ammonium salts and probably nitrate can be used as nitrogen source; reported to be able to fix dinitrogen. Optimum temperature: 30–35°C; growth range temperature: 10–37°C (no growth at 42°C). Optimum pH: about 2.5; growth range pH: 1.3–4.5. Isolated from many locations worldwide where oxidizable iron, sulfide mineral, and sulfur are exposed; particularly prevalent in acid drainage waters of mines for sulfide minerals, mineral leach dumps, and drainage waters from coal mines and coal or spoil heaps. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 58–59 (T_m).

Type strain: ATCC 23270, NCIB 8455.

Family II. **Thermithiobacillaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Therm.i.thi.o.ba.cil.la'ce.ae. M.L. masc. n. *Thermithiobacillus* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Thermithiobacillaceae* the *Thermithiobacillus* family.

The family *Thermithiobacillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the family contains the genus *Thermithiobacillus* (type genus).

Description is the same as for the genus *Thermithiobacillus*.

Type genus: **Thermithiobacillus** Kelly and Wood 2000, 515[VP].

Genus I. **Thermithiobacillus** *Kelly and Wood 2000, 515[VP]*

Ann P. Wood and Donovan P. Kelly

Therm.i.thi.o.ba.cil'lus. L. n. *thermae* warm baths; Gr. n. *thios* sulfur; L. n. *bacillus* a small rod; L. masc. n. *Thermithiobacillus* warmth-loving sulfur rodlet.

Gram-negative, nonsporeforming rods, 0.5 × 1–2 µm. Obligate aerobes, moderately thermophilic and obligately chemolithoautotrophic on reduced inorganic sulfur compounds (thiosulfate, polythionates, sulfur, and sulfide, but not thiocyanate); unable to oxidize ferrous iron. Contain ubiquinone Q-8. Other general characteristics are those of *Thiobacillus*. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 66–67.

Type species: **Thermithiobacillus tepidarius** (Wood and Kelly 1985) Kelly and Wood 2000, 515 (*Thiobacillus tepidarius* Wood and Kelly 1985, 436.)

Further descriptive information

This genus was created to accommodate the single species of moderate thermophile, *Thiobacillus tepidarius.* While this species showed many physiological similarities to *Thiobacillus neapolitanus* (now *Halothiobacillus neapolitanus*) (Wood and Kelly, 1985, 1986), it was shown by 16S rRNA gene sequence analysis to be unrelated to that genus (Kelly and Wood, 2000). The properties, taxonomy, and differentiation of the genera of sulfur-oxidizing chemolithoautotrophic Gram-negative rod-shaped bacteria are summarized in Tables 1 and 2 and Fig. 1 in the chapter on the genus *Thiobacillus* which appear in Volume 2 Part C in this *Manual.*

List of species of the genus Thermithiobacillus

1. **Thermithiobacillus tepidarius** (Wood and Kelly 1985) Kelly and Wood 2000, 515[VP] (*Thiobacillus tepidarius* Wood and Kelly 1985, 436.)
tep.i.dar'ius. L. n. *tepidarium* a warm bath fed by natural thermal water; M.L. adj. *tepidarius* warm-bathing (*Thiobacillus*).

Small rods, 0.5 × 1.0–2.0 µm. Motile by a single polar flagellum (5–10 µm in length). Gram negative, nonsporeforming. Colonies grown on thiosulfate agar at 43°C are small (1–2 mm), circular, convex and smooth and become white or yellow with precipitated sulfur. In liquid batch culture on thiosulfate, quantitative production of tetrathionate

takes place before growth continues to effect complete oxidation to sulfate. Sulfur may be precipitated. pH drops to 4.5–5.0. Chemostat cultures do not accumulate intermediates during growth on sulfide, thiosulfate, tetrathionate, or trithionate. This organism oxidizes sulfide, thiosulfate, trithionate, tetrathionate, hexathionate, heptathionate, and sulfite, but not thiocyanate. Obligately chemolithotrophic and autotrophic. Uses ammonium salts as nitrogen source. Aerobic. Optimum temperature: 43–45°C; range: 20–52°C (no growth at 15 or 55°C). Optimum pH: 6.8–7.5; range: 5.2–8.0. Isolated from the Great Roman Bath at the Temple of Sulis Minerva, Bath, Avon, England; distribution unknown. Member of the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 66.6 (UV ratios; Bd).

Type strain: DSM 3134, ATCC 43215.

Order III. **Xanthomonadales** *ord. nov.*

Gerard S. Saddler and John F. Bradbury

Xan.tho.mo.na.da' les. Xanthomonas type genus of the order; *-ales* ending to denote order; M.L. fem. pl. n. *Xanthomonadales* the *Xanthomonas* order.

Gram-negative straight rods lacking prosthecae; hyaline stalks found in one genus (*Nevskia*). Endospores are not produced, no accumulation of poly-β-hydroxybutyrate inclusions. Motile with polar flagellation, flexing/gliding (*Lysobacter*), or nonmotile. Obligate aerobes, having a strictly respiratory metabolism with oxygen as the terminal electron acceptor. Catalase positive. Nitrate not reduced, with the exception of *Stenotrophomonas*. Oxidase production varies. Fatty acid profiles are complex; branched chain and/or hydroxy fatty acids are found. Ubiquinone Q8 is generally found. Optimum temperature 20–35°C; except *Thermomonas*, 37–50°C.

Type genus: **Xanthomonas** Dowson 1939, 187, emend. Vauterin, Hoste, Kersters and Swings 1995, 483.

Family I. **Xanthomonadaceae** *fam. nov.*

Gerard S. Saddler and John F. Bradbury

Xan.tho.mo.na.da' ce.ae. M.L. fem. n. *Xanthomonas* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Xanthomonadaceae* the *Xanthomonas* family.

The characteristics are as given for the order. There are twelve genera: *Xanthomonas*, *Frateuria*, *Fulvimonas**, *Luteimonas*, *Lysobacter*, *Nevskia*, *Pseudoxanthomonas*, *Rhodanobacter*, *Schineria*, *Stenotrophomonas*, *Thermomonas*, and *Xylella*. Differential characters are given in Table BXII.γ.17 of the chapter describing the genus *Xanthomonas*.

Type genus: **Xanthomonas** Dowson 1939, 187, emend. Vauterin, Hoste, Kersters and Swings 1995, 483.

Genus I. **Xanthomonas** *Dowson 1939, 187[AL] emend. Vauterin, Hoste, Kersters and Swings 1995, 483*

Gerard S. Saddler and John F. Bradbury

*Xan.tho' mo.nas or Xan.tho.mo' nas.** Gr. adj. *xanthus* yellow; Gr. fem. n. *monas* unit, monad; M.L. fem. n. *Xanthomonas* yellow monad.

Straight rods, 0.4–0.6 × 0.8–2.0 μm, mostly single or in pairs, occasionally short chains, filaments rarely seen. Gram negative. Do not produce poly-β-hydroxybutyrate inclusions, nor have sheaths, prosthecae, or resting stages. **Motile by a single polar flagellum. Obligately aerobic, having a strictly respiratory type of metabolism** with oxygen as the terminal electron acceptor. **No denitrification or nitrate reduction occurs. Colonies are usually yellow**, smooth and butyrous, mucoid or viscid. The pigments are highly characteristic brominated aryl polyenes or "xanthomonadins". A characteristic extracellular acidic heteropolysaccharide called xanthan is produced by most strains giving the viscous consistency. Growth is inhibited by 6% NaCl, 30% glucose, 0.01% lead acetate, methyl green, or thionin, and by 0.1% (and usually by 0.02%) triphenyl tetrazolium chloride. **Catalase positive**; **oxidase negative or weak**; urease not produced. H_2S is usually produced, but not indole or acetoin. Acid is not produced in litmus milk or purple milk. Chemoorganotrophic; able to use various carbohydrates and salts of organic acids as sole carbon sources. Small amounts of acid are produced from many carbohydrates, but not from L-rhamnose, adonitol, sorbose, D-sorbitol, *meso*-inositol, or *meso*-erythritol. Metabolic activity is shown in Biolog GN microplate tests with D-fructose, D-glucose, D-mannose and methylpyruvate, but not with α-cyclodextrin, adonitol, D-arabitol, *meso*-erythritol, *meso*-inositol, xylitol, D-glucosaminate, γ-hydroxybutyrate, itaconate, sebacate, L-ornithine, L-pyroglutamate, D-serine, D,L-carnitine, γ-aminobutyrate, phenylethylamine, putrescine, 2-aminoethanol, or 2,3-butanediol. L-asparagine, L-glutamine, and glycine cannot be used as sole sources of both

**Editorial Note:* The genus *Fulvimonas* was described after the cut-off date for inclusion of new taxa in this volume of the *Manual*; hence, there is no separate chapter devoted to it. Characteristics of the genus *Fulvimonas* are given in Table BXII.γ.17 of the chapter describing the Genus *Xanthomonas*.

**Editorial Note:* The first pronunciation is according to strict Latin usage while the second is more commonly used.

takes place before growth continues to effect complete oxidation to sulfate. Sulfur may be precipitated. pH drops to 4.5–5.0. Chemostat cultures do not accumulate intermediates during growth on sulfide, thiosulfate, tetrathionate, or trithionate. This organism oxidizes sulfide, thiosulfate, trithionate, tetrathionate, hexathionate, heptathionate, and sulfite, but not thiocyanate. Obligately chemolithotrophic and autotrophic. Uses ammonium salts as nitrogen source. Aerobic. Optimum temperature: 43–45°C; range: 20–52°C (no growth at 15 or 55°C). Optimum pH: 6.8–7.5; range: 5.2–8.0. carbon and nitrogen. Among the nine fatty acids that predominate in whole cell preparations are 9-methyl decanoic acid ($C_{11:0\ iso}$), 3-hydroxy-9-methyl decanoic acid ($C_{11:0\ iso\ 3OH}$), and 3-hydroxy-11-methyl dodecanoic acid ($C_{13:0\ iso\ 3OH}$), which are highly characteristic of this genus. The ubiquinone that is present has eight isoprene units. Spermidine is the main polyamine; spermine is usually detectable, but not 2-hydroxyputrescine or 1,3-diaminopropane. Species so far described are plant pathogens or are plant associated.

The mol% G + C of the DNA is: 63.3–69.7 (T_m).

Type species: **Xanthomonas campestris** (Pammel 1895) Dowson 1939, 190, emend. Vauterin Hoste, Kersters and Swings 1995, 484 (*"Bacillus campestris"* Pammel 1895, 130.)

Further descriptive information

Cell morphology Cells examined directly from plant tissues, or from old cultures, may show irregularities in size and shape, but those from actively growing cultures are reasonably uniform rods with rounded ends. The vast majority of cells are within the range 0.4–0.6 × 0.8–2.0 µm and predominantly motile by a single polar flagellum. Capsules are visible in many isolates using simple staining techniques though results are variable and depend on handling and conditions prior to staining. The capsular polysaccharides are loosely associated with the cells and the production of large amounts of extracellular polysaccharide results in the slimy or mucoid colonies seen on carbohydrate-rich media.

Fine structure The structure of the cell envelope in *Xanthomonas* appears to be similar to that of other Gram-negative cells, as reviewed by Costerton et al. (1974). Schnaitman (1970) found that the cell wall morphology of a *X. campestris* isolate, as viewed with the electron microscope, was similar to that described for *Escherichia coli* by De Petris (1967). The cell wall is relatively electron transparent, with nuclear material, ribosomes, and granular-like inclusions visible within the cell (Horino, 1973). In cells actively growing in broth cultures, ribosomes are observed throughout the cytoplasm with DNA strands occupying the central part of the cell. Polyribosomes and osmophilic vacuoles were found to be present only in actively growing cells (Al-Mousawi and Richardson, 1990). Studies on *X. hyacinthi*, which causes yellow disease in *Hyacinthus*, have shown the presence of polar fimbriae of (5 nm × 6 µm), thought to be involved in the early stages of infection as they were found to attach selectively to stomatal cells (van Doorn et al., 1994). The single polar flagellum may be demonstrated by flagella staining or by electron microscopy of cells from the syneresis water of young cultures. The wavelength of normal flagella averages 1.79 µm, but occasionally variants with wavelengths of 2–3 µm occur. Very rarely cells with two polar flagella occur (Leifson, 1960).

Cell wall composition As with all Gram-negative bacteria, the cell wall of xanthomonads contains three distinct layers: cytoplasmic or inner membrane, peptidoglycan layer, and outer membrane. The inner and outer membranes are made up of proteins and phospholipids, in addition, lipopolysaccharides are found in the outer membrane. Lipopolysaccharides consist of a heteropolysaccharide portion to which "lipid A" is covalently bonded. The backbone of lipid A in strains from various genera, including *Xanthomonas*, has been shown to contain β-1′,6-linked glucosamine disaccharides carrying two phosphate groups, one glycosidically linked and one with ester linkage (Hase and Rietschel, 1976). Hydroxy fatty acids are joined to the LPS backbone through ester and amide linkages (Rietschel et al., 1975). Early studies of the polysaccharide portion of the LPS of *Xanthomonas* were conducted by Volk (1966, 1968a, b), who obtained D-galacturonic acid-1-phosphate, glucose, mannose, and 2-keto-3-deoxyoctonate. The latter, predictably, predominates in the outer membrane of the cell wall (dos Santos and Dianese, 1985). Volk (1968b) found different ratios of uronic acid:mannose, roughly 1.2:1 and 0.66:1. Most also contained xylose or fucose, but not both. Low amounts of rhamnose were present in two isolates. In addition, 4,7-anhydro- and 4,8-anhydro-3-deoxyoctulosonic acids (Volk et al., 1972) and 3-acetamido-3,6-dideoxy-D-galactose (Hickman and Ashwell, 1966) have been isolated. The high rhamnose content, low content of 2-keto-3-deoxyoctonate, presence of D-galacturonic acid, and absence of heptoses are also found in *Stenotrophomonas maltophilia* (Wilkinson, 1968b; Neal and Wilkinson, 1979).

In early studies on cell envelope proteins, Schnaitman (1970) found that the electrophoretic pattern from *Xanthomonas* was broadly similar to that from *E. coli*, but the major protein constituent had a slightly lower mobility. More detailed analysis demonstrated that strains of *X. campestris* pathovar *campestris* could be differentiated from other xanthomonads and a range of Gram-negative bacteria on the basis of membrane protein patterns (Dianese and Schaad, 1982; Minsavage and Schaad, 1983), and that the antigenic determinants of pathovar-specific peptides were resistant to a range of treatments, with the exception of protease Type 1 digestion (Thaveechai and Schaad, 1986). Analysis of the cell envelopes of cassava pathogens, *X. axonopodis* pathovar *manihotis* and *X. cassavae*, revealed two major components relating to the inner and outer membranes of the cell wall (dos Santos and Dianese, 1985). The lighter fraction showed high nicotinamide adenine dinucleotide oxidase and succinate dehydrogenase activities, and larger numbers of peptides than are usually found in the inner membrane of other bacteria. The heavier component showed low enzyme activity and was characteristic of an outer membrane pattern. Heat-modifiable proteins were found in the cell envelopes of both pathovars. Membrane-bound proteins associated with the pigments (xanthomonadins) in *Xanthomonas* have been found in several other genera including a number of Gram-positive bacteria (Lawani et al., 1990).

Studies of the fatty acid component of xanthomonad LPS gave preliminary data on the uniqueness of the fatty acid profile (Rietschel et al., 1975). The taxonomic significance of fatty acid profiles within the genus *Xanthomonas* was further established in a preliminary study of 14 *X. campestris* pathovars pathogenic for hosts in the family *Gramineae* (Stead, 1989). Profiles were found to be complex, containing up to 40 acids, most of which were *iso-* and *anteiso-*branched acids. Grouping of profile types generally correlated with pathovar, although pathovar *translucens*, pathovar *hordei*, pathovar *cerealis*, pathovar *secalis*, and pathovar *undulosa* could not be differentiated. In a comprehensive study of 975 *Xanthomonas* strains 65 different fatty acids were detected and nine were predominantly found in all members of the genus (Yang et al., 1993d): 9-methyl decanoic acid ($C_{11:0\,iso}$), 3-hydroxy-9-methyl decanoic acid ($C_{11:0\ iso\ 3OH}$), 3-hydroxydodecanoic acid ($C_{12:0\ 3OH}$), 3-hydroxy-11-methyl dodecanoic acid ($C_{13:0\ iso\ 3OH}$), 13-methyl tetradecanoic acid ($C_{15:0\ iso}$), *cis*-9-hexadecenoic acid ($C_{16:1\ \omega7c}$), hexadecanoic acid ($C_{16:0}$), 15-methyl hexadecenoic acid isomer F ($C_{17:1\ iso\ F}$), and 15-methyl hexadecanoic acid ($C_{17:0\ iso}$), and three of which, $C_{11:0\ iso}$, $C_{11:0\ iso\ 3OH}$, and $C_{13:0\ iso\ 3OH}$, are useful in differentiating xanthomonads from other bacteria (Stead, 1992; Yang et al., 1993d). Fatty acids are a valuable tool

in systematic studies and serve as a distinguishing characteristic in assigning new species to the genus (Hu et al., 1997), describing hitherto unrealized diversity within the species *X. fragariae* (Roberts et al., 1998), *X. albilineans* (Yang et al., 1993c), and *X. vesicatoria* (Stall et al., 1994), and differentiating between pathogenic and nonpathogenic strains isolated from the same host (Sahin and Miller, 1996; Vauterin et al., 1996a).

Pigmentation Yellow pigments are present in all species of *Xanthomonas*, but nonpigmented strains sometimes occur. *X. axonopodis* pathovar *manihotis* and some strains of pathovar *ricini* occur naturally as nonpigmented organisms. Occasionally nonpigmented mutants arise in culture (Bryan, 1932; Durgapal, 1977) and studies have shown that the absence of xanthomonadins, and other characters such as EPS production have a limiting effect on epiphytic survival and host infection (Jenkins and Starr, 1982a; Poplawsky and Chun, 1998). Although the presence of yellow pigment is an important characteristic for identification, its absence does not exclude an organism from the genus if other characteristics are in agreement. Starr and Stephens (1964), examining a number of isolates belonging to *X. campestris*, found that all contained one or more pigments that showed absorption maxima at 418 (a shoulder), 437, and 463 nm when dissolved in petroleum ether. The pigments were released from disrupted cells at the same rate as a component of the cytoplasmic membrane, suggesting their attachment to the cell envelope (Stephens and Starr, 1963). Later they were shown to be brominated aryl polyenes and were named xanthomonadins. From two to five different xanthomonadins are present in the various species examined (Andrewes et al., 1973; Starr et al., 1977). Xanthomonadin I, the main component of the pigment of *"Xanthomonas juglandis"*, now *X. arboricola* pathovar *juglandis*, was found to be 17 (4 bromo-3-methoxyphenyl)17-bromo-heptadeca-2,4,6,8,10,12,14,16 octaenoic-acid (Andrewes et al., 1976). The detection of xanthomonadins is highly significant and their presence (Irey and Stall, 1982; Jenkins and Starr, 1982b; Gitaitis et al., 1987; Angeles-Ramos et al., 1991), or that of the gene cluster coding for their synthesis (Poplawsky et al., 1993), can be used to assign unknown strains to the genus *Xanthomonas*.

Quinones Isoprenoid quinones occur in the cytoplasmic membranes of most procaryotes, where they have an important role as electron carriers in electron transport. Members of the *Alphaproteobacteria*, *Betaproteobacteria*, and *Gammaproteobacteria* contain only ubiquinones, with the latter possessing Q7, Q8, Q9, and Q12 (Suzuki et al., 1993a). The only ubiquinone detected in members of the genus *Xanthomonas*, thus far, is ubiquinone Q8 (Ikemoto et al., 1980).

Colonial or cultural characteristics and life cycles Colonies of all species of *Xanthomonas* are normally smooth, round, entire, and butyrous, at least when young, but may show surface markings such as striations and become lobed when older. The production of mucoid, butyrous colonies is an essential feature for discriminating certain pathogenic xanthomonads from saprophytes (Samson et al., 1989). Mutant colonies of different appearance occasionally occur. These may be less mucoid and tend toward rough (Corey and Starr, 1957a) or may be crenated (Whitfield et al., 1981).

When they are first visible, colonies are transparent and buff to very pale yellow, but the color soon deepens and then varies according to the species and the medium used. Pathovars of *X. campestris* and *X. axonopodis* darken towards a buttercup yellow or light cadmium, especially on nutrient agar supplemented with 5% glucose or sucrose. *X. fragariae* remains small and pale on nutrient agar, but gives abundant, spreading, orange-yellow growth on addition of 1% glucose. *X. albilineans* grows on an agar medium containing 2% sucrose and 1% peptone, as buff-yellow or honey-colored colonies.

Growth rates vary widely in the genus. The faster-growing strains produce visible colonies from single cells in 24–36 h at 25°C. Slower-growing strains may take 2–3 days for single colonies to become visible. The time taken to produce colonies about 1 mm in diameter at this temperature varies from 2 to 3 days, to a week or 10 days. The slowest-growing species take about a week to appear, and often longer on isolation plates.

Differences in colonial morphology have been used for identification. CKTM medium[1] (Sijam et al., 1991) can be used to differentiate pepper and tomato strains of *X. vesicatoria* (Sijam et al., 1992). After 2–3 d growth on this medium, all strains produce circular, raised colonies that are yellow and are surrounded by a clear ring. Minute crystals can be seen within the clear ring within 4 d. Strains isolated from tomato then develop opaque haloes around the colonies during a further 2–6 d, unlike pepper strains. Of 69 strains studied, 60 were correctly identified to host by colony characteristics on this medium. Similarly, it is possible to differentiate colonies of *X. arboricola* pathovar *pruni* from other yellow-pigmented organisms by viewing colony morphology on nutrient agar through a lined template, subilluminated by a fluorescent light box (Gitaitis et al., 1988). The clarity and refractive quality of colonies of the pathogen contrasted with distorted and opaque patterns obtained from other organisms.

There is some evidence that colony morphology may be linked to pathogenicity and virulence characteristics. Early studies on *X. phaseoli* found that the size and number of lesions on the host was reduced when using rough colonial variants instead of the mucoid wild type (Corey and Starr, 1957a). Similarly, *X. oryzae* pathovar *oryzae* (*X. oryzae*) exhibited a range of colonial variants. Nwigwe (1973) described two such variants: yellow, with wax-yellow, entire, glistening colonies of 2.5–3.5 mm diameter, and white, with spherical, entire, butyrous colonies of 3.5–5.5 mm diameter. The nonpigmented larger colonies grew faster and were more apparent in cultures known to be less virulent. Subsequent reports have given details of further colonial variants, again linking these variations to differences in pathogenicity and virulence (Choi et al., 1981; Dath and Devadath, 1982; Tsuchiya et al., 1982). Similar findings linking colony morphology and virulence have been presented for *X. oryzae* pathovar *oryzicola* (Rao and Devadath, 1977), *X. axonopodis* pathovar *vasculorum* (Peros, 1988), and *X. axonopodis* pathovar *phaseoli* (Jindal and Patel, 1984). Plasmid loss has been implicated in this phenomenon (Chakrabarty et al., 1995; Ulaganathan and Mahadevan, 1991), as have the actions of transposable elements (Dai et al., 1991).

Nutrition and growth conditions *Xanthomonas* species are chemoorganotrophic. In purely synthetic media containing minerals, ammonium nitrogen, and a suitable carbon source such

1. CKTM medium consists of (g/900 ml, unless otherwise stated): Soy peptone, 2.0; Bacto tryptone, 2.0; dextrose, 1.0; L-glutamine 6.0; L-histidine, 1.0; $(NH_4)_2HPO_4$, 0.8; KH_2PO_4, 1.0; $MgSO_4{\cdot}7H_2O$, 0.4; anhydrous CaCl, 0.25; Bacto Agar (Difco), 12.0; Tween 80, 10 ml; Pourite (Analytical Products, Belmont CA), 1 drop. Subsequent to autoclaving, the medium is cooled to 45°C and the following are added; cycloheximide, 0.5 ml (1.0 g in 5 ml methanol); bacitracin, 2.0 ml (1.0 g in 20 ml distilled H_2O); neomycin sulfate, 0.5 ml (0.4 g in 20 ml distilled H_2O); cephalexin (65 mg); 5-fluorouracil (12 mg); and tobramycin (0.4 mg); all dissolved in 100 ml distilled H_2O.

as glucose, amino acid supplements are required by most strains of all species. Usually glutamate or methionine, but occasionally both, are needed. There is evidence that methionine may play a role in pathogenesis, as studies on methylthiopropionic acid (MTPA), a phytotoxin produced by *X. axonopodis* pathovar *manihotis*, have demonstrated that methionine is a precursor of MTPA (Ewbank and Maraite, 1990). *X. axonopodis* pathovar *axonopodis* and *X. fragariae* will grow when vitamin-free casein hydrolysate is added, but their exact amino acid requirements are unknown (Kennedy and King, 1962), and *X. arboricola* pathovar *pruni* also requires nicotinic acid (Starr, 1946). Experiments have shown that in this pathovar nicotinic acid can be replaced by tryptophan, which is then converted to nicotinic acid (Wilson and Henderson, 1963).

Ammonium salts, e.g., ammonium phosphate, can serve as nitrogen sources, but nitrates are often less acceptable. Patel and Kulkarni (1949) reported that *X. axonopodis* pathovar *malvacearum* uses potassium nitrate, but not sodium nitrate. Kotasthane et al. (1965) examined 16 pathovars of *X. campestris* and found that all would accept DL-alanine, L-glutamate, and L-proline as sole carbon sources. Glycine, L-leucine, DL-methionine, DL-serine, and DL-norleucine were not used. As sole nitrogen source, DL-alanine, L-glutamate, L-proline, DL-methionine, DL-threonine, DL-aspartate, L-asparagine, L-hydroxyproline, and L-histidine were accepted by all: DL-serine, DL-norleucine, and L-tyrosine by none; while results with glycine, DL-valine, L-tryptophan, L-leucine, DL-isoleucine, L-arginine, DL-lysine, and L-cystine varied with the pathovar. Asparagine can serve as a nitrogen source if glucose is supplied, but it cannot serve as a simultaneous source of both carbon and nitrogen (Starr and Weiss, 1943; Starr, 1946). This is used as a diagnostic test for *Xanthomonas* (Dye, 1962), since yellow *Enterobacteriaceae* and many *Pseudomonas* species will grow with asparagine as sole source of both elements (da Silva Romeiro and Moura, 1998; Schaad and Stall, 1988; Pernezny et al., 1995). Glutamate or alanine can serve in this way for *Xanthomonas* (Lewis, 1930).

Studies from the optimization of xanthan gum production have shown that production is influenced by the type and initial concentrations of the carbon and nitrogen sources (de Vuyst and Vermeire, 1994). The optimal sole carbon source was found to be either 4% glucose, 4–5% sucrose (optionally as 10% molasses) or 2.8% Sirodex A (a glucose syrup, of which the glucose content was 95–96%); other components were 2.0% corn steep liquor as a combined nitrogen-phosphate source. Similar studies found that a medium containing 8% sucrose and 4% peptone was optimal, and it was noted that the bacterium preferentially consumed glucose and fructose formed during sterilization of the sucrose-containing medium (Bruggeman et al., 1998).

The optimum growth temperature is usually in the range 25–30°C, but lower for *X. populi* at about 20°C. The minimum is above 4°C and the maximum varies from 27.5 to 39°C.

Respiratory chain Xanthomonads are obligately aerobic and use oxygen as the terminal electron acceptor. They are oxidase negative by the Kovacs test, indicating that cytochrome *c* is not present (Jones and Poole, 1985). Hochster and Nozzolillo (1960) postulated that the respiratory chain in *X. axonopodis* pathovar *phaseoli* is comprised of cytochrome a_1, a_2, b_1, and flavoprotein. The spectra found at liquid air temperature showed a slight shoulder at 549 nm, suggesting a very small cytochrome *c* content, and with cell-free extracts, they showed some reduced nicotinamide adenine dinucleotide (NADH)-cytochrome *c* reductase activity. Similar results were found by Rye et al. (1988), who reported cytochromes *b*, *c*, aa_3, *o* type, and possibly a_1, present, with cytochrome *c* only present in reduced amounts. The difference spectra of Sands et al. (1967) for *Pseudomonas syringae*, and of Stanier et al. (1966) for *S. maltophilia*, are very similar, but do not show any noticeable peak or shoulder at or near 549 nm. Both of these latter species are oxidase negative and thought to contain no cytochrome *c*.

Carbohydrate metabolism Studies of eight of the currently accepted species indicate that glucose catabolism in *Xanthomonas* is similar to that in *Pseudomonas*. Glucose is oxidized readily, but not gluconate. No gluconate or 2-keto-gluconate is produced from glucose (Lockwood et al., 1941). The Entner–Doudoroff pathway is present (Katznelson, 1955, 1958; Whitfield et al., 1982) and is the predominant pathway of glucose catabolism, with only 8–16% of the glucose following the pentose phosphate pathway. The hexose cycle is not significantly used (Zagallo and Wang, 1967). The tricarboxylic acid and glyoxylate cycles are present in *X. axonopodis* pathovar *phaseoli* (Madsen and Hochster, 1959), and the presence of the TCA cycle confirmed in *X. campestris* (Whitfield et al., 1982). Two enzymes of the tricarboxylic acid cycle that show interesting variations of taxonomic significance are citrate synthase and succinate thiokinase (Weitzman, 1980). *X. hyacinthi* has a citrate synthase that is typical of Gram-negative aerobes: it is a large molecule (molecular weight is ~250,000), is inhibited by NADH, and is reactivated by adenosine monophosphate. The succinate thiokinase is also typical of Gram-negative bacteria, being large in size (molecular weight is 140,000–150,000).

With respect to the breakdown of oligosaccharides, Hayward (1977) assessed the glycosidase activity of various bacteria, mostly plant pathogens; of 39 strains of *Xanthomonas* from nine of the currently accepted species, all showed β-glucosidase activity, as did *Stenotrophomonas maltophilia*. α-Glucosidase activity was weak in *X. albilineans* and absent in both of the two strains of *X. hortorum* pathovar *vitians* and *X. vasicola* pathovar *holcicola*. It was also absent from the four strains of *X. arboricola* pathovar *pruni*, but present in *X. arboricola* pathovar *juglandis*. Dekker and Candy (1979) showed that β-mannanases and carboxymethylcellulases produced by *X. campestris* were present both as membrane-bound constituents and extracellularly. Fructose is phosphorylated by a specific phosphoenolpyruvate-dependent phosphotransferase system in *X. campestris* pathovar *campestris* (de Crecy-Lagard et al., 1991a, b). Transposon mutagenesis studies revealed that mutants incapable of metabolizing fructose also failed to utilize mannose, sucrose, and mannitol. Pectolytic activity has been shown for xanthomonads, but varies among strains. Small variations in methodology can also cause variation in results. Dye (1960) examined 142 isolates of various pathovars of *X. campestris* and 3 isolates of *X. albilineans*. Some of the *X. campestris* strains had as much activity as *Erwinia carotovora*, but many showed little or no activity. Two of the *X. albilineans* strains showed only weak polygalacturonase activity, while one also showed some pectin methylesterase activity. Using pectate gels at various pH levels, Hildebrand (1971) found that the pitting produced by two pathovars of *X. campestris* was strong and unaffected by pH, whereas with *X. arboricola* pathovar *juglandis* and *X. axonopodis* pathovar *phaseoli* and pathovar *vitians* there was greatest activity at pH 5. Two isolates of *X. fragariae* and one of *X. axonopodis* pathovar *dieffenbachiae* showed slight activity. Lange and Knösel (1970) examined eight strains belonging to three species and detected strong pectin methylesterase, pectic transeliminase, and some polygalacturonase activity in *X. vesicatoria* (one isolate); *X. axonopodis* path-

ovar *begoniae* and *X. hortorum* pathovar *pelargonii* showed slight or no activity. These authors also demonstrated significant C_x cellulase and proteolytic activity in all strains except one of pathovar *begoniae*.

Metabolism of aromatic compounds Degradation of protocatechuate, phenylalanine, and synephrine by six pathovars from four species of *Xanthomonas* and four pathovars of uncertain affiliation was found to occur by meta cleavage (William and Mahadevan, 1980). These compounds could serve as carbon sources for growth, but benzoate and *o*-hydroxybenzoate could not be used. More recently, studies on the degradation of xenobiotic compounds such as 1-chloro-2,4-dinitrobenzene and the herbicide alachlor, have demonstrated the presence of glutathione-S-transferase, a key enzyme in the detoxification of xenobiotics, in *X. campestris* (Zablotowicz et al., 1995).

In the synthesis of aromatic amino acids by *Xanthomonas*, the first step is the combination of the multifunctional metabolites D-erythrose-4-phosphate and phosphoenolpyruvate to form 3-deoxy-D-arabinoheptulosonate-7-phosphate (DAHP), the first metabolite that is specific to the pathway. The step is catalyzed by the enzyme DAHP synthetase. The subsequent pathway is multibranched and the activity of DAHP synthetase may be governed by various regulatory systems. Thirty-two genera were examined by Jensen et al. (1967) and found to have one of six different control patterns. Control in *X. campestris* and *X. hyacinthi* was unusual. It was identified as sequential feedback inhibition by chorismate. Arogenate also produced some inhibition, but prephenate, phenylalanine, and tyrosine had little or no effect. There was also some inhibition by tryptophan in *X. hyacinthi* but little or none in *X. campestris*. Whitaker et al. (1981a) examined, among other species, five isolates of *X. campestris* (pathovars not specified), one of *X. albilineans*, one of *X. axonopodis*, two of *S. maltophilia*, one of *"Pseudomonas gardneri"*, and the type strain of *Pseudomonas geniculata*, and found that all had DAHP synthetases that showed sequential feedback inhibition by chorismate and lack of stimulation by divalent cations. These properties have not been found in any other groups of bacteria. It is interesting to note that Dye (1966b) found an isolate of *"P. gardneri"* to be a synonym of *X. vesicatoria*, and De Ley (1978) considered it *Xanthomonas* based on DNA–rRNA hybridization. Whitaker et al. (1981a) point out that the isolate of *P. geniculata* was originally deposited in the ATCC as a strain of *P. maltophilia*.

The enzymes involved in the biosynthesis of tyrosine and phenylalanine from prephenate also have taxonomic importance. The dehydrogenases of the two pathways to tyrosine were studied by Byng et al. (1980). They found that although both dehydrogenase activities (i.e., prephenate dehydrogenase and arogenate dehydrogenase) were shown by nearly all species of *Pseudomonas* and *Xanthomonas* studied, the enzymes varied in the cofactor required and in their inhibition by tyrosine (feedback control). Isolates of *X. axonopodis* (pathovar *axonopodis*, pathovar *malvacearum* and pathovar *phaseoli*) *X. hyacinthi*, *X. hortorum* pathovar *pelargonii*, *X. albilineans*, and *S. maltophilia* all showed an NAD-dependent prephenate dehydrogenase that was inhibited by tyrosine, and all showed an NAD-dependent arogenate dehydrogenase, except *X. axonopodis* pathovar *axonopodis*, which showed no activity.

The dehydratases of the two pathways to phenylalanine (i.e., prephenate dehydratase and arogenate dehydratase) were studied by Whitaker et al. (1981b). They found that not only was one or the other of these enzymes absent in some groups, but that the degree of activation of prephenate dehydratase by tyrosine varied considerably between groups. The combination of these characteristics gave a fine taxonomic tool for distinguishing not only the five rRNA–DNA hybridization groups, but also two subgroups of group II and three subgroups of group III, along the same lines as found with DNA hybridization. Group V organisms contained arogenate dehydratase and prephenate dehydratase, which was not activated by tyrosine. They could not be distinguished from group Ib using these enzymes. Assigned to group V were *S. maltophilia*, *X. campestris* (three isolates), *X. albilineans*, *X. axonopodis*, *"P. gardneri"*, and *P. geniculata*.

A further metabolic pathway involving aromatic amino acids is relatively well known, at least in one pathovar of *X. arboricola*, pathovar *pruni*, which requires nicotinic acid for growth, but can accept tryptophan or 3-hydroxyanthranilic acid as a substitute. This it does by synthesis of nicotinic acid from these substances by a pathway that leads to synthesis of nicotinamide adenine dinucleotide (NAD) from tryptophan (Wilson and Henderson, 1963). This pathway has been found in animals, the fungus *Neurospora crassa*, yeasts, and some *Streptomyces* species, but is absent from various bacteria that have been examined (Yanofsky, 1954; Lingens et al., 1966). The first three enzymes involved, tryptophan pyrrolase, kynurenine formamidase, and kynureninase, are coordinately induced by L-tryptophan (Brown and Wagner, 1970). Wagner and Brown (1970) presented evidence that the pathway is regulated by the first step from tryptophan. The activity of the allosteric enzyme involved, tryptophan pyrrolase, is under feedback control (inhibition) by the end products of the pathway, NADH and NADH phosphate.

Van Eys (1960) has shown that nicotinic acid may also be replaced by NAD for growth of *X. arboricola* pathovar *pruni*. The final step in degradation of NAD to nicotinic acid is catalyzed by a pyridine ribosidase that shows unusual preference for the pyridine-riboside linkage over the purine-riboside linkage.

Catabolism of nucleoside triphosphates Huang et al. (1975) found that ATPase is bound to the cell membrane of *X. oryzae* pathovar *oryzae* by a mechanism that involves magnesium ions, which also stabilize this enzyme. Nucleoside tri- and diphosphates are hydrolyzed, but not monophosphates. The pathway for degradation of ATP has been elucidated by Hochster and Madsen (1959). Working with *X. oryzae* pathovar *oryzae*, Yang et al. (1975) obtained evidence for the extracellular breakdown of deoxycytidine triphosphate to the diphosphate, monophosphate, and finally to deoxycytidine. The material was taken up by the cell and incorporated into DNA, probably by stepping up again through mono-, di-, and triphosphates.

Genetics Early studies demonstrated genetic transformation in *X. axonopodis* pathovar *phaseoli* using DNA from strains differing in colony type or in streptomycin resistance (Corey and Starr, 1957b, c). Subsequently, exchange of genetic material has been achieved by conjugal plasmids (Daniels et al., 1984) transformation by electroporation (Wang and Tseng, 1992; Ferreira et al., 1995) and transducing phage (Weiss et al., 1994). Studies using a transposon (Tn5-SC), constructed to quantify genetic deletions or amplifications, demonstrated that the genomic stability of *X. campestris* pathovar *campestris* was as great as that of other Gram-negative bacteria (Martinez-Salazar et al., 1993). Similarly, homologous recombination between plasmid sequences was found to occur at a similar level to that reported for other Gram-negative bacteria.

Much study has been directed towards pathogenicity, xanthomonadin, and xanthan gum production (see Daniels and Leach,

1993). Transposon-induced mutagenesis has been employed widely to characterize components within the pathogenicity function. Hu et al. (1992) found that nonpathogenic mutants of *X. campestris* pathovar *campestris* accumulated extracellular polygalacturonate lyase, α-amylase, and endoglucanase in the periplasm, but were deficient in a signal peptidase involved in protein secretion. Similarly, Tn5-induced mutants of *X. campestris* pathovar *campestris* deficient in protease and extracellular polysaccharide production were found to be nonpathogenic to turnip seedlings (Rosato et al., 1994). In contrast, no differences in the production of protease, polygalacturonase, extracellular polysaccharides or growth rate were found between an avirulent, transposon-induced, mutant of *X. vesicatoria* and the wild type (Yun et al., 1995). A 5.4-kb DNA fragment from the type strain of *X. campestris* pathovar *campestris* was found to alter the phenotype of *X. campestris* pathovar *armoraciae* 417 when inoculated onto cabbage (Chen et al., 1994). This transfer conferred the ability to cause blight on the recipient, which generally causes a nonsystemic leaf spot of crucifers. It was suggested that the genes conferring the ability to induce blight symptoms may be unique to *X. campestris* pathovar *campestris* and can affect the apparent pathovar status of the recipient strain.

The *hrp* gene cluster determines functions necessary for pathogenicity on host plants.

Cross-complementation showed that *X. axonopodis* pathovar *vitians* and *X. campestris* pathovar *campestris hrp* sequences are functionally interchangeable, and there is evidence to suggest that there is some functional homology between the *hrp* gene cluster of *Ralstonia solanacearum* and a range of xanthomonads (Arlat et al., 1991). Other complementation studies have revealed that the *hrp* region is organized into at least six different groups (Bonas et al., 1991) and in some pathovars homology was high enough to permit marker gene exchange or complementation of nonpathogenic mutants. Further, *X. campestris* pathovar *campestris* and *X. oryzae* pathovar *oryzae* were found to contain a 1428-base pair *hrp*X gene, involved in the regulation of *hrp* genes (Oku et al., 1998). Sixteen distinct xanthomonad pathovars and 12 strains of *X. oryzae* pathovar *oryzae* were shown to contain homologs of *hrp*X, which were not apparent in heterologous bacteria such as *Agrobacterium*, *Erwinia*, and *Pseudomonas* spp.

Expression of *hrp* genes was found to be repressed when the organisms were grown on rich media, and in minimal medium the level of expression depended on the carbon source supplied to the cells (Arlat et al., 1991). Similar results were obtained by Schulte and Bonas (1992b) who found that expression of *hrp* genes and the hypersensitive response were suppressed in complex media, but induced in plants. Using a minimal medium, both sucrose and methionine were required for induction of *hrp* genes at expression levels similar to those found by induction in plants. Further studies showed that plant filtrates were able to induce *hrp* genes (Schulte and Bonas, 1992a); the inducing molecule(s) were heat stable and hydrophilic.

Seven transcriptional units (*pig*A through *pig*G) involved in xanthomonadin production have been identified (Poplawsky and Chun, 1997). Inactivation of the *pig*B unit resulted in reduced xanthomonadin and extracellular polysaccharide slime production. This phenomenon was reversible when *pig*B mutant strains were grown with other xanthomonadin transcriptional mutants, the wild type, or other xanthomonads. This finding suggests that *pig*B is involved in a regulatory function, which can be restored by a nontransforming diffusible factor (DF). The DF is thought to be novel and different from other signal molecules, such as homoserine lactone derivatives found in *Vibrio*, *Agrobacterium*, *Erwinia*, *Pseudomonas* and *Burkholderia* spp. (Chun et al., 1997). This finding was similar to that obtained from a recent survey of 106 isolates from seven genera of Gram-negative plant-associated bacteria (Chung et al., 1998a), in which relatively few xanthomonads produced any detectable homoserine lactones.

Nonmucoid mutants deficient in xanthan gum production have been restored by conjugal mating (Thorne et al., 1987). Groups of clones that contained overlapping homologous DNA were found to complement specific mutations, suggesting clustering of the genetic loci involved in xanthan synthesis. Further work has shown that the xanthan gum gene cluster is made up of 12 genes, mainly expressed as an operon under the control of a promoter situated upstream from the first gene, *gum*B (Katzen et al., 1996).

The chromosome map of *X. campestris* pathovar *campestris* has recently been elucidated (Tseng et al., 1999) and the positions of eight loci involved in EPS (xanthan gum) production, nine auxotrophic markers, the gene cluster for xanthomonadin production, and two 16S rRNA operons have been determined.

Molecular biology A range of fingerprinting methods have been applied to xanthomonads, usually at the species/pathovar/strain level. Hartung and Civerolo (1987) digested genomic DNA from a collection of *X. axonopodis* pathovar *citri* isolates with the restriction endonuclease *Eco*R1, the fragments were separated by PAGE, and the resulting genomic DNA fingerprints compared. Fingerprints varied among separate disease outbreaks and within single outbreaks. Subsequent studies using a conventional RFLP approach, probing *Eco*RI and *Pvu*II polymorphisms with seven cosmid clones selected from a library of *X. axonopodis* pathovar *citri* XC62, demonstrated that *X. axonopodis* pathovar *citri* has a clonal population structure, consistent with previous findings (Hartung and Civerolo, 1989). A relatively heterogeneous group of related strains was isolated only from Florida citrus nurseries, and these were circumscribed into two groups in a subsequent study (Hartung and Civerolo, 1991). RFLP analysis has formed the basis of characterization studies for "*X. campestris* pathovar *citrumelo*" (Gottwald et al., 1991), *X. axonopodis* pathovar *vignicola* (Verdier et al., 1998a), " *X. campestris* pathovar *zeae*" (Qhobela et al., 1990), *X. axonopodis* pathovar *manihotis* (Verdier et al., 1998b), *X. oryzae* pathovar *oryzae* (Leach et al., 1992), *X. campestris* pathovar *mangiferaeindicae* (Gagnevin et al., 1997), and *X. vesicatoria* (Chung et al., 1996). Variations on this basic method have been used to detect polymorphisms in *hrp* genes (Leite et al., 1994a, b) and insertion sequences (Berthier et al., 1994; Adhikari et al., 1995; Chen et al., 1999a), for strain characterization or in conjunction with pulsed-field gel electrophoresis (Cooksey and Graham, 1989; Davis et al., 1997; Roberts et al., 1998).

DNA sequences corresponding to conserved motifs of repetitive bacterial elements (REP, ERIC, and BOX) are widely distributed in phytopathogenic *Xanthomonas* and *Pseudomonas* strains (Louws et al., 1994) and have been used to characterize *X. hortorum* pathovar *pelargonii* (Sulzinski et al., 1995), *X. vesicatoria* (Louws et al., 1995), and *X. fragariae* (Opgenorth et al., 1996). The AFLP technique (Vos et al., 1995), based on the selective PCR amplification of restriction fragments from a total digest of genomic DNA, has been used to study *X. axonopodis* pathovars and *X. vasicola* (Janssen, et al., 1996; Restrepo et al., 1999). From the former analysis, pathovars of *X. axonopodis*, which mainly cause disease in citrus and grasses, were recovered

in two groups separate from *X. vasicola*, which correlated well with studies using other techniques.

Plasmids Early studies by Lai et al. (1977a) demonstrated transmission of plasmids RP4 and RK2 from *Escherichia coli* to *X. vesicatoria*, conferring resistance to various antibiotics and production of penicillinase. The transconjugants were able to transmit the plasmids to other strains of the same pathovar, as well as to other pathovars, and also to other bacterial phytopathogens belonging to a number of Gram-negative genera. Stability of the plasmids in the transconjugants varied. A high proportion were retained in bacteria in leaf lesions on plants, in detached leaves kept moist at 5°C, and in dried leaves, but were rapidly lost from cells grown on agar (Lai et al., 1977b). More recently, copper resistance was found to be plasmid borne and self-transmissible in strains of *X. vesicatoria* (Stall et al., 1986). Copper resistance appears to be linked to avirulence, as avirulent, copper-resistant transconjugants were detected subsequent to mating copper-resistant strains with virulent, copper-sensitive strains. Further studies into the emergence of copper resistance have confirmed the wide transmissibility of plasmids coding for this attribute (Bender et al., 1990; Park and Cho, 1996). Copper resistance was transferred to sensitive strains of the same pathovar at a rate of 4.3×10^{-3} to 1.0×10^{-5}, and could be transferred to other pathovars of *X. campestris*. Within *X. vesicatoria*, there is also evidence that race determinants are coded on plasmids, as race shifts have been observed (Swanson et al., 1988; Kousik and Ritchie, 1996). Race shifting was thought to result from the loss of a plasmid carrying avirulence genes or the inactivation of the avirulence gene by an insertion element. In an extensive study of 522 strains of *X. vesicatoria*, the number and size of plasmids was found to vary widely, the latter ranging from 3 to 300 kb (Canteros et al., 1995). Seventy-one different profiles were observed, with a maximum of five plasmid classes present in any one profile. No plasmid or plasmid profile was found to be characteristic for the species (pathovar) and exchange of plasmids in natural populations was thought to be widespread.

Although plasmids are not found universally in xanthomonads (Lazo and Gabriel, 1987), they have been found in *X. axonopodis* pathovar *cyamopsidis*, pathovar *dieffenbachiae*, and pathovar *glycines*, and *X. hortorum* pathovar *hederae* (Lazo and Gabriel, 1987), *X. arboricola* pathovar *pruni* and *X. axonopodis* pathovar *vitians* (Kado and Liu, 1981; Lazo and Gabriel, 1987), *X. campestris* pathovar *sesami* (Sheela et al., 1994), *X. axonopodis* pathovar *manihotis* (Lin et al., 1979), *X. axonopodis* pathovar *malvacearum* (Lazo and Gabriel, 1987; de Feyter and Gabriel, 1991), *X. oryzae* pathovar *oryzae* (Choi et al., 1989b; Amuthan and Mahadevan, 1994), *X. axonopodis* pathovar *vignicola* (Lazo and Gabriel, 1987; Ulaganathan and Mahadevan, 1988), *X. axonopodis* pathovar *vasculorum* (Ezavin et al., 1992), and *X. axonopodis* pathovar *citri* (Civerolo, 1985; Lazo and Gabriel, 1987). In the case of the latter, the number of plasmids varies from 1 to 5, sizes ranging from 7 to 100 kb (Pruvost et al., 1992). In general, strains associated with the same form of citrus bacterial canker disease shared the same plasmid types and these exhibited similar restriction patterns. This uniformity, also present in other pathovars within the genus, has enabled the exploitation of plasmids as high-resolution markers in population studies of *X. vesicatoria* (Hwang et al., 1995), *X. axonopodis* pathovar *manihotis* (Restrepo and Verdier, 1997), and *X. axonopodis* pathovar *citri* itself (Hartung et al., 1996). In the case of the latter, a nested PCR approach relied on the use of labeled primers to allow detection of the amplification product in a microtiter plate. All strains of *X. axonopodis* pathovar *citri* tested were detected with this system, as were some strains of *X. axonopodis* pathovar *aurantifolii* but not other xanthomonads such as *X. axonopodis* citrumelo, which causes citrus bacterial spot disease.

Antigenic structure Polyclonal antibodies as taxonomic tools have been limited in their impact in the study of *Xanthomonas*. Work has mostly resulted in multiple groupings of pathovars and many cross-reactions. Thus, Elrod and Braun (1947a), using whole cells as antigens for agglutination, found that 36 nomenspecies fell into five groups. Cross-reactions were reduced if the exopolysaccharides were removed by thorough washing, or if the cells were grown on medium low in carbohydrate. Further work on one group (Elrod and Braun, 1947b), using cross-absorbed antisera, separated two "serologically good species," *"Xanthomonas juglandis"* (four isolates) and *"Xanthomonas carotae"* (three isolates). With *X. vesicatoria*, results have varied. Lovrekovich and Klement (1965) found two serovars among 34 strains and reported correlation with phagovars and host of origin. Charudattan et al. (1973) also found two serovars in 72 strains and Schaad (1976), using ribosome preparations from 25 strains, found two serovars and a single isolated strain. Both used double gel-diffusion and neither found any correlation with host origin or pathogenicity. Yano et al. (1979) found nine serovars in 31 isolates belonging to 14 pathovars of *X. campestris*. They used whole cells washed in formalized saline for injection, preparations of extracellular polysaccharide as antigens, and indirect hemagglutination. Cross-reactions were evident, as serovars did not correspond to pathovars. Similar results were obtained by Anderson and Nameth (1990) using polyclonal antisera raised against *X. hortorum* pathovar *pelargonii*. The antisera, when used to develop an immunogold silver stain dot-immunobinding assay and ELISA, were found to be highly reactive for *X. hortorum* pathovar *pelargonii*, but five of seven other pathovars tested also gave moderate reactions. When used in conjunction with other methods, such as immunofluorescence microscopy (Schaad, 1978; Franken, 1992) or for immunocapture prior to use of a PCR assay (Lopes and Damann, 1996; Hartung et al., 1997), polyclonals clearly have value.

The use of monoclonal antibodies (MAbs) has greatly increased specificity. Thus Alvarez et al. (1985) were able to distinguish *Xanthomonas* spp. from a large number of other bacteria using one carefully selected MAb. Using three others they could separate *X. campestris* pathovar *campestris* from various other pathovars, and using a further five MAbs they separated pathovar *campestris* into six groups, finding interesting epidemiological correlations. Extension of these methods allowed identification of *X. albilineans* (Alvarez, et al., 1996), *X. axonopodis* pathovar *citri* (Benedict et al., 1985; Alvarez et al., 1991), *X. axonopodis* pathovar *citrumelo* (Alvarez et al., 1991; Gottwald et al., 1991), *X. axonopodis* pathovar *dieffenbachiae* (Lipp et al., 1992), *X. vesicatoria* (Bouzar et al., 1994), *X. oryzae* pathovar *oryzae* and pathovar *oryzicola* (Benedict et al., 1989), and *X. hortorum* pathovar *pelargonii* and *X. axonopodis* begoniae (Benedict et al., 1990). Franken et al. (1992), using polyclonal and monoclonal antibodies made with whole cells and with flagella preparations of *X. campestris* pathovar *campestris*, found that four MAbs reacted with lipopolysaccharides, whereas two reacted with proteins of 39 and 29 kDa. These proteins were apparently present only in *Xanthomonas* and may be the same proteins found in the outer membrane extracts (Minsavage and Schaad, 1983; Laakso et al., 1990). There was an interesting correlation with ability to hydrolyze starch, but again

no correlation with pathogenicity. Out of 16 other *Xanthomonas* isolates included in the tests, only two isolates of *X. campestris* pathovar *campestris* cross-reacted with *X. vesicatoria*.

Antibiotic and drug sensitivity Isolates of *X. oryzae* pathovar *oryzae* were found to be sensitive to streptomycin, ampicillin, novobiocin, erythromycin, oleandomycin, vancomycin, rifampicin, and oxymycin (all at 5μg/ml). The MIC of penicillin G was 40 μg/ml and pimaricin did not inhibit growth up to 100 μg/ml (Choi et al., 1988). In a study of *X. campestris* pathovar *mangiferaeindicae*, strains were also found to be sensitive to streptomycin, in addition to kanamycin, gentamycin, oxytetracycline, and erythromycin (Pruvost et al., 1998). Other antibiotics active against some xanthomonads include ascamycin (Sudo et al., 1996), xanthobacidin (Huang and Chang, 1975), and zhongshenmycin (Zhang et al., 1996).

Pathogenicity and ecology Species and pathovars of *Xanthomonas* have been reported to cause disease in at least 124 monocotyledons and 268 dicotyledons, but no gymnosperms, ferns, or lower plants (Leyns et al., 1984). The host ranges and geographical distributions of these pathovars vary widely (Bradbury, 1986). The symptoms produced also vary widely and are helpful, sometimes essential, for identification of the pathogen involved. Most species and pathovars produce leaf spots, at least initially. These may spread very little, or be limited by the leaf veins, causing angular leaf spots in dicotyledons. They may spread to include the veins and then may develop systemically. Systemic infections produce wilts, death of shoots, or cankers on twigs and branches, or combinations of these symptoms, and if severe the whole plant may be killed. The extent of symptom development and type of symptoms expressed may also depend on the environmental conditions and the cultivar of the host plant (see Rudolph, 1993).

The mechanisms involved in symptom production are incompletely known. Metabolic products such as toxins and enzymes have been shown to be involved. In the case of the latter, protease-deficient mutants showed considerable loss of virulence in pathogenicity tests (Dow et al., 1990) and endoglucanase is thought to play a role, albeit minor, in the early stages of disease development (Gough et al., 1988). Certain enzymes involved in pectin and polygalacturonate degradation appear to have a limited role in pathogenesis (Dow et al., 1989; Beaulieu et al., 1991), though Boher et al. (1995) found that during the infection process the middle lamellae, primary, and secondary plant cell walls were degraded by cellulolytic and pectolytic activity. In addition, their results suggest that bacterial exocellular polysaccharides were involved in plant cell surface degradation (Boher et al., 1997). Similar findings have been made in other studies (Kingsley et al., 1993; Dow et al., 1995) and the involvement of extracellular polysaccharides has long been considered (Morris et al., 1977). El Banoby and Rudolph (1979) found that specific fractions of these polysaccharides from several xanthomonads produced persistent water-soaked spots when introduced into leaves of the host plants from which the bacteria came. Similar results were found with EPS prepared from culture filtrates of *X. vesicatoria*, in which watersoaking and, in some cases, foliar discoloration or necrosis, could be induced by EPS alone (Walkes and O'Garro, 1996). Ramirez et al. (1988) found a correlation between virulence and parameters such as the final viscosity of the culture, the viscosifying capacity of the polymer, and the amount of acetyl substituents in the gum. Infrared spectral analysis revealed that intramolecular interaction of gum constituents could play a significant role in virulence. Dow et al. (1995) found that a pathogenicity locus within *X. campestris* pathovar *campestris* comprises two genes governing the biosynthesis of lipopolysaccharide within the bacterial cell. They suggested that the LPS protects the bacteria against antibacterial substances produced by the plant early in the infection process. Subsequent studies on the early phases of infection detected the LPS produced by *X. axonopodis* pathovar *manihotis* on the outer surface of the bacterial envelope and in areas of the plant middle lamellae in the vicinity of the pathogen (Boher et al., 1997). Lipopolysaccharides are also thought to be involved in the induction of the hypersensitive response and resistance in susceptible hosts (Newman et al., 1995, 1997; Romeiro and Kimura, 1997); they may also have value in epidemiological studies, as differences in the LPS of *X. albilineans* isolated in different locations has been reported (Pillay et al., 1995).

Host specificity is high in pathovars of *Xanthomonas*. In the lists of pathovars below, only about half a dozen have been found to have hosts in more than one plant family. On the other hand, Schnathorst (1966) found that *X. axonopodis* pathovar *malvacearum*, when inoculated onto *Phaseolus* sp., produced early stages of infection very similar to those of pathovar *phaseoli*. The two pathovars were also serologically related, according to earlier experiments. His experiments helped to disprove earlier ideas that host specificity could be changed by artificial passage through nonhost plants.

A critical point in the life cycle of xanthomonads, as with other plant pathogens, is transmission to a new host, particularly if a period of survival in the absence of the host is necessary (see Stall et al., 1993). Such survival may be achieved in many ways, such as with seed, plant residues, perennial hosts, epiphytically, saprophytically in soil, and in insects (Schuster and Coyne, 1974). Many xanthomonads solve this problem by transmission with the seed of their host. These organisms are listed by Richardson (1990). The bacteria may be carried in detritus with the seed, on or in the seed coat, or deeper inside the tissues of the seed itself. Epiphytic survival is becoming well known, e.g., *X. axonopodis* pathovar *manihotis* and *X. arboricola* pathovar *pruni* are both known to spend the interseasonal time epiphytically (Persley, 1978; Young, 1978). In agriculture, many pathogens are most effectively carried by the activities of man, either in infected planting material, which may be symptomless (Hayward, 1974), or on tools, wheeled vehicles, and even grazing animals, as for *X. axonopodis* (Castaño et al., 1964). Survival in soil saprophytically is unusual, but has been suggested by the work of Goto et al. (1978) for *X. axonopodis* pathovar *citri*. Xanthomonads have occasionally been detected in run-off water and ditches around fields of infected plants. Results suggest that survival in this situation would be short (Steadman et al., 1975).

All organisms currently named in the genus *Xanthomonas* are plant pathogens, but isolates that are apparently non-pathogenic are also found (Vauterin et al. 1996a). Some have been identified as known pathogens growing epiphytically, e.g., *X. axonopodis* pathovar *phaseoli* isolated from symptomless weeds (Angeles-Ramos et al., 1991). Most of those examined by SDS-PAGE of proteins and fatty acid analysis can be identified with the currently accepted *Xanthomonas* spp. But identification to the pathovar level in the absence of a pathogenicity test is more difficult (Vauterin et al., 1996a). In any case, the naming of a nonpathogenic organism, with no known connection with disease, as a pathovar is unacceptable. The vast majority of *Xanthomonas* spp. found so far have been associated with plants, but recently organisms be-

longing to this genus or closely related to it have been shown to form a significant proportion of the bacteria present in microbial communities of hydrothermal vents. These organisms were also found to be related to several *Thiobacillus* spp. (Moyer et al., 1995).

Enrichment and Isolation Procedures

With plant-pathogenic bacteria, the plant itself is probably the ideal "enrichment medium" and isolation is best made from plant material using a dilution procedure, unless contraindicated, onto a nonselective medium. Nutrient agar is usually satisfactory for isolation because it is not sufficiently rich to encourage growth of saprophytes. Supplementing Difco nutrient agar with yeast extract (5 g/l) has been recommended for general isolation work (Dye, 1980; Schaad and Stall, 1988). YSP[2] medium has been recommended for the isolation of *X. albilineans* (Dye, 1962) or SP[3] medium supplemented with cycloheximide and penicillin G (Hayward, 1979). Dye′s GYCA medium[4] is useful for pigment production, and it is good for *X. cassavae*, which grows poorly and is short lived on media containing peptone. GYCA is also good for keeping stock cultures, as is YDC[5] (Schaad and Stall, 1988).

Semi-selective media for particular xanthomonads have also been described: CKTM for *X. vesicatoria* (Sijam et al., 1991). The selectivity depends on cycloheximide, bacitracin, neomycin, cephalexin, 5-fluorouracil, tobramycin, and Tween 80. Strains of *X. vesicatoria* can be distinguished from strains of other xanthomonads by the formation of a clear ring around their colonies. *X. arboricola* pathovar *pruni* has been recovered from soil and plant material using XPSM[6] medium (Civerolo et al., 1982), which also suppresses the growth of saprophytic bacteria and fungi generally found in soil samples. The use of nutrient agar supplemented with sodium deoxycholate (200 mg/l), has been used for the selective isolation of *X. vesicatoria* (Bashan and Assouline, 1983), as has a medium containing carboxymethyl cellulose and gelatin (Gitaitis et al., 1991). For a more detailed account, see Kado and Heskett (1970) and Schaad and Stall (1988).

A number of plating assays for detecting *X. campestris* pathovar *campestris* in crucifer seeds have been evaluated (Franken, et al., 1991). Centrifugation prior to plating had no appreciable effect, but the addition of Tween 20, benomyl, and chlorothalonil to the saline (0.85% NaCl) centrifugation solution generally resulted in lower recovery of the target organism. It was found that shaking at room temperature for 2.5 h and soaking at 4–6°C for 1.5 h increased the number of colony forming units recovered, but did not result in more infected seed lots being detected. No significant differences were found between the plating media tested: FS (Yuen et al., 1987), NSCA, and NSCAA (Randhawa and Schaad, 1984). In a similar study, CS20ABN medium was developed by incorporation of bacitracin, neomycin, and cycloheximide into CS20A (Chang et al., 1991). Comparison with CS20A, NSCA, NSCAA, and FS showed that all media recovered high numbers of saprophytic bacteria, that were too numerous to count and overgrew *X. campestris* pathovar *campestris* colonies, with the exception of CS20ABN, where 59–100% of recovered colonies were identified as *X. campestris* campestris.

Maintenance Procedures

Stock cultures may be maintained on GYCA for periods up to six months, with regular subculturing at approximately monthly intervals. Hokawat and Rudolph (1991) found that there was no appreciable decrease in virulence in cultures stored for two years on YDC agar slants. Less frequent subculturing is possible with most isolates at lower-than-room-temperature, e.g., in a refrigerator at ~7–10°C, but care should be taken to ensure that the isolate can tolerate the temperature. *X. axonopodis* pathovar *citri*, cultured on agar plates inverted and stored at 4°C in darkness, could be maintained for at least 26 weeks on a semi-enriched minimal medium (Wu et al., 1990), with no loss of virulence or alteration in colonial morphology. Cultures on richer media did not survive storage.

For longer periods of storage, most isolates can be freeze dried and will keep for years (Lelliott, 1965; Hokawat and Rudolph, 1991). Freeze-dried cultures of *X. oryzae* suspended in 10% sucrose and 1% gelatin retained viability and virulence in a suspending medium containing 2% dextrin, 0.5% ascorbic acid, 0.5% ammonium chloride, 0.5% thiourea, and 0.85% NaCl (Hwang and Cho, 1986). Liquid cultures, applied and then dried onto Whatman 3M paper, have also been used effectively to store xanthomonads (Kidby et al., 1977). *X. albilineans*, which does not keep well in the lyophilized condition, can be kept on an agar slope under sterile mineral oil for periods up to approximately two years.

Procedures for Testing Special Characters

The significance of polyamines as a tool in differentiating xanthomonads from other members of the *Gammaproteobacteria* has been established (Auling et al., 1991; Hamana and Matsuzaki, 1993), and in an extensive study of polyamine profiles of 140 *Xanthomonas* strains, spermidine was found to predominate in all members of the genus (Yang et al., 1993b). In contrast, *Stenotrophomonas maltophilia*—at that time encompassed within the genus *Xanthomonas*—contained spermidine and large amounts of cadaverine.

Exopolysaccharides are generally heteropolysaccharides that have repeat structures with carbohydrate and noncarbohydrate substituents (Leigh and Coplin, 1992). The EPS produced by *Xanthomonas* is similar in structure to class 1 capsular polysaccharides and is known commercially as xanthan gum. Xanthans are high-molecular-weight, acidic, anionic heteropolysaccharides composed mainly of D-glucose, D-mannose, and D-glucuronic acid in a ratio of 2:2:1, with small amounts of pyruvic and acetic acids that vary with strains and conditions (Cadmus et al., 1978; Whitfield et al., 1981; Sutherland, 1993). Because of their physical properties and lack of toxicity to man and animals, xanthans

2. YSP medium consists of (g/l): yeast extract, 5.0; sucrose, 20.0; peptone, 10.0; and agar 15.0.

3. SP medium consists of (g/l): peptone, 5.0; K_2HPO_4, 0.5; $MgSO_4 \cdot 7H_2O$, 0.25; sucrose, 10.0 or 20.0; agar, 15.0. To control growth of saprophytes, cycloheximide (100 mg/l) and penicillin G (200 IU/ml) can be added.

4. GYCA medium consists of (g/l): yeast extract, 5.0; glucose, 5.0, $CaCO_3$, 40.0, and agar, 15.0. The carbonate is mixed well into the medium just before solidification.

5. YDC medium consists of (g/l): yeast extract, 5.0; dextrose, 20.0, $CaCO_3$, 20.0, and agar, 15.0. The carbonate is mixed well into the medium just before solidification.

6. XPSM medium consists of (g/l except where indicated): alginic acid, 2.0; 8-azaguanine, 0.2; nicotinic acid, 2 mg; cysteine, 3 mg; KH_2PO_4, 0.8; K_2HPO_4, 0.8; $MgSO_4$, 0.1; Bacto agar, 15.0. Subsequent to autoclaving, the medium is cooled to 45°C and chlorothalonil (Diamond Shamrock, Cleveland, OH) and kasugamicin are added aseptically to a final concentration of 80 and 16 mg/ml, respectively.

have a wide range of uses in industry. They are gelling agents, emulsifiers, stabilizing agents, and plasticizers, particularly in the food industry (Jeannes, 1974; Sutherland and Ellwood, 1979). For the genetic control of xanthan synthesis, see Köplin et al. (1992).

Differentiation of the genus *Xanthomonas* from other genera

Characteristics useful for differentiating *Xanthomonas* from other genera are listed in Table BXII.γ.17.

Taxonomic Comments

Xanthomonas is a well-defined, homogeneous genus. This is particularly true now that the closely related yet distinctive species, *Xanthomonas maltophilia*, as described by Swings et al. (1983), is accommodated in its own genus, *Stenotrophomonas* (Palleroni and Bradbury, 1993). In addition, *Xanthomonas ampelina* (Panagopoulos, 1969), as described in the previous edition, has been relocated to *Xylophilus* (Willems et al., 1987) in the family *Pseudomonadaceae*, from which *Xanthomonas* was removed. The exact position of *Xylella* may need further investigation, as its very different G + C ratio suggests a genus rather distantly related to other members of the family.

Phylogenetic treatment Our current understanding of the phylogenetic position of the genus *Xanthomonas* owes much to early nucleic acid hybridization studies (Palleroni et al., 1973; De Ley, 1978; De Vos and De Ley, 1983). In this work, the first indications of the multigeneric nature of the genus *Pseudomonas* were presented, as well as strong evidence that the genus *Xanthomonas*, traditionally associated with pseudomonads, was well defined and distinct (De Ley, 1992). The pioneering work of Palleroni and co-workers (1973) assigned the genus *Xanthomonas* to rRNA hybridization group V, distinct from the majority of fluorescent and nonfluorescent taxa of the genus *Pseudomonas*. Congruent results were presented in subsequent studies, and in these broader analyses encompassing a wider range of Gram-negative genera, both the genus *Xanthomonas* and *Pseudomonas sensu stricto* were placed in rRNA super-family II (De Ley, 1978). In addition, results from these studies demonstrated that *Stenotrophomonas maltophilia* (at that time considered a member of the genus *Pseudomonas*) was related to the genus *Xanthomonas* and was subsequently renamed as *Xanthomonas maltophilia* (Swings et al., 1983; see also Van Zyl and Steyn, 1992; Palleroni and Bradbury, 1993).

Subsequently, cataloging of 16S rRNA sequences placed the genus *Xanthomonas* in the *Gammaproteobacteria* (purple bacteria; Stackebrandt et al., 1988), along with *Pseudomonas sensu stricto* (Woese et al., 1985), the subdivision being broadly synonymous with rRNA super families I and II (De Ley, 1978). In a more detailed overview of the phylogeny of the genus *Pseudomonas* and traditionally associated genera and species, the genera *Xanthomonas*, *Stenotrophomonas*, and *Xylella* were recovered together based on 16S rDNA sequence information (Kersters et al., 1996). This grouping broadly equated with rRNA hybridization group V (Palleroni et al., 1973). In this analysis, however, some doubt was expressed as to the true phylogenetic position of the group, as it was not possible to unequivocally place it within either the *Gammaproteobacteria* or *Betaproteobacteria*. Subsequently, the position of all three genera was confirmed within the *Gammaproteobacteria* and the monophyletic lineage of the genus *Xanthomonas* demonstrated (Moore et al., 1997). In this analysis, a core set of species was found to be closely related; *X. axonopodis* pathovar *axonopodis*, *X. campestris* pathovar *campestris*, *X. fragariae*, *X. populi* pathovar *populi*, and *X. oryzae* pathovar *oryzae* all clustered together, with *X. albilineans* more distant. A high degree of homogeneity was evident within the genus, and indeed *S. maltophilia* was found to share 95–97% sequence similarity with the xanthomonads studied here. In a subsequent, more detailed study by Hauben et al. (1997), similar findings were presented. The mean similarity value derived from the comparison of 16S rDNA sequence data from 46 xanthomonads, including 20 type strains, was found to be 98.2%. The genus was recovered in three clusters, one of which contained *X. albilineans*, *X. hyacinthi*, *X. theicola*, and *X. translucens*, while the second contained *X. sacchari*, and the remaining cluster the "core" species of the genus. In addition, *S. maltophilia*, although closely related to *Xanthomonas*, was clearly distinct. This finding, and similar results reported by Moore et al. (1997), was in keeping with an earlier study of restriction maps of the 16S rRNA gene, which demonstrated that the genera *Stenotrophomonas* and *Xanthomonas* were closely related, sharing 69 restriction sites, though a number of sites specific to *Stenotrophomonas* gave indications of the distinctiveness of the genera (Nesme et al., 1995).

Pathovars Within the genus *Xanthomonas*, it has long been known that *X. campestris*, with its many pathovars, was heterogeneous. Some pathovars are very similar; others show clear distinctions in phenotype and genotype, especially when sensitive methods are used. DNA–DNA hybridization studies of 54 pathovars then considered to belong to *X. campestris* indicated six groups and four ungrouped pathovars (Hildebrand et al., 1990; Vauterin et al., 1990; Palleroni et al., 1993). Extending these studies with more strains confirmed the six groups and added 14 more, to make 20 genomic species in the genus as a whole (Vauterin et al., 1995). Four of these equate to the existing species *X. albilineans*, *X. fragariae*, *X. oryzae*, and *X. populi*. The remaining 16 are derived from the heterogeneous *X. campestris*. Rather surprisingly, Vauterin et al. (1995) found that the phenotypically distinct species *X. axonopodis*, as studied by classical methods, belongs to the largest DNA hybridization group, which therefore takes its name. In the case of the latter, the emended species was found to encompass 37 pathovars, together with a further 11 included based on a previous study by Palleroni et al. (1993). In a similar way, *X. campestris* pathovar *plantaginis* has been added to the six pathovars in the emended description of *X. campestris*, and pathovar *carotae* and pathovar *taraxaci* added to the three already in *X. hortorum*. The inclusion of these pathovars on the basis of previously collected results is open to debate, as Vauterin et al. employed spectrophotometric determination of renaturation rates to measure DNA hybridization values (De Ley et al., 1970), whilst Palleroni et al. used an S1 nuclease radiolabeling procedure (Hildebrand et al., 1990). In addition, in the study of Palleroni et al., some of the individual reassociation values reported were very low. The reassociation values reported for *X. axonopodis* pathovar *betlicola* did not exceed 43% to any other member of the species *X. axonopodis*, as defined by Vauterin et al. (1995), and average reassociation values for each of the other pathovars studied were seldom in excess of 50% to other members of the species. These findings, coupled with ambiguous results derived from fatty acid analysis (Yang et al., 1993d) and SDS-PAGE analysis of whole cell proteins (Vauterin et al., 1991), further call into question the assumptions made about these pre-

viously studied pathovars in the current treatment of the genus. Clearly, further study is required to confirm the species affiliations of the pathovars studied by Palleroni et al. (1993); for the purposes of this review, we have highlighted those concerned.

Subsequent to the recent treatment of the genus by Vauterin et al. (1995), the number of recognized pathovars within *X. axonopodis* was reduced, as some of them were considered invalid in terms of the Standards for Naming Pathovars (Dye et al., 1980) *viz*: *X. axonopodis* pathovar *aurantifolii* and *X. axonopodis* pathovar *citrumelo* (See Young et al., 1991b), and *X. axonopodis* pathovar *cassavae*, *X. axonopodis* pathovar *phaseoli* biovar fuscans and *X. axonopodis* pathovar *vesicatoria* (Young et al., 1996b). Similarly, *X. arboricola* pathovar *poinsettiicola*, *X. hortorum* pathovar *vitians*, *X. translucens* pathovar *hordei*, and *X. vasicola* pathovar *vasculorum*, all described by Vauterin et al. (1995), were also considered defective in terms of the Standards for Naming Pathovars and not included in the list of Young et al. (1996b). In the case of the latter, by invalidating *X. vasicola* pathovar *vasculorum*, the need to maintain *X. vasicola* pathovar *holcicola* is removed and the pathovar is reduced to a synonym of *X. vasicola*. The remaining pathovars are listed as *Pathovars Incertae Sedis*, together with all other pathovars not studied by Vauterin et al. (1995) under their names as pathovars of *X. campestris sensu lato*.

In conclusion, the complexity of the genus *Xanthomonas* is recognized and few would argue with Vauterin and Swings (1997) that the genus represents a continuum of genotypic and phenotypic diversity, albeit encompassing a number of distinctive taxa. The heterogeneity within *X. campestris sensu lato* was self-evident and much valuable information has been produced over the years to support this. This said, it is our opinion that the classification produced by Vauterin et al. (1995) and described below is unconvincing, especially for some of the more heterogenous taxa, such as *X. axonopodis*. The power and value of DNA hybridization data for bacterial taxonomy is well established, but when the groupings derived from this method are not conclusively backed up by other techniques such as 16S rRNA gene sequencing (Hauben et al., 1997), SDS-PAGE analysis of whole-cell proteins (Vauterin et al., 1991), fatty acids (Yang et al., 1993d; Vauterin et al., 1996b), and biochemical tests (Vauterin et al., 1995), which is particularly true for *X. axonopodis*, a classification driven by these data alone is weakened, as the method cannot be used in any practical sense to perform identifications. Diagnosticians with poor resources will have problems operating within the current system, even when the polyphasic methods concur, as classical phenotypic data are of marginal relevance. Polyphasic methods will only work for the four existing species of *Xanthomonas*, *viz*: *X. albilineans*, *X. fragariae*, *X. oryzae*, and *X. populi* (see Table BXII.γ.18), as the 16 recently proposed species were derived from *X. campestris sensu lato* and classical phenotypic tests were not included in their description (Vauterin et al., 1995). It should be recognized that many diagnosticians are currently identifying putative xanthomonads to the genus level, noting the diseased host and identifying straight to the pathovar level, paying little heed to the species affiliation. Clearly, this situation is unacceptable in the long term, and much work remains to be done to develop an alternative strategy for characterization within the genus *Xanthomonas*.

TABLE BXII.γ.18. Characteristics of some *Xanthomonas* species that can be determined by classical methods[a,b]

Characteristic	*X. albilineans*	*X. fragariae*	*X. oryzae*	*X. populi*
Mucoid growth on nutrient agar + 5% glucose	−	+	+	+
Hydrolysis of gelatin	D	+	−[c]	−

List of species of the genus Xanthomonas

1. **Xanthomonas campestris** (Pammel 1895) Dowson 1939, 190[AL] emend. Vauterin, Hoste, Kersters and Swings 1995, 484 (*"Bacillus campestris"* Pammel 1895, 130.)
cam.pes' tris. L. gen. n. *campestris* of a level field; also the specific epithet of *Brassica campestris*, a host plant.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The original isolates of this species caused a vascular disease of *Brassica* spp. Currently, the species includes a number of pathovars that cause diseases predominantly within the family Cruciferae. In general, pathovars are not distinguishable by phenotypic characterization and identification is reliant on knowledge of their hosts.

Seventeen strains isolated from host plants in the family Cruciferae fell into DNA hybridization group 15 with the type strain of *X. campestris* (Vauterin et al., 1995). The average DNA binding value within the group was 87% ± 7%. Analysis of strains by fatty acid methyl esters recovered the majority in Cluster 2 (Yang et al., 1993d), which also contains strains from *X. arboricola*, *X. axonopodis*, and *X. vesicatoria* (Table BXII.γ.19). Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in cluster 1 (Vauterin et al., 1991), though only strains from pathovar *campestris* were examined in this study. Metabolic activity on carbon compounds, as shown by Biolog GN microplates, clearly distinguishes 14 of the other 19 species, but not the remaining five *viz X. hortorum*, *X. arboricola*, *X. cassavae*, *X. axonopodis*, and *X. vasicola* (see Table BXII.γ.20). Laboratory identification of the species without complex apparatus and processes would seem to be uncertain.

In the following list of the seven currently acceptable pathovars of *X. campestris* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), names of host plants and their respective families are given. It should be noted that *X. campestris* pathovar *plantaginis* was not studied by Vauterin et al. (1995) and its inclusion in the species was based on the work of Palleroni et al. (1993). The validity of this action could be questioned, as DNA from this pathovar was not hybridized against the full range of pathovars covered in the study of Vauterin et al. and operational differences between the analyses may have occurred.

The mol% G + C of the DNA is: 65.8–66.6; 68.0–68.3 (T_m) for *Xanthomonas campestris* pathovar *incanae*.

Type strain: ATCC 33913, CFPB 2350, DSM 3586, ICMP 13, LMG 568, NCPPB 528.

GenBank accession number (16S rRNA): X95917.

a. **Xanthomonas campestris** *pathovar* **campestris** (Pammel 1895) Dowson 1939.

Hosts: *Brassica* spp., *Capsella bursa-pastoris*, *Lepidium sativum*, *Matthiola* spp., *Raphanus sativus*, *Amorica rusticana*, (fam. Cruciferae). The one report on *Boerhaavia erecta* (fam. Nyctaginaceae) seems doubtful and has not been confirmed.

Type strain: ATCC 33913, CFBP 2350; ICMP 13; LMG 568; NCPPB 528.

b. **Xanthomonas campestris** *pathovar* **aberrans** (Knösel 1961) Dye 1978.

Host: *Brassica oleracea* var. *botrytis*, (fam. Cruciferae).

Type strain: ICMP 4805, LMG 9037, NCPPB 2986.

c. **Xanthomonas campestris** *pathovar* **armoraciae** (McCulloch 1929) Dye 1978.

Hosts: *Armoracia rusticana*. By inoculation *Brassica oleracea* var. *botrytis*, *B. oleracea* var. *capitata* (fam. Cruciferae), *Phaseolus vulgaris* (fam. Leguminosae).

Type strain: ICMP 7, LMG 535, NCPPB 347.

d. **Xanthomonas campestris** *pathovar* **barbareae** (Burkholder 1941) Dye 1978.

Host: *Barbarea vulgaris* (fam. Cruciferae).

Type strain: ATCC 13460, ICMP 438, LMG 547, NCPPB 983.

e. **Xanthomonas campestris** *pathovar* **incanae** (Kendrick and Baker 1942) Dye 1978.

Host: *Matthiola incanae* (fam. Cruciferae).

Type strain: ATCC 13462, CFBP 2527, ICMP 574, LMG 7490, NCPPB 937.

f. **Xanthomonas campestris** *pathovar* **plantaginis** (Thornberry and Anderson 1937) Dye 1978.

Hosts: *Plantago* spp. (fam. Plantaginaceae).

Type strain: ATCC 23382, ICMP 1028, LMG 848, NCPPB 1061.

g. **Xanthomonas campestris** *pathovar* **raphani** (White 1930) Dye 1978.

Hosts: *Brassica* spp., *Raphanus sativus*, (fam. Cruciferae), *Capsicurn annuum*, *Lycopersicon esculentum*, *Nicotiana tabacum* (fam. Solanaceae).

Type strain: ATCC 49079, ICMP 1404, LMG 860, NCPPB 1946.

2. **Xanthomonas albilineans** (Ashby 1929) Dowson 1943, 11[AL] emend. van den Mooter and Swings 1990, 367 (*"Bacterium albilineans"* Ashby 1929, 135.)
al.bi.lin' e.ans. L. adj. *albus* white; L. part. adj. *lineans* striping; M.L. adj. *albilineans* white striping.

The characteristics are as described for the genus and as listed in Tables BXII.γ.18, BXII.γ.19, and BXII.γ.20. Causes leaf scald disease of sugar cane (*Saccharum officinarum*); other natural hosts include *Brachiaria piligera*, *Imperata cylindrica* var. *major*, *Paspalum conjugatum* (fam. Gramineae). Colonies are yellowish buff on Dye's YSP medium or similar sucrose-peptone media. Growth usually fails or is very poor on nutrient agar. Glutamate and methionine are required for growth. Esculin is hydrolyzed, but not starch.

[a]For symbols see standard definitions. Numbers in parentheses indicate the number of strains tested.

[b]Adapted from Vauterin et al. (1995).

[c]89% positive.

H_2S is not produced from peptone. The maximum sodium chloride tolerance is 0.5%. Maximum growth temperature is 37°C. Acid is produced within 21 days in Dye's medium C from glucose, sucrose, mannose, and xylose, but not from arabinose, fructose, trehalose, cellobiose, rhamnose, adonitol, mannitol, sorbitol, dulcitol, *meso*-inositol, salicin, inulin, or α-methylglucoside. Two strains isolated from the host plant *Saccharum officinarum* showed an average DNA binding value of 97% (Vauterin et al., 1995). The fatty acid methyl ester profile (Table BXII.γ.19) recovers the majority of strains studied in Cluster 31 of Yang et al. (1993d). Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins was unable to recover the strains in a single cluster, though the three strains included in this study showed greater similarity to each other than to any other xanthomonad examined (Vauterin et al. 1991). Metabolic activity on carbon compounds as shown by Biolog GN microplates is shown in Table BXII.γ.20.

Certain strains isolated from *Saccharum officinarum*, exclusively from Guadeloupe, were originally included in this species but are now encompassed within *X. sacchari*, as they are clearly distinct on the basis of DNA hybridization studies, fatty acids, and protein profiling.

The mol% G + C of the DNA is: 63.1–64.5 (Bd, T_m).

Type strain: ATCC 33915, CFBP 2523, ICMP 196, LMG 494, NCPPB 2969.

GenBank accession number (16S rRNA): X95918.

3. **Xanthomonas arboricola** Vauterin, Hoste, Kersters and Swings 1995, 484[VP]

ar.bo.ri' co.la. L. n. *arbor* a tree; L. suff. *-cola* dweller; M.L. adj. n. *arboricola* tree dweller.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause disease mainly in temperate trees, including hazelnut, walnut, and *Prunus* spp. In general, pathovars are not distinguishable by phenotypic characterization and identification is reliant on knowledge of their hosts. The species was recovered as DNA hybridization group 4 by Vauterin et al. (1995). The average DNA binding value within the group was 79% ± 15%. Three of the five pathovars were closely related, with hybridization values of 89%, and were distinguished from other strains by their quinate metabolism (Lee et al., 1992). *X. arboricola* pathovar *populi* and pathovar *poinsettiicola* were related to other group 4 pathovars at average DNA hybridization values of 57% and 68%, respectively, and ranged from 48 to 76%, indicating some lack of homogeneity in the species. Fatty acid methyl ester composition (Table BXII.γ.19) placed the strains in Cluster 2 of Yang et al. (1993d), a position shared by three pathovars of *X. axonopodis*, several pathovars of *X. campestris*, and *X. vesicatoria*. Subsequent analysis of fatty acid data demonstrated a high degree of homogeneity within the species (Vauterin et al., 1996b). Most strains were recovered in Cluster 7c by protein SDS-PAGE analysis (Vauterin et al., 1991), though some strains of *X. arboricola* pathovar *juglandis* were recovered in Cluster 2 and *X. arboricola* pathovar *poinsettiicola* LMG 5403 was unclustered in this study. Metabolic activity on various carbon sources, determined using GN microplates, distinguishes this species from 15 of the 20 in the genus (see Table BXII.γ.20), but distinction from *X. hortorum*, *X. cassavae*, *X. axonopodis*, *X. vasicola*, and *X. campestris* is not clear. Laboratory identification of the species without complex apparatus and processes would seem to be uncertain.

In the following list of currently acceptable pathovars of *X. arboricola* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), the synonyms, names of host plants, and their respective families are given. It should be noted that *X. campestris* pathovar *celebensis* was not studied by Vauterin et al. (1995) and its inclusion in this species was based on the work of Palleroni et al. (1993). The validity of this action could be questioned, as DNA from this pathovar was not hybridized against the full range of pathovars covered in the study of Vauterin et al. and operational differences between the analyses may have occurred.

The mol% G + C of the DNA is: 66.0–67.0 (T_m).

Type strain: ATCC 49083, ICMP 35, LMG 747, NCPPB 411.

GenBank accession number (16S rRNA): Y10757.

Additional Remarks: This is also the pathotype strain of *X. arboricola* pathovar *juglandis* (there being no *X. arboricola* pathovar *arboricola*).

a. **Xanthomonas arboricola** *pathovar* **celebensis** (Gäumann 1923) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *celebensis* (Gäumann 1923) Dye 1978.)

Hosts: *Musa* spp. (fam. Musaceae).

Type strain: ATCC 19045, ICMP 1488, LMG 677, NCPPB 1832.

b. **Xanthomonas arboricola** *pathovar* **corylina** (Miller, Bollen, Simmons, Gross and Barss 1940) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *corylina* (Miller, Bollen, Simmons, Gross and Barss 1940) Dye 1978.)

Hosts: *Corylus* spp. (fam. Betulaceae).

Type strain: ATCC 19313, CFBP 1159, ICMP 5726, LMG 689, NCPPB 935.

c. **Xanthomonas arboricola** *pathovar* **juglandis** (Pierce 1901) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *juglandis* (Pierce 1901) Dye 1978.)

Hosts: *Juglans* spp. (fam. Juglandaceae).

Type strain: ATCC 49083, CFBP 2528, ICMP 35, LMG 747, NCPPB 411.

d. **Xanthomonas arboricola** *pathovar* **populi** (ex de Kam 1984) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *populi* (ex de Kam 1984) Young, Bradbury, Davis, Dickey, Ercolani, Hayward and Vidaver 1991a.)

Hosts: *Populus* spp. (fam. Salicacae).

Type strain: ICMP 8923, LMG 12141.

e. **Xanthomonas arboricola** *pathovar* **pruni** (Smith 1903) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *pruni* (Smith 1903) Dye 1978.)

Hosts: *Prunus* spp., *Sorbus japonica* (fam. Rosaceae).

Type strain: ATCC 19316, CFBP 2535, ICMP 51, LMG 852, NCPPB 416.

4. **Xanthomonas axonopodis** Starr and Garcés 1950, 81[AL] emend. Vauterin, Hoste, Kersters and Swings 1995, 484 (*Xanthomonas axonoperis* (sic) Starr and Garcés 1950, 81.)

a.xo.no' po.dis. M.L. n. *Axonopus* generic name of a grass; M.L. gen. n. *axonopodis* of *Axonopus*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. As originally constituted, this species was slower growing and less metabolically active than *X. campestris*, from which it was clearly differentiated phenotypically. The emended description now includes isolates from a wide variety of host plants and *X. axonopodis* is the most heterogeneous species currently recognized in the genus. In general, pathovars are not distinguishable by phenotypic characterization and identification is reliant on knowledge of their hosts. The species was recovered as DNA hybridization group 9 by Vauterin et al. (1995). The average DNA binding value within the group was 77% ± 15%. The type strain of the species shows a mean DNA binding within the group of only 66%. *X. axonopodis* and *X. campestris* pathovar *vasculorum* type A were closely related and were assigned to Group 9 with an overall level of DNA hybridization of 58% with other strains of the group. The individual values ranged from 47 to 71%, indicating a lack of homogeneity in the group. Fatty acid methyl ester composition (Table BXII.γ.19) recovered the bulk of isolates in Cluster 1, but isolates were also found in Clusters 2, 4, 5, 15, 18, 21, 28, and 29, together with several pathovars belonging to different species, as currently described (Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a low homogeneity within the species (Vauterin et al., 1996b). Most isolates were recovered in Cluster 3 by protein SDS-PAGE analysis (Vauterin et al., 1991), alongside isolates of *X. cucurbitae.* Other isolates were recovered in clusters 5, 6, 8, 9, and a sizeable number were unclustered by this method. Metabolic activity on various carbon sources, determined using Biolog GN microplates, distinguishes this species from 10 others, but not from the remaining nine, *viz X. hortorum*, *X. arboricola*, *X. cassavae*, *X. oryzae*, *X. vasicola*, *X. melonis*, *X. vesicatoria*, *X. campestris*, and *X. translucens* (Table BXII.γ.20).

In the following list of currently acceptable pathovars of *X. axonopodis* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), the synonyms, names of host plants, and their respective families are given. It should be noted that *X. campestris* pathovar *betlicola*, *X. campestris* pathovar *biophyti*, *X. campestris* pathovar *fasicularis*, *X. campestris* pathovar *khayae*, *X. campestris* pathovar *maculifoliigardeniae*, *X. campestris* pathovar *martyniicola*, *X. campestris* pathovar *mehusii*, *X. campestris* pathovar *nakataecorchori*, *X. campestris* pathovar *pedalii*, *X. campestris* pathovar *physalidicola*, and *X. campestris* pathovar *punicae* were not studied by Vauterin et al., (1995) and their inclusion in this species was based on the work of Palleroni et al. (1993). The validity of this action could be questioned, as DNA from these pathovars were not hybridized against the full range of pathovars covered in the study of Vauterin et al. and operational differences between the analyses may have occurred.

The mol% G + C of the DNA is: 62.6–65 (Bd, T_m).

Type strain: ATCC 19312, ICMP 50, LMG 538, NCPPB 457.

GenBank accession number (16S rRNA): X95919.

a. **Xanthomonas axonopodis** *pathovar* **axonopodis** Starr and Garcés 1950.

Hosts: *Axonopus scoparius*, *A. micay*, *A. compressus*, and *A. affinis*. By inoculation, *Digitaria decumbens*, *Hypharrhenia rufa*, *Panicum* sp., and *Saccharum officinarum* (fam. Gramineae).

Type strain: ATCC 19312, ICMP 50, LMG 538, NCPPB 457.

b. **Xanthomonas axonopodis** *pathovar* **alfalfae** (Riker, Jones and Davis 1935) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *alfalfae* (Riker, Jones and Davis 1935) Dye 1978.)

Hosts: *Medicago sativa*, *Melilotus indica*, *Pisum sativum*, *Phaseolus vulgaris*, *Trigonella foenum-graecum* (fam. Leguminosae).

Type strain: ICMP 5718, LMG 497, NCPPB 2062.

c. **Xanthomonas axonopodis** *pathovar* **bauhiniae** (Padhya, Patel and Kotasthane 1965a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *bauhiniae* (Padhya, Patel and Kotasthane 1965a) Dye 1978.)

Host: *Bauhinia racemosa* (fam. Leguminosae).

Type strain: ICMP 5720, LMG 548, NCPPB 1335.

d. **Xanthomonas axonopodis** *pathovar* **begoniae** (Takimoto 1934) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *begoniae* (Takimoto 1934) Dye 1978.)

Host: *Begonia* spp. (fam. Begoniaceae).

Type strain: ATCC 49082, CFBP 2524, ICMP 194, LMG 7303, NCPPB 1926.

e. **Xanthomonas axonopodis** *pathovar* **betlicola** (Patel, Kulkarni and Dhande 1951b) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *betlicola* (Patel, Kulkarni and Dhande 1951b) Dye 1978.)

Hosts: *Piper betle*, *P. hookeri*, *P. longum* (fam. Piperaceae).

Type strain: ATCC 11677, ICMP 312, LMG 555, NCPPB 2972.

f. **Xanthomonas axonopodis** *pathovar* **biophyti** (Patel, Chauhan, Kotasthane and Desai 1969) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *biophyti* (Patel, Chauhan, Kotasthane and Desai 1969) Dye 1978.)

Host: *Biophytum sensitivum* (fam. Oxalidaceae).

Type strain: ICMP 2780, LMG 556, NCPPB 2228.

g. **Xanthomonas axonopodis** *pathovar* **cajani** (Kulkarni, Patel and Abhyankar 1950) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *cajani* (Kulkarni, Patel and Abhyankar 1950) Dye 1978.)

Host: *Cajanus cajan* (fam. Leguminosae).

Type strain: ATCC 11639, ICMP 444, LMG 558, NCPPB 573.

h. **Xanthomonas axonopodis** *pathovar* **cassiae** (Kulkarni, Patel and Dhande 1951) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *cassiae* (Kulkarni, Patel and Dhande 1951) Dye 1978.)

Hosts: *Cassia tora*, *C. occidentalis*, *Cicer arietinum*, *Pisum sativum* (fam. Leguminosae).

Type strain: ATCC 11638, ICMP 358, LMG 675, NCPPB 2973.

i. **Xanthomonas axonopodis** *pathovar* **citri** (Hasse 1915) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas citri* (ex Hasse 1915) Gabriel, Kingsley, Hunter and Gottwald 1989; *Xanthomonas campestris* pathovar *citri* (Hasse 1915) Dye 1978.)

Hosts: *Aegle marmelos*, *Atalantia* spp. *Balsamocitrus paniculata*, *Casimiroa edulis*, *Chaetospermum glutinosa*, *Citropsis*

schweinfurthii, *Citrus* spp. and hybrids, *Clausena lansium*, *Eremocitrus glauca*, *Evodia* spp. *Feronia* spp., *Feroniella* spp., *Fortunelia* spp., *Hesperethusa crenulata*, *Limonia* spp., *Melicope triphylla*, *Microcitrus* spp., *Murraya erotica*, *Paramigyna longipedunculata*, *Poncirrus trifoliata* and hybrids, *Severina buxifolia*, *Toddalia asiatica*, *Zanthoxylum* spp. (fam. Rutaceae).

Type strain: CFBP 2525, ICMP 24, LMG 682, NCPPB 409.

j. **Xanthomonas axonopodis** *pathovar* **clitoriae** (Pandit and Kulkarni 1979) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *clitoriae* (Pandit and Kulkarni 1979) Dye, Bradbury, Goto, Hayward, Lelliott and Schroth 1980.)

Host: *Clitoria biflora* (fam. Leguminosae).

Type strain: ICMP 6574, LMG 9045, NCPPB 3092.

k. **Xanthomonas axonopodis** *pathovar* **coracanae** (Desai, Thirumalachar and Patel 1965) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *coracanae* (Desai, Thirumalachar and Patel 1965) Dye 1978.)

Host: *Eleusine coracana* (fam. Gramineae).

Type strain: ICMP 5724, LMG 686; NCPPB 1786.

l. **Xanthomonas axonopodis** *pathovar* **cyamopsidis** (Patel, Dhande and Kulkarni 1953) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *cyamopsidis* (Patel, Dhande and Kulkarni 1953) Dye 1978.)

Host: *Cyamopsis tetragonoloba* (fam. Leguminosae).

Type strain: ICMP 616, LMG 691, NCPPB 637.

m. **Xanthomonas axonopodis** *pathovar* **desmodii** (Patel 1949) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *desmodii* (Patel 1949) Dye 1978.)

Host: *Desmodium diffusum* (fam. Leguminosae).

Type strain: ATCC 11640, ICMP 315, LMG 692, NCPPB 481.

n. **Xanthomonas axonopodis** *pathovar* **desmodiigangetici** (Patel and Moniz 1948) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *desmodiigangetici* (Patel and Moniz 1948) Dye 1978.)

Host: *Desmodium gangeticum* (fam. Leguminosae).

Type strain: ATCC 11671, ICMP 577, LMG 693, NCPPB 577.

o. **Xanthomonas axonopodis** *pathovar* **desmodiilaxiflori** (Pant and Kulkarni 1976a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *desmodiilaxiflori* (Pant and Kulkarni 1976a.)

Hosts: *Desmodium laxiflorum*, *Tamarindus indica* (fam. Leguminosae).

Type strain: ICMP 6502, LMG 9046, NCPPB 3086.

p. **Xanthomonas axonopodis** *pathovar* **desmodiirotundifolii** (Desai and Shah 1960) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *desmodiirotundifolii* (Desai and Shah 1960) Dye 1978.)

Host: *Desmodium rotundifolium* (fam. Leguminosae).

Type strain: ICMP 168, LMG 694, NCPPB 885).

q. **Xanthomonas axonopodis** *pathovar* **dieffenbachiae** (McCulloch and Pirone 1939) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *dieffenbachiae* (McCulloch and Pirone 1939) Dye 1978.)

Hosts: *Aglaonema robellinii*, *Anthurium andraeanum*, *Dieffenbachia* spp. (fam. Araceae), *Dracaena fragrans* (fam. Liliaceae).

Type strain: ICMP 5727, LMG 695, NCPPB 1833.

r. **Xanthomonas axonopodis** *pathovar* **erythrinae** (Patel, Kulkarni and Dhande 1952a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *erythrinae* (Patel, Kulkarni and Dhande 1952a) Dye 1978.)

Host: *Erythrina indica* (fam. Leguminosae).

Type strain: ATCC 11679, ICMP 446, LMG 698, NCPPB 578.

s. **Xanthomonas axonopodis** *pathovar* **fascicularis** (Patel and Kotasthane 1969b) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *fascicularis* (Patel and Kotasthane 1969b) Dye 1978.)

Host: *Corchorus fascicularis* (fam. Tiliaceae).

Type strain: ICMP 5731, LMG 9047, NCPPB 2230.

t. **Xanthomonas axonopodis** *pathovar* **glycines** (Nakano 1919) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *glycines* (Nakano 1919) Dye 1978.)

Hosts: *Brunnichia cirrhosa* (fam. Polygonaceae), *Dolichos uniflorus*, *Glycine* spp. *Phaseolus lunatus*, *P. vulgaris* (fam. Leguminosae).

Type strain: ATCC 43911, CFBP 2526, ICMP 5732, LMG 712, NCPPB 554.

u. **Xanthomonas axonopodis** *pathovar* **khayae** (Sabet 1959) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *khayae* (Sabet 1959) Dye 1978.)

Hosts: *Khaya senegalensis*, *K. grandifoliola* (fam. Meliaceae).

Type strain: ICMP 671, LMG 753, NCPPB 536.

v. **Xanthomonas axonopodis** *pathovar* **lespedezae** (Ayers, Lefebvre and Johnson 1939) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *lespedezae* (Ayers, Lefebvre and Johnson 1939) Dye 1978.)

Host: *Lespedeza* spp. (fam. Leguminosae).

Type strain: ATCC 13463, ICMP 439, LMG 757, NCPPB 993.

w. **Xanthomonas axonopodis** *pathovar* **maculifoliigardeniae** (Ark and Barrett 1946) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *maculifoliigardeniae* (Ark and Barrett 1946) Dye 1978.)

Hosts: *Gardenia* spp., *Ixora coccinea* (fam. Rubiaceae).

Type strain: CFBP 1155, ICMP 318, LMG 758, NCPPB 971.

x. **Xanthomonas axonopodis** *pathovar* **malvacearum** (Smith 1901) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *malvacearum* (Smith 1901) Dye 1978.)

Hosts: *Gossypium* spp., *Thespesia lambas* (fam. Malvaceae), *Ceiba pentandra* (fam. Bombacaceae).

Type strain: CFBP 2530, ICMP 5739, LMG 761, NCPPB 633.

y. **Xanthomonas axonopodis** *pathovar* **manihotis** (Bondar 1915) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *manihotis* (Bondar 1915) Dye 1978.)

Host: *Manihot* spp. (fam. Euphorbiaceae).

Type strain: ATCC 49073, CFBP 2603, ICMP 5741, LMG 773, NCPPB 1834.

z. **Xanthomonas axonopodis** *pathovar* **martyniicola** (Moniz and Patel 1958) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *martyniicola* (Moniz and Patel 1958) Dye 1978.)
Host: *Martynia diandra* (fam. Martyniaceae).
Type strain: ICMP 82, LMG 9049, NCPPB 1148.

aa. **Xanthomonas axonopodis** *pathovar* **melhusii** (Patel, Kulkarni and Dhande 1952a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *melhusii* (Patel, Kulkarni and Dhande 1952a) Dye 1978.)
Host: *Tectona grandis* (fam. Verbenaceae).
Type strain: ATCC 11644, ICMP 619, LMG 9050, NCPPB 994.

ab. **Xanthomonas axonopodis** *pathovar* **nakataecorchori** (Padhya and Patel 1963b) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *nakataecorchori* (Padhya and Patel 1963b) Dye 1978.)
Host: *Corchorus acutangulus* (fam. Tiliaceae).
Type strain: ICMP 5742, LMG 786, NCPPB 1337.

ac. **Xanthomonas axonopodis** *pathovar* **patelii** (Desai and Shah 1959) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *patelii* (Desai and Shah 1959) Dye 1978.)
Host: *Crotalaria juncea* (fam. Leguminosae).
Type strain: ICMP 167, LMG 811, NCPPB 840.

ad. **Xanthomonas axonopodis** *pathovar* **pedalii** (Patel and Jindal 1972) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *pedalii* (Patel and Jindal 1972) Dye 1978.)
Host: *Pedalium murex* (fam. Pedaliaceae).
Type strain: ICMP 3030, LMG 812, NCPPB 2368.

ae. **Xanthomonas axonopodis** *pathovar* **phaseoli** (Smith 1897) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas phaseoli* (ex Smith 1897) Gabriel, Kingsley, Hunter and Gottwald 1989; *Xanthomonas campestris* pathovar *phaseoli* (Smith 1897) Dye 1978.)
Hosts: *Lablab purpureus* (syn. *Dolichos lablab*), *Lupinus polyphyllus*, *Phaseolus lunatus*, *Phaseolus vulgaris* (fam. Leguminosae).
Type strain: ATCC 9563, CFBP 2534, ICMP 5834, LMG 7455, NCPPB 3035.

af. **Xanthomonas axonopodis** *pathovar* **phyllanthi** (Sabet, Ishag and Khalil 1969) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *phyllanthi* (Sabet, Ishag and Khalil 1969) Dye 1978.)
Host: *Phyllanthus niruri* (fam. Euphorbiaceae).
Type strain: ICMP 5745, LMG 844, NCPPB 2066.

ag. **Xanthomonas axonopodis** *pathovar* **physalidicola** (Goto and Okabe 1958) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *physalidicola* (Goto and Okabe 1958) Dye 1978.)
Host: *Physalis alkekengi* var. *francheti* (fam. Solanaceae).
Type strain: ATCC 49077, ICMP 586, LMG 845, NCPPB 761.

ah. **Xanthomonas axonopodis** *pathovar* **poinsettiicola** (Patel, Bhatt and Kulkarni 1951a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *poinsettiicola* (Patel, Bhatt and Kulkarni 1951a) Dye 1978.)
Hosts: *Euphorbia pulcherrima*, *E. milii*, *Manihot escutenta* (fam. Euphorbiaceae).
Type strain: ATCC 11643, ICMP 5779, LMG 849, NCPPB 581.

ai. **Xanthomonas axonopodis** *pathovar* **punicae** (Hingorani and Singh 1959) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *punicae* (Hingorani and Singh 1959) Dye 1978.)
Host: *Punica granatum* (fam. Punicaceae).
Type strain: ICMP 360, LMG 859, NCPPB 466.

aj. **Xanthomonas axonopodis** *pathovar* **rhynchosiae** (Sabet, Ishag and Khalil 1969) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *rhynchosiae* (Sabet, Ishag and Khalil 1969) Dye 1978.)
Hosts: *Lupinus termis*, *Mucuna pruriens* (syn. *Stizolobium alterrimum*), *Rhynchosia memnonia* (fam. Leguminosae).
Type strain: ICMP 5748, LMG 8021, NCPPB 1827.

ak. **Xanthomonas axonopodis** *pathovar* **ricini** (Yoshii and Takimoto 1928) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *ricini* (Yoshii and Takimoto 1928) Dye 1978.)
Host: *Ricinus communis* (fam. Euphorbiaceae).
Type strain: ATCC 19317, ICMP 5747, LMG 861, NCPPB 1063.

al. **Xanthomonas axonopodis** *pathovar* **sesbaniae** (Patel, Kulkarni and Dhande 1952b) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *sesbaniae* (Patel, Kulkarni and Dhande 1952b) Dye 1978.)
Host: *Sesbania aegyptiaca* (fam. Leguminosae).
Type strain: ATCC 11675, (ICMP 367, LMG 867, NCPPB 582.

am. **Xanthomonas axonopodis** *pathovar* **tamarindi** (Patel, Bhatt and Kulkarni 1951a) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *tamarindi* (Patel, Bhatt and Kulkarni 1951a) Dye 1978.)
Hosts: *Caesalpina sepiaria*, *Tamarindus indica* (fam. Leguminosae).
Type strain: ATCC 11673, ICMP 572, LMG 955, NCPPB 584.

an. **Xanthomonas axonopodis** *pathovar* **vasculorum** (Cobb 1893) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *vasculorum* (Cobb 1893) Dye 1978.)
Hosts: *Bambusa vulgaris*, *Brachiaria mutica*, *Coix lacryma-jobi*, *Panicum maximum*, *Pennisetum purpureum*, *Saccharum officinarum*, *Sorghum* spp., *Thysanolaena maxima*, *Zea mays* (fam. Gramineae), *Cocos nucifera*, *Dictyosperma alba* (fam. Palmae).
Type strain: ATCC 35938, CFBP 2602, ICMP 5757, LMG 901, NCPPB 796.

ao. **Xanthomonas axonopodis** *pathovar* **vignaeradiatae** (Sabet, Ishag and Khalil 1969) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *vignaeradiatae* (Sabet, Ishag and Khalil 1969) Dye 1978.)
Hosts: *Lablab purpureus* (syn. *Dolichos lablab*), *Vigna radiata* (fam. Leguminosae).
Type strain: ICMP 5759, LMG 936, NCPPB 2058.

ap. **Xanthomonas axonopodis** *pathovar* **vignicola** (Burkholder 1944) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *vignicola* (Burkholder 1944) Dye 1978.)

Hosts: *Phaseolus vulgaris*, *Vigna pubigera*, *V. unguiculata* (fam. Leguminosae).

Type strain: ATCC 11648, ICMP 333, LMG 8752, NCPPB 1838.

aq. **Xanthomonas axonopodis** *pathovar* **vitians** (Brown 1918) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *vitians* (Brown 1918) Dye 1978.)

Host: *Lactuca* spp. (fam. Compositae).

Type strain: ATCC 19320, CFBP 2538, ICMP 336, LMG 937, NCPPB 976.

Additional Remarks: This strain may originally have been inappropriately chosen as the pathotype strain (Vauterin et al., 1995).

5. **Xanthomonas bromi** Vauterin, Hoste, Kersters and Swings 1995, 485[VP]

bro′ mi. L. masc. gen. M.L. n. *Bromus* generic name for the bromegrass; M.L. gen. n. *bromi* of *Bromus*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates were all recovered from *Bromus* spp. (fam. Gramineae) and cause a wilting disease. Three strains studied were recovered in DNA hybridization group 7 (Vauterin et al., 1995). The average DNA binding value within the group was 88% ± 6%. The fatty acid methyl ester profile (Table BXII.γ.19) belongs to cluster 25 of Yang et al. (1993d), which only contains isolates from *Bromus* spp. Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). All *Bromus* isolates were recovered in Cluster 7 by protein SDS-PAGE analysis (Vauterin et al., 1992), distinct from other xanthomonads isolated from cereals and grasses. Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes the two strains studied from all other species within the genus (Table BXII.γ.20).

The mol% G + C of the DNA is: 65.6 (T_m).

Type strain: CFBP 1976, ICMP 12545, LMG 947.

GenBank accession number (16S rRNA): Y10764.

6. **Xanthomonas cassavae** (ex Wiehe and Dowson 1953) Vauterin, Hoste, Kersters and Swings 1995, 485[VP]

cas.sa′ vae. M.L. fem. gen. n. *Cassava* the English form of the flour made from *Manihot esculenta*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause leaf spotting and necrosis of *Manihot* spp. (fam. Euphorbiaceae). Of the five strains received as this pathogen and studied in DNA hybridization experiments (Vauterin et al., 1995), four, including the pathotype strain, showed an average DNA binding value of 94% ± 2%. The remaining strain showed binding at 87% with group 9 and was included in *X. axonopodis* as pathovar *cassavae.* The fatty acid methyl ester profile (Table BXII.γ.19) of the majority of strains studied belongs to Cluster 5 of Yang et al. (1993d). Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in cluster 5 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from 14 of the other 19 species, but not the remaining five *viz X. hortorum*, *X. arboricola*, *X. axonopodis*, *X. vesicatoria*, or *X. campestris* (Table BXII.γ.20).

The mol% G + C of the DNA is: 64.2–66.1 (T_m).

Type strain: ICMP 204, LMG 673, NCPPB 101.

GenBank accession number (16S rRNA): Y10762.

7. **Xanthomonas codiaei** Vauterin, Hoste, Kersters and Swings 1995, 485[VP]

co.di.ae′ i. M.L. neut. n. *codiaeum* generic name of croton; M.L. gen. n. *codiaei* of *Codiaeum*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause a wilt of *Codiaeum variegatum* (fam. Euphorbiaceae). Two of four strains of *X. campestris* pathovar *poinsettiicola* studied were recovered in DNA hybridization group 6 in the study of Vauterin et al. (1995), with an average DNA binding value of 99%. They were considered sufficiently distinct from the pathotype and from all other groups to be separated as a species. These strains were recovered in Cluster 2 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al. 1993d), alongside strains of *X. arboricola*, *X. axonopodis*, *X. campestris*, and *X. vesicatoria.* Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species, though it should be noted that only two strains were studied (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 3c (Vauterin et al. 1991), alongside *X. axonopodis* pathovar *alfalfae* and *X. axonopodis* pathovar *ricini.* Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (Table BXII.γ.20).

The mol% G + C of the DNA is: 66.3 (T_m).

Type strain: ICMP 9513, LMG 8678.

GenBank accession number (16S rRNA): Y10765.

8. **Xanthomonas cucurbitae** (ex Bryan 1926) Vauterin, Hoste, Kersters and Swings 1995, 485[VP]

cu.cur′ bit.ae. M.L. fem. n. *Cucurbita* generic name of squash; M.L. gen. n. *cucurbitae* of *Cucurbita*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause necrotic spots on leaves, and occasionally stems, petioles, and fruits of *Citrullus vulgaris*, *Cucumis sativus*, and *Cucurbita* spp. (fam. Cucurbitaceae). Two strains of *X. campestris* pathovar *cucurbitae* were recovered in DNA hybridization group 8 in the study of Vauterin et al. (1995), with an average DNA binding value of 88%. They were considered sufficiently distinct from all other groups to be separated as a species. These strains were recovered in Cluster 1 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d), alongside many strains of *X. axonopodis.* Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species, though it should be noted that only two strains were studied (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 10 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others, except *X. translucens* from which there are no clear differences (Table BXII.γ.20). The negative reaction with gentiobiose is particularly useful for diagnosis.

The mol% G + C of the DNA is: 66.1–66.8 (T_m).

Type strain: ICMP 2299, LMG 690, NCPPB 2597.

GenBank accession number (16S rRNA): Y10760.

9. **Xanthomonas fragariae** Kennedy and King 1962, 875[AL] emend. van den Mooter and Swings 1990, 367.
fra.gar' i.ae. M.L. n. *Fragaria* generic name of strawberry; M.L. gen. n. *fragariae* of *Fragaria*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.18, BXII.γ.19, and BXII.γ.20. The isolates cause leaf spot disease of *Fragaria* spp. (fam. Rosaceae). Two strains of *X. fragariae* studied were recovered in DNA hybridization group 1 in the study of Vauterin et al. (1995), with an average DNA binding value of 91%. These strains were recovered in Cluster 12 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 18 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (Table BXII.γ.20).

The mol% G + C of the DNA is: 62.6–63.3 (Bd, T_m).

Type strain: ATCC 33239, CFBP 2157, ICMP 5715, LMG 708, NCPPB 1469.

GenBank accession number (16S rRNA): X95920.

10. **Xanthomonas hortorum** Vauterin, Hoste, Kersters and Swings 1995, 485[VP]
hor.to' rum. L. gen. n. *hortorum* of gardens.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. In general, pathovars are not distinguishable by phenotypic characterization and identification is reliant on knowledge of their hosts. Six strains isolated from necrotic spots on a variety of plants, mainly on leaves, were recovered in DNA hybridization group 2 in the study of Vauterin et al. (1995), with an average DNA binding value of 92% ± 10%. These strains were recovered in Cluster 10 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d), though *X. campestris* pathovar *vitians* type B (LMG 938), now included in this species, was found to be loosely associated with Cluster 1. Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 7e (*X. hortorum* pathovar *hederae*) and 15 (*X. hortorum* pathovar *pelargonii*; Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from 14 of the other 19 species, but not the remaining five *viz X. arboricola*, *X. cassavae*, *X. axonopodis*, *X. vesicatoria*, and *X. campestris* (Table BXII.γ.20). Laboratory identification of the species without complex apparatus and processes would seem to be uncertain.

In the following list of currently acceptable pathovars of *X. hortorum* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), the synonyms, names of host plants, and their respective families are given. It should be noted that *X. campestris* pathovar *carotae* and *X. campestris* pathovar *taraxaci* were not studied by Vauterin et al. (1995) and their inclusion in this species was based on the work of Palleroni et al. (1993). The validity of this action could be questioned, as DNA from this pathovar was not hybridized against the full range of pathovars covered in the study of Vauterin et al. and operational differences between the analyses may have occurred.

The mol% G + C of the DNA is: 63.6–65.1 (T_m).

Type strain: ICMP 453, LMG 733, NCPPB 939.

GenBank accession number (16S rRNA): Y10759.

Additional Remarks: This is also the pathotype strain of *X. hortorum* pathovar *hederae* (there being no *X. hortorum* pathovar *hortorum*).

a. **Xanthomonas hortorum** *pathovar* **carotae** (Kendrick 1934) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *carotae* (Kendrick 1934) Dye 1978.)

Host: *Daucus carota* (fam. Umbelliferae).

Type strain: ICMP 5723, LMG 8646, NCPPB 1422.

Additional Remarks: This strain has been reported to be unsuitable as a pathotype strain (Young et al. 1991a).

b. **Xanthomonas hortorum** *pathovar* **hederae** (Arnaud 1920) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *hederae* (Arnaud 1920) Dye 1978.)

Host: *Hedera helix* (fam. Araliaceae).

Type strain: ICMP 453, LMG 733, NCPPB 939.

c. **Xanthomonas hortorum** *pathovar* **pelargonii** (Brown 1923) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *pelargonii* (Brown 1923) Dye 1978.)

Host: *Geranium* spp., *Pelargonium* spp. (fam. Geraniaceae).

Type strain: CFBP 2533, ICMP 4321, LMG 7314, NCPPB 2985.

d. **Xanthomonas hortorum** *pathovar* **taraxaci** (Niederhauser 1943) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *taraxaci* (Niederhauser 1943) Dye 1978.)

Host: *Taraxacum bicorne* (fam. Compositae).

Type strain: ATCC 19318, CFBP 410, ICMP 579, LMG 870, NCPPB 940.

11. **Xanthomonas hyacinthi** (ex Wakker 1883) Vauterin, Hoste, Kersters and Swings 1995, 486[VP]
hy.a.cin' thi. Gr. *hyakinthos* used as M.L. masc. n. *Hyacinthus* generic name; M.L. gen. n. *hyacinthi* of *Hyacinth*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause yellow leaf stripes and wilt in *Hyacinthus orientalis* (fam. Liliaceae). Three strains of *X. campestris* pathovar *hyacinthi* studied were recovered in DNA hybridization group 17 of Vauterin et al. (1995), with an average DNA binding value of 98% ± 2%. They were considered sufficiently distinct from all other groups to be separated as a species. These strains were recovered in Cluster 19 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 4 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (Table BXII.γ.20).

The mol% G + C of the DNA is: 69.2–69.3 (T_m).

Type strain: ATCC 19314, ICMP 189, LMG 739, NCPPB 599.

GenBank accession number (16S rRNA): Y10754.

12. **Xanthomonas melonis** Vauterin, Hoste, Kersters and Swings 1995, 486[VP]
me.lo′nis. L. fem. gen. n. *melonis* of melon.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause a soft rot of fruit of *Cucumis melo* (fam. Cucurbitaceae). Two strains of *X. campestris* pathovar *melonis* studied were recovered in DNA hybridization group 13 of Vauterin et al. (1995), with an average DNA binding value of 88%. They were considered sufficiently distinct from all other groups to be separated as a species. These strains were recovered in Cluster 4 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d), alongside strains of *X. axonopodis* pathovar *citri*, *X. campestris* pathovar *lantanae*, and *X. campestris* pathovar *viticola*, the latter two pathovars were not examined by Vauterin et al. (1995) and their exact taxonomic position is at present uncertain. Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 19 (Vauterin et al., 1991), alongside two strains of *X. campestris* pathovar *poinsettiicola*; the latter were not examined by Vauterin et al. (1995) and their exact taxonomic position is at present uncertain. Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others, except *X. axonopodis* (see Table BXII.γ.20).

The mol% G + C of the DNA is: 66.1 (T_m).

Type strain: ICMP 8682, LMG 8670, NCPPB 3434.

GenBank accession number (16S rRNA): Y10756.

13. **Xanthomonas oryzae** (ex Ishiyama 1922) Swings, van den Mooter, Vauterin, Hoste, Gillis, Mew and Kersters 1990, 309[VP] emend. van den Mooter and Swings 1990, 367.
o.ry′zae. M.L. gen. n. *Oryza* the generic name for rice; M.L. gen. n. *oryzae* of *Oryza*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.18, BXII.γ.19, and BXII.γ.20. The isolates cause blight and leaf streak of *Oryza* spp. (fam. Gramineae). Six strains of *X. campestris* pathovar *oryzae* and *X. campestris* pathovar *oryzicola* studied were recovered in DNA hybridization group 10 of Vauterin et al. (1995), with an average DNA binding value of 91% ± 7%. These strains were recovered in Cluster 22 (*X. oryzae* pathovar *oryzicola*) and 24 (*X. oryzae* pathovar *oryzae*) by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 14 (*X. oryzae* pathovar *oryzae*) and 15 (*X. oryzae* pathovar *oryzicola*) (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (see Table BXII.γ.20).

In the following list of currently acceptable pathovars of *X. oryzae* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), the synonyms, names of host plants, and their respective families are given.

The mol% G + C of the DNA is: 64.6–65 (T_m).

Type strain: YK9, ATCC 35933, CFBP 2532, ICMP 3125, LMG 5047, NCPPB 3002.

GenBank accession number (16S rRNA): X95921.

a. **Xanthomonas oryzae** *pathovar* **oryzae** (Ishiyama 1922) Swings, Van den Mooter, Vauterin, Hoste, Gillis, Mew and Kersters 1990 (*Xanthomonas campestris* pathovar *oryzae* (Ishiyama 1922) Dye 1978.)

Hosts: *Isachne globosa*, *Leersia* spp., *Leptochola* spp., *Oryza* spp., *O. sativa*, *Phalaris arundinaceae*, *Phragmites communis*, *Zizania aquatica* (fam. Gramineae).

Type strain: ATCC 35933, CFBP 2532, ICMP 3125, LMG 5047, NCPPB 3002.

b. **Xanthomonas oryzae** *pathovar* **oryzicola** (Fang, Ren, Chen, Chu, Faan and Wu 1957) Swings, Van den Mooter, Vauterin, Hoste, Gillis, Mew and Kersters 1990 (*Xanthomonas campestris* pathovar *oryzicola* (Fang, Ren, Chen, Chu, Faan and Wu 1957) Dye 1978.)

Hosts: *Oryza sativa*, *Oryza* spp., *Leersia hexandra* (weak) (fam. Gramineae).

Type strain: ATCC 49072, CFBP 2286, ICMP 5743, LMG 797, NCPPB 1585.

14. **Xanthomonas pisi** (ex Goto and Okabe 1958) Vauterin, Hoste, Kersters and Swings 1995, 486[VP]
pi′si. M.L. gen. n. *Pisum* genus of peas; M.L. gen. n. *pisi* of *Pisum*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause necrotic spots and rotting of *Pisum sativum* (fam. Leguminosae), and are strongly pectolytic, causing soft rot in vegetable tissue. The one strain of *X. campestris* pathovar *pisi* studied was recovered in DNA hybridization group 12 of Vauterin et al. (1995) and considered sufficiently distinct from all other groups to be separated as a species. This strain was distantly related to Cluster 1 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d), the latter encompassing many strains of *X. axonopodis*. As only one strain has been studied to date, no assessment of the homogeneity of this species can be made. SDS-PAGE analysis of total proteins could not cluster this strain with any other xanthomonad examined in this study (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (see Table BXII.γ.20). This is by far the most reactive species of *Xanthomonas*, being metabolically active on 70 out of the 95 carbon compounds on microplates (Vauterin et al., 1995). Especially useful diagnostically are the activities shown on *N*-acetyl-D-galactosamine, formate, D-galacturonate, *p*-hydroxyphenylacetate, glucuronamide, and thymidine, which are positive for *X. pisi* and negative for all other species studied.

The mol% G + C of the DNA is: 64.6 (T_m).

Type strain: ATCC 35939, ICMP 570, LMG 847, NCPPB 762.

GenBank accession number (16S rRNA): Y10758.

15. **Xanthomonas populi** (ex Ridé 1958) van den Mooter and Swings 1990, 367[VP]
po′pu.li. M.L. masc. n. *Populus* generic name of the poplar tree; M.L. n. *populi* of *Populus*.

The characteristics are as described for the genus and as listed in Tables BXII.γ.18, BXII.γ.19, and BXII.γ.20. In Dye's Medium C, acid was produced within 21 days from glucose, sucrose, mannose, galactose, trehalose, and fruc-

tose (Ridé and Ridé, 1978), but not from arabinose and cellobiose, which agrees with the results obtained from GN plates. Sodium chloride tolerance is low at 0.4–0.6%, and maximum growth temperature is the lowest in all xanthomonads at 27.5°C. Few of the cells in culture have a flagellum, but it can be detected by immunofluorescence. The isolates cause a weeping canker of poplar (*Populus* spp.) and all species in the sections *Aigeros*, *Deltoides*, *Tacamahaca*, *Leuce* (subsections *Albidae* and *Trepidae*) and their hybrids are susceptible (fam. Salicaceae). Three strains of *X. populi* studied were recovered in DNA hybridization group 3 of Vauterin et al. (1995), with an average DNA binding value of 96% ± 1%. These strains were recovered in Cluster 30 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a low internal homogeneity within the species, which may be due to poor or non-reproducible growth (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 13 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others. One of the least reactive species, it is unequivocally positive for only 10 compounds; these are glycogen, sucrose, D-trehalose, D-fructose, α-D-glucose, and maltose, as well as the four shown in Table BXII.γ.20.

The mol% G + C of the DNA is: 62–65 (T_m).

Type strain: ATCC 51165, ICMP 5816, LMG 5743, NCPPB 2959.

GenBank accession number (16S rRNA): X95922.

16. **Xanthomonas sacchari** Vauterin, Hoste, Kersters and Swings 1995, 486[VP]

sac′cha.ri. L. gen. n. *sacchari* from sugar.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates, all of which have been isolated from Guadeloupe, cause a disease of sugarcane (*Saccharum officinarum*; fam. Gramineae) very like leaf scald. Two strains studied were recovered in DNA hybridization group 19 of Vauterin et al. (1995), with an average DNA binding value of 98%. They were considered sufficiently distinct from *X. albilineans* and all other groups to be separated as a species. All six strains were recovered in Cluster 27 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). All Guadeloupe isolates were recovered in Cluster 6 by protein SDS-PAGE analysis (Vauterin et al., 1992), distinct from other xanthomonads from cereals and grasses, except for *X. campestris* pathovar *vasculorum* LMG 8285; the latter was not examined by Vauterin et al. (1995) and its exact taxonomic position is at present uncertain. Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (Table BXII.γ.20). Other clear results not shown in the table include metabolic activity on quinate and L-phenylalanine, which also distinguish this species from most others.

The mol% G + C of the DNA is: 68.5 (T_m).

Type strain: LMG 471.

GenBank accession number (16S rRNA): Y10766.

17. **Xanthomonas theicola** Vauterin, Hoste, Kersters and Swings 1995, 486[VP]

the.i′co.la. L. fem. gen. n. *Thea* the generic name for tea; L.v. *colere* to inhabit; M.L. adj. *theicola* living in tea.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause bacterial canker of tea (*Camellia sinensis*; fam. Theaceae). A strain of *X. campestris* pathovar *theicola* was recovered in DNA hybridization group 18 in the study of Vauterin et al. (1995), and considered sufficiently distinct from all other groups to be separated as a species. Three strains of the species were recovered in Cluster 20 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b), though only three strains were studied. SDS-PAGE analysis of total proteins placed strains in Cluster 16 (Vauterin et al., 1991). Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from all others (see Table BXII.γ.20). *X. theicola* differs for three or more compounds from 15 species, differs clearly for two compounds from *X. axonopodis*, and only for α-ketovalerate from *X. vasicola* and *X. translucens*.

The mol% G + C of the DNA is: 69.2 (T_m).

Type strain: ICMP 6774, LMG 8684.

GenBank accession number (16S rRNA): Y10763.

18. **Xanthomonas translucens** (ex Jones, Johnson and Reddy 1917) Vauterin, Hoste, Kersters and Swings 1995, 487[VP]

trans.lu′cens. L. v. *transluceo* to be translucent; L. part. adj. *translucens* being translucent.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause disease in various members of the family Gramineae. Twenty-three strains were recovered in DNA hybridization group 16 in the study of Vauterin et al. (1995), with an average DNA binding value of 78% ± 11%. These strains were recovered in three closely related clusters, Clusters 7, 8, and 9, by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al. 1993d). Subsequent analysis of fatty acid data demonstrated a relatively low level of internal homogeneity within the species (Vauterin et al., 1996b). All isolates were recovered in Cluster 1 by protein SDS-PAGE analysis of total proteins (Vauterin et al., 1992), distinct from other xanthomonads isolated from cereals and grasses. Metabolic activity on carbon compounds, determined using Biolog GN microplates, enables clear distinction from 14 of the species, although seven of these used only one C-compound for clear differentiation (see Table BXII.γ.20). The remaining five species, not clearly differentiated by any of the 95 compounds, were *X. cucurbitae*, *X. axonopodis*, *X. oryzae*, *X. vasicola*, and *X. vesicatoria*.

In the following list of currently acceptable pathovars of *X. translucens* and their pathotype strains (Vauterin et al., 1995; Young et al., 1996b), the synonyms, names of host plants, and their respective families are given.

The mol% G + C of the DNA is: 69.1–69.7 (T_m).

Type strain: ATCC 19319, ICMP 5752, LMG 876, NCPPB 973.

GenBank accession number (16S rRNA): X99299.

a. **Xanthomonas translucens** *pathovar* **translucens** (Jones, Johnson and Reddy 1917) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *hordei* (Hagborg 1942) Dye 1978) *Xanthomonas campestris* pathovar *translucens* (Jones, Johnson and Reddy 1917) Dye 1978.)

Hosts: *Hordeum* spp. and other cereals (fam. Gramineae).

Type strain: ATCC 19319, CFBP 2054, ICMP 5752, LMG 876, NCPPB 973.

b. **Xanthomonas translucens** *pathovar* **arrhenatheri** (Egli and Schmidt 1982) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *arrhenatheri* Egli and Schmidt 1982.)

Host: *Arrhenatherum elatius* (fam. Poaceae).

Type strain: ATCC 33803, CFBP 2056, ICMP 7727, LMG 727, NCPPB 3229.

c. **Xanthomonas translucens** *pathovar* **cerealis** (Hagborg 1942) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *cerealis* (Hagborg 1942) Dye 1978.)

Hosts: *Agropyron* spp., *Avena* spp., *Bromus* spp., *Hordeum* spp., *Secate cereale*, *Triticum* spp. (fam. Gramineae).

Type strain: CFBP 2541, ICMP 1409, LMG 679, NCPPB 1944.

d. **Xanthomonas translucens** *pathovar* **graminis** (Egli, Goto and Schmidt 1975) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *graminis* (Egli, Goto and Schmidt 1975) Dye 1978.)

Hosts: *Alopecurus pratensis*, *Dactylis glomerata*, *Festuca* spp., *Lolium multiflorum*, *L. perenne*, *Phleum pratense* (fam. Gramineae).

Type strain: ATCC 29091, CFBP 2053, ICMP 5733, LMG 726, NCPPB 2700.

e. **Xanthomonas translucens** *pathovar* **phlei** (Egli and Schmidt 1982) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *phlei* Egli and Schmidt 1982.)

Host: *Phleum pratense* (fam. Gramineae).

Type strain: ATCC 33805, CFBP 2062, ICMP 7725, LMG 730, NCPPB 3231.

f. **Xanthomonas translucens** *pathovar* **phleipratensis** (Wallin and Reddy 1945) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *phleipratensis* (Wallin and Reddy 1945) Dye 1978.)

Host: *Phleum pratense* (fam. Gramineae).

Type strain: CFBP 2540, ICMP 5744, LMG 843, NCPPB 1837.

g. **Xanthomonas translucens** *pathovar* **poae** (Egli and Schmidt 1982) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *poae* Egli and Schmidt 1982.)

Host: *Poa trivialis* (fam. Gramineae).

Type strain: ATCC 33804, CFBP 2057, ICMP 7726, LMG 728, NCPPB 3230.

h. **Xanthomonas translucens** *pathovar* **secalis** (Reddy, Godkin and Johnson 1924) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *secalis* (Reddy, Godkin and Johnson 1924) Dye 1978.)

Hosts: *Secale cereale*; *Hordeum* and *Triticurn* spp. may become artificially infected (fam. Gramineae).

Type strain: CFBP 2539, ICMP 5749, LMG 883, NCPPB 2822.

i. **Xanthomonas translucens** *pathovar* **undulosa** (Smith, Jones and Reddy 1919) Vauterin, Hoste, Kersters and Swings 1995 (*Xanthomonas campestris* pathovar *undulosa* (Smith, Jones and Reddy 1919) Dye 1978.)

Hosts: *Triticum* spp. (fam. Gramineae), *Secale cereale*, *Hordeum* spp. by inoculation.

Type strain: ATCC 35935, CFBP 2055, ICMP 5755, LMG 892, NCPPB 2821.

19. **Xanthomonas vasicola** Vauterin, Hoste, Kersters and Swings 1995, 487^{VP}

vas.i' co.la. L. neut. n. *vas* a vessel; M.L. a duct or vessel as in a vascular bundle; *cola* dwelling in; M.L. adj. (indecl.) *vasicola* living in vascular bundles.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause leaf streak of *Sorghum* spp. (fam. Gramineae), which may cover large areas and produce much bacterial exudate. Strains have also been found to cause a gummosis of sugar cane (*Saccharum officinarum*; fam. Gramineae). The three strains of *X. campestris* pathovar *holcicola* studied and three of the seven strains originally assigned to *X. campestris* pathovar *vasculorum* were recovered in Group 11, with an average DNA binding value of 90% ± 4%. As the remaining four strains of *X. campestris* pathovar *vasculorum*, including the pathotype strain, were quite different, Group 11 was considered a separate species and named *X. vasicola* (Vauterin et al., 1995). These strains were recovered in Cluster 21 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al., 1993d). Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). All isolates were recovered in Cluster 8 by protein SDS-PAGE analysis (Vauterin et al., 1992), distinct from other xanthomonads isolated from cereals and grasses. Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from 13 other *Xanthomonas* species, but no clear results distinguish it from the remaining six species *viz X. fragariae*, *X. arboricola*, *X. axonopodis*, *X. oryzae*, *X. vesicatoria*, and *X. translucens* (see Table BXII.γ.20).

Vauterin et al. (1995) proposed two pathovars, pathovar *holcicola* attacking *Sorghum* spp. and pathovar *vasculorum* attacking *Saccharum* sp.; however as no direct comparisons of their pathogenicity have been conducted, their status is uncertain.

The mol% G + C of the DNA is: 64.2 (T_m).

Type strain: ICMP 3103, LMG 736, NCPPB 2417.

GenBank accession number (16S rRNA): Y10755.

20. **Xanthomonas vesicatoria** (ex Doidge 1920) Vauterin, Hoste, Kersters and Swings 1995, 487^{VP}

ve.si.ca.to' ri.a. L. *vesica* a blister; M.L. adj. *vesicatorius* causing a blister.

The characteristics are as described for the genus and as listed in Tables BXII.γ.19 and BXII.γ.20. The isolates cause necrotic lesions on leaves, stems, fruit and other parts of *Capsicum* spp. and *Lycopersicon* spp. (fam. Solanaceae). The two strains of *X. campestris* pathovar *vesicatoria* type B studied were recovered in DNA hybridization group 14 of Vauterin et al. (1995), with an average DNA binding value of 99%, and were quite different from three pathovar *ve-*

sicatoria type A strains that fell into *X. axonopodis*. They were considered sufficiently distinct from all other groups to be separated as a species. These strains were recovered in Cluster 2 by fatty acid methyl ester analysis (Table BXII.γ.19; Yang et al. 1993d), alongside strains of *X. arboricola*, *X. axonopodis*, and *X. campestris*. Subsequent analysis of fatty acid data demonstrated a very high degree of internal homogeneity within the species (Vauterin et al., 1996b). SDS-PAGE analysis of total proteins placed strains in Cluster 7 (Vauterin et al., 1991), alongside strains of *X. arboricola* and *X. hortorum*. Metabolic activity on carbon compounds, determined using Biolog GN microplates, clearly distinguishes this species from 13 of the other *Xanthomonas* spp., but not from *X. hortorum*, *X. cassavae*, *X. axonopodis*, *X. vasicola*, or *X. translucens* (Table BXII.γ.20). The only clear methods to distinguish this species from *X. axonopodis* seem to be SDS-PAGE of cell proteins and DNA hybridization. More suitable phenotypic tests are needed. Because of the re-arrangement of the original taxon into two species, the host ranges of both need re-examination.

The mol% G + C of the DNA is: 65.6 (T_m).
Type strain: ICMP 63, LMG 911, NCPPB 422.
GenBank accession number (16S rRNA): Y10761.

*Species Incertae Sedis**

1. **Xanthomonas campestris** *pathovar* **alangii** (Padhya and Patel 1962) Dye 1978.
Host: *Alangium lamarckii* (fam. Alangiaceae).
Deposited strain: ICMP 5717, LMG 470; NCPPB 1336.

2. **Xanthomonas campestris** *pathovar* **amaranthicola** (Patel, Wankar and Kulkarni 1952c) Dye 1978.
Host: *Amaranthus* spp. (fam. Amaranthaceae).
Deposited strain: ATCC 11645, ICMP 441, LMG 498, NCPPB 570.

3. **Xanthomonas campestris** *pathovar* **amorphophalli** (Jindal, Patel and Singh 1972) Dye 1978.
Host: *Amorphophallus campanulatus* (fam. Araceae).
Deposited strain: ICMP 3033, LMG 499, NCPPB 2371.

4. **Xanthomonas campestris** *pathovar* **aracearum** (Berniac 1974) Dye 1978.
Host: *Xanthosoma sagittifolium* (fam. Araceae).
Deposited strain: ICMP 5381, LMG 532, NCPPB 2832.

5. **Xanthomonas campestris** *pathovar* **arecae** (Rao and Mohan 1970) Dye 1978.
Host: *Areca catechu* (fam. Palmaceae).
Deposited strain: ICMP 5719, LMG 533, NCPPB 2649.

6. **Xanthomonas campestris** *pathovar* **argemones** (Srinivasan, Patel and Thirumalachar 1961b) Dye 1978.
Host: *Argemone mexicana* (fam. Papaveraceae).
Deposited strain: ICMP 1617, LMG 534, NCPPB 1593.

7. **Xanthomonas campestris** *pathovar* **arracaciae** (Pereira, Paradella and Zagatto 1971) Dye 1978.
Host: *Arracacia xanthorrhiza* (fam. Umbelliferae).
Deposited strain: ICMP 3158, LMG 536, NCPPB 2436.

8. **Xanthomonas campestris** *pathovar* **asclepiadis** Flynn and Vidaver 1995.
Host: *Asclepias* spp. (fam. Asclepiadaceae).
Deposited strain: ICMP 10007.

9. **Xanthomonas campestris** *pathovar* **azadirachtae** (Desai, Gandhi, Patel and Kotasthane 1966) Dye 1978.
Host: *Azadirachta indica* (fam. Meliaceae).
Deposited strain: ICMP 3102, LMG 543, NCPPB 2388.

10. **Xanthomonas campestris** *pathovar* **badrii** (Patel, Kulkarni and Dhande 1950) Dye 1978.
Hosts: *Xanthium strumarium* (fam. Compositae), *Pisum sativum* (fam. Leguminosae).
Deposited strain: ATCC 11672, ICMP 571, LMG 546, NCPPB 571.

11. **Xanthomonas campestris** *pathovar* **betae** Robbs, Kimura and Ribeiro 1981.
Host: *Beta vulgaris* (fam. Chenopodiaceae).
Deposited strain: ICMP 8917, LMG 9040, NCPPB 2592.

12. **Xanthomonas campestris** *pathovar* **bilvae** Chakravarti, Sarma, Jain and Prasad 1984.
Host: *Aegle marmelos* (fam. Rutaceae).
Deposited strain: ICMP 8918, NCPPB 3213.

13. **Xanthomonas campestris** *pathovar* **blepharidis** (Srinivasan and Patel 1956) Dye 1978.
Hosts: *Blepharis boerhaavifolia*, *B. molluginifolia* (fam. Acanthaceae).
Deposited strain: ATCC 17995, ICMP 5722, LMG 557, NCPPB 1757.

14. **Xanthomonas campestris** *pathovar* **boerhaaviae** (Mathur, Swarup and Sinha 1964) Bradbury 1986.
Host: *Boerhaavia repens* (fam. Nyctaginaceae).
Deposited strain: ICMP 9423, LMG 9041, NCPPB 1612.

15. **Xanthomonas campestris** *pathovar* **brunneivaginae** (Luo, Liao and Chen 1988) Young, Saddler, Takikawa, De Boer, Vauterin, Gardan, Gvozdyak and Stead 1996b.
Host: *Oryza sativa* (fam. Gramineae).
Deposited strain: ICMP 9991.

16. **Xanthomonas campestris** *pathovar* **cannabis** Severin 1978.
Host: *Cannabis sativa* (fam. Moraceae).
Deposited strain: ICMP 6570, LMG 9042, NCPPB 2877.

17. **Xanthomonas campestris** *pathovar* **cannae** Easwaramurthy, Kaviyarasan and Gnanamanickam 1984.
Host: *Canna generalis* (fam. Cannaceae).
Deposited strain: ICMP 8306, LMG 9043.

18. **Xanthomonas campestris** *pathovar* **carissae** (Moniz, Sabley and More 1964) Dye 1978.
Hosts: *Carissa congesta*, *C. carandas*, *Thevetia nerifolia* (fam. Apocynaceae), *Cestrum nocturnum* (fam. Solanaceae).
Deposited strain: ICMP 3034, LMG 669, NCPPB 2373.

19. **Xanthomonas campestris** *pathovar* **centellae** Basnyat and Kulkarni 1979.
Host: *Centella asiatica* (fam. Umbelliferae).
Deposited strain: ICMP 6746, LMG 9044, NCPPB 3245.

20. **Xanthomonas campestris** *pathovar* **clerodendri** (Patel, Kulkarni and Dhande 1952b) Dye 1978.
Host: *Clerodendron phlomoides* (fam. Verbenaceae).

**Editorial Note:* The following pathovars of *X. campestris* were not examined by Vauterin et al. (1995), and their exact taxonomic position is uncertain.

Deposited strain: ATCC 11676, ICMP 445, LMG 684, NCPPB 575.

21. **Xanthomonas campestris** *pathovar* **convolvuli** (Nagarkoti, Banerjee and Swarup 1973) Dye 1978.
Host: *Convolvulus arvensis* (fam. Convolvulaceae).
Deposited strain: ICMP 5380, LMG 685, NCPPB 2498.

22. **Xanthomonas campestris** *pathovar* **coriandri** (Srinivasan, Patel and Thirumalachar 1961a) Dye 1978.
Hosts: *Coriandrum sativum*, *Foeniculum vulgare* (fam. Umbelliferae).
Deposited strain: ATCC 17996, ICMP 5725, LMG 687, NCPPB 1758.

23. **Xanthomonas campestris** *pathovar* **daturae** (Jain, Dange and Siradhana 1975) Bradbury 1986.
Host: *Datura metel* (fam. Solanaceae).
Deposited strain: ICMP 12546, NCPPB 2932.

24. **Xanthomonas campestris** *pathovar* **durantae** (Srinivasan and Patel 1957) Dye 1978.
Host: *Duranta repens* (fam. Verbenaceae).
Deposited strain: ICMP 5728, LMG 696, NCPPB 1456.

25. **Xanthomonas campestris** *pathovar* **esculenti** (Rangaswami and Easwaran 1962) Dye 1978.
Host: *Hibiscus esculentus* (fam. Malvaceae).
Deposited strain: ICMP 5729, LMG 699, NCPPB 2190.

26. **Xanthomonas campestris** *pathovar* **eucalypti** (Truman 1974) Dye 1978.
Hosts: *Eucalyptus citriodora*, *E. maculata* (fam. Myrtaceae).
Deposited strain: ICMP 5382, LMG 700, NCPPB 2337.

27. **Xanthomonas campestris** *pathovar* **euphorbiae** (Sabet, Ishag and Khalil 1969) Dye 1978.
Host: *Eurphorbia acalyphoides* (fam. Euphorbiaceae).
Deposited strain: ICMP 5730, LMG 863, NCPPB 1828.

28. **Xanthomonas campestris** *pathovar* **fici** (Cavara 1905) Dye 1978.
Host: *Ficus religiosa* (fam. Moraceae).
Deposited strain: ICMP 3036, LMG 701, NCPPB 2372.

29. **Xanthomonas campestris** *pathovar* **guizotiae** (Yirgou 1964) Dye 1978.
Host: *Guizotia abyssinica* (fam. Compositae).
Deposited strain: ICMP 5734, LMG 731, NCPPB 1932.

30. **Xanthomonas campestris** *pathovar* **gummisudans** (McCulloch 1924) Dye 1978.
Host: *Gladiolus* sp. (fam. Iridaceae).
Deposited strain: ICMP 5780, LMG 732, NCPPB 2182.

31. **Xanthomonas campestris** *pathovar* **heliotropii** (Sabet, Ishag and Khalil 1969) Dye 1978.
Hosts: *Heliotropium aegypticum*, *H. sudanicum* (fam. Boraginaceae).
Deposited strain: ICMP 5778, LMG 735, NCPPB 2057.

32. **Xanthomonas campestris** *pathovar* **ionidii** (Padhya and Patel 1963a) Dye 1978.
Host: *Ionidium heterophyllum* (fam. Violaceae).
Deposited strain: ICMP 5736, LMG 744, NCPPB 1334.

33. **Xanthomonas campestris** *pathovar* **lantanae** (Srinivasan and Patel 1957) Dye 1978.
Host: *Lantana camara* var. *aculeata* (fam. Verbenaceae).
Deposited strain: ICMP 5737, LMG 754, NCPPB 1455.

34. **Xanthomonas campestris** *pathovar* **laureliae** (Dye 1963a) Dye 1978.
Host: *Laurelia novae-zelandiae* (fam. Monimiaceae).
Deposited strain: ICMP 84, LMG 755, NCPPB 1155.

35. **Xanthomonas campestris** *pathovar* **lawsoniae** (Patel, Bhatt and Kulkarni 1951a) Dye 1978.
Host: *Lawsonia alba* (fam. Lythraceae).
Deposited strain: ATCC 11674, ICMP 319, LMG 756, NCPPB 579.

36. **Xanthomonas campestris** *pathovar* **leeana** (Patel and Kotasthane 1969a) Dye 1978.
Host: *Leea edgeworthii* (fam. Vitaceae).
Deposited strain: ICMP 5738, LMG 9048, NCPPB 2229.

37. **Xanthomonas campestris** *pathovar* **leersiae** (ex Fang, Ren, Chen, Chu, Faan and Wu 1957) Young, Bradbury, Davis, Dickey, Ercolani, Hayward and Vidaver 1991a.
Host: *Leersia hexandra* (fam. Gramineae).
Deposited strain: ICMP 8788.

38. **Xanthomonas campestris** *pathovar* **malloti** Goto 1993.
Host: *Mallotus japonicus* (fam. Euphorbiaceae).
Deposited strain: ATCC 51262, ICMP 11536.

39. **Xanthomonas campestris** *pathovar* **mangiferaeindicae** (Patel, Moniz and Kulkarni 1948) Robbs, Ribeiro and Kimura 1974.
Hosts: *Anacardium occidentale*, *Mangifera indica*, *Spondias mangifera* (fam. Anacardiaceae).
Deposited strain: ATCC 11637, CFBP 1716, ICMP 5740, LMG 941, NCPPB 490.

40. **Xanthomonas campestris** *pathovar* **merremiae** (Pant and Kulkarni 1976b) Dye, Bradbury, Goto, Hayward, Lelliott and Schroth 1980.
Host: *Merremia gangetica* (fam. Convolvulaceae).
Deposited strain: ICMP 6747, LMG 9051, NCPPB 3114.

41. **Xanthomonas campestris** *pathovar* **mirabilis** (Durgapal and Trivedi 1976) Young, Bradbury, Davis, Dickey, Ercolani, Hayward and Vidaver 1991a.
Host: *Mirabilis jalapa* (fam. Nyctaginaceae).
Deposited strain: ICMP 8949.

42. **Xanthomonas campestris** *pathovar* **musacearum** (Yirgou and Bradbury 1968) Dye 1978.
Hosts: *Ensete ventricosum*, *Musa* spp. (fam. Musaceae).
Deposited strain: ATCC 49084, ICMP 2870, LMG 785, NCPPB 2005.

43. **Xanthomonas campestris** *pathovar* **nigromaculans** (Takimoto 1927) Dye 1978.
Host: *Arctium lappa* (fam. Compositae).
Deposited strain: ATCC 23390, ICMP 80, LMG 787, NCPPB 1935.

44. **Xanthomonas campestris** *pathovar* **obscurae** Chand and Singh 1994.
Host: *Ipomoea obscura* (fam. Convolvulaceae).
Deposited strain: ICMP 12547, NCPPB 3759 (incorrectly reported as NCPPB 3359 in Chand and Singh 1994).

45. **Xanthomonas campestris** *pathovar* **olitorii** (Sabet 1957) Dye 1978.
Host: *Corchorus olitorius* (fam. Tiliaceae).
Deposited strain: ICMP 359, LMG 9052, NCPPB 464.

46. **Xanthomonas campestris** *pathovar* **papavericola** (Bryan and McWhorter 1930) Dye 1978.
   Hosts: *Argemone mexicana*, *Eschscholzia californica*, *Meconopsis baileyi*, *Papaver* spp. (fam. Papaveraceae).
   Deposited strain: ATCC 14179, ICMP 220, LMG 809, NCPPB 2970.

47. **Xanthomonas campestris** *pathovar* **parthenii** Chand, Singh, Singh and Singh 1995.
   Host: *Parthenium hysteriphorus* (fam. Compositae).
   Deposited strain: ICMP 12476, NCPPB 3888.

48. **Xanthomonas campestris** *pathovar* **passiflorae** (Pereira 1969) Dye 1978.
   Host: *Passiflora edulis* (fam. Passifloraceae).
   Deposited strain: ICMP 3151, LMG 810, NCPPB 2346.

49. **Xanthomonas campestris** *pathovar* **paulliniae** Robbs, Medeiros and Kimura 1982.
   Host: *Paullinia cupana* var. *sorbilis* (fam. Sapindaceae).
   Deposited strain: ICMP 8919, LMG 9053, NCPPB 3079.

50. **Xanthomonas campestris** *pathovar* **pennamericanum** Qhobela and Claflin 1988.
   Hosts: *Panicum milaceum*, *Pennisetum americanum* (fam. Gramineae).
   Deposited strain: ATCC 49152, ICMP 9627.

51. **Xanthomonas campestris** *pathovar* **phormiicola** (Takimoto 1933) Dye 1978.
   Host: *Phormium tenax* (fam. Agavaceae).
   Deposited strain: ICMP 4294, LMG 702, NCPPB 2983.

52. **Xanthomonas campestris** *pathovar* **physalidis** (Srinivasan, Patel and Thirumalachar 1962) Dye 1978.
   Hosts: *Physalis minima*, *P. peruviana* (fam. Solanaceae).
   Deposited strain: ATCC 17994, ICMP 5746, LMG 846, NCPPB 1756.

53. **Xanthomonas campestris** *pathovar* **sesami** (Sabet and Dowson 1960) Dye 1978.
   Host: *Sesamum orientale* (fam. Pedaliaceae).
   Deposited strain: ICMP 621, LMG 865, NCPPB 631.

54. **Xanthomonas campestris** *pathovar* **spermacoces** (Srinivasan and Patel 1956) Dye 1978.
   Host: *Spermacoce hispida* (fam. Rubiaceae).
   Deposited strain: ATCC 17998, ICMP 5751, LMG 868, NCPPB 1760.

55. **Xanthomonas campestris** *pathovar* **syngonii** Dickey and Zumoff 1987.
   Host: *Syngonium podophyllum* (fam. Araceae).
   Deposited strain: ICMP 9154, LMG 9055, NCPPB 3586.

56. **Xanthomonas campestris** *pathovar* **tardicrescens** (McCulloch 1937) Dye 1978.
   Hosts: *Belamcanda* sp., *Iris* spp. (fam. Iridaceae).
   Deposited strain: ICMP 4295, LMG 9056, NCPPB 2984.

57. **Xanthomonas campestris** *pathovar* **thespesiae** Patil and Kulkarni 1981.
   Host: *Thespesia populnea* (fam. Malvaceae).
   Deposited strain: ICMP 7466, LMG 9057.

58. **Xanthomonas campestris** *pathovar* **thirumalacharii** (Padhya and Patel 1964) Dye 1978.
   Host: *Triumfetta pilosa* (fam. Tiliaceae).
   Deposited strain: ATCC 23577, ICMP 5852, LMG 872, NCPPB 1452.

59. **Xanthomonas campestris** *pathovar* **tribuli** (Srinivasan and Patel 1956) Dye 1978.
   Host: *Tribulus terrestris* (fam. Zygophyllaceae).
   Deposited strain: ICMP 5753, LMG 873, NCPPB 1454.

60. **Xanthomonas campestris** *pathovar* **trichodesmae** (Patel, Kulkarni and Dhande 1952a) Dye 1978.
   Host: *Trichodesma zeylanicum* (fam. Boraginaceae).
   Deposited strain: ATCC 11678, ICMP 5754, LMG 874, NCPPB 585.

61. **Xanthomonas campestris** *pathovar* **uppalii** (Patel 1948) Dye 1978.
   Hosts: *Ipomoea muricata* (fam. Convolvulaceae), *Tropaeolum majus* (fam. Tropaeolaceae).
   Deposited strain: ATCC 11641, ICMP 5756, LMG 893, NCPPB 586.

62. **Xanthomonas campestris** *pathovar* **vernoniae** (Patel, Desai and Patel 1968) Dye 1978.
   Host: *Vernonia cinerea* (fam. Compositae).
   Deposited strain: ICMP 5758, LMG 9058, NCPPB 1787.

63. **Xanthomonas campestris** *pathovar* **viegasii** Robbs, Neto, Malavolta and Kimura 1989.
   Host: *Pachystachys lutea* (fam. Acanthaceae).
   Deposited strain: ICMP 9261.

64. **Xanthomonas campestris** *pathovar* **viticola** (Nayudu 1972) Dye 1978.
   Hosts: *Azadirachta indica* (fam. Meliaceae), *Phyllanthus maderaspatensis* (fam. Euphorbiaceae), *Vitis vinifera* (fam. Vitaceae).
   Deposited strain: ICMP 3867, LMG 965, NCPPB 2475.

65. **Xanthomonas campestris** *pathovar* **vitiscarnosae** (Moniz and Patel 1958) Dye 1978.
   Host: *Vitis carnosa* (fam. Vitaceae).
   Deposited strain: ICMP 90, LMG 939, NCPPB 1149.

   Host: *Zinnia elegans* (fam. Compositae).
   Deposited strain: ICMP 5762, LMG 8692, NCPPB 2439.

Genus II. **Frateuria** *Swings, Gillis, Kersters, De Vos, Gosselé and De Ley 1980, 555*[VP]

JEAN SWINGS AND MARTIN SIEVERS

Fra.teur' i.a. M.L. fem. n. *Frateuria* named after the late Joseph Frateur (1903–1974), eminent Belgian microbiologist.

Regular straight rods, 0.5–0.7 × 0.7–3.5 μm, occurring singly or in pairs. Gram negative. **Generally motile by polar flagella or nonmotile. Obligately aerobic.** Optimum temperature for growth 25–30°C. Colonies on mannitol–yeast extract–peptone (MYP) agar[1] are yellow to orange. On glucose–yeast extract–$CaCO_3$ (GYC) agar,[2] most strains produce a typical brown water-soluble pigment. Oxidase negative. Grows at pH 3.6. No nitrate reduction. Starch and gelatin are not hydrolyzed. H_2S is produced. Chemoorganotrophic. Acid is produced from ethanol and a number of carbon sources. On D-glucose and D-xylose, the pH drops below 4.0. From D-glucose, 2-keto-, and 2,5-diketogluconic acids are formed, but not 5-ketogluconic acid. No requirements for growth factors. Isolated from *Lilium auratum* and from the fruit of *Rubus parvifolius* (raspberry) in Japan.

The mol% G + C of the DNA is: 62–64 (T_m).

Type species: **Frateuria aurantia** Swings, Gillis, Kersters, De Vos, Gosselé and De Ley 1980, 555.

FURTHER DESCRIPTIVE INFORMATION

On GYC agar, cells of *Frateuria* appear mostly as rods, rarely as ovoids, never in chains. Some strains form filaments. Frateuria grows luxuriantly on this medium and forms typical dark coffee-brown colonies, which measure 2–5 mm in diameter with a dark center, and are glistening or rough, flat, or raised, and circular with a regular edge. The pigment also diffuses into the agar. Colonies on MYP agar are yellow to orange, glistening or rough, regular or irregular, highly convex, measuring 1–3 mm in diameter. All strains can be grown in a defined Hoyer medium[3] with ammonium sulfate as the sole nitrogen source and mannitol as the carbon source. Luxuriant growth is obtained when mixtures of amino acids are supplied instead of NH_4^+. Some strains grow in yeast extract broth or in peptone broth, but for routine cultivation of *Frateuria*, D-mannitol and D-glucose are incorporated in the media as carbon sources. In a mannitol–salts–vitamins medium[4], several single amino acids are used by *Frateuria* as sole nitrogen sources. L-Alanine, L-aspartic acid, L-glutamic acid, and L-proline are not utilized as carbon and nitrogen sources by *Frateuria*.

The following physiological tests are positive for all the strains: catalase, production of H_2S, ketogenesis on glycerol and on D-mannitol, and oxidation of DL-lactate to CO_2 and water. The following tests are universally negative: oxidase, reduction of nitrates, indole formation, gelatin hydrolysis, and oxidation of acetate.

Injected into apples or pears, *Frateuria* causes browning and rotting symptoms (Vanden Abeele et al., 1980).

Frateuria is able to grow and to degrade aniline at pH 4.0–7.0 (Aoki et al., 1984).

For growth on natural gas, co-cultures of *Methylococcus capsulatus* with *Frateuria aurantia* have been proposed. *Frateuria aurantia* consumes ethanol and acetate, both exometabolites of the underoxidation of the ethane (present in natural gas) by *Methylococcus capsulatus*. Both exometabolites inhibit the growth of *M. capsulatus* (Romanovskaya et al., 1992).

Frateuria strains produce the polyene antibiotics enacyloxin IIa, IIIa and IVa (Watanabe et al., 1992a, b, c).

1. Mannitol–yeast extract–peptone (MYP) agar has the following composition (g/l): mannitol, 25.0; yeast extract, 5.0; peptone, 3.0; and agar, 25.0.

2. Glucose–yeast extract–$CaCO_3$ (GYC) agar consists of (g/l): D-glucose, 50.0; yeast extract, 10.0; $CaCO_3$, 30.0; and agar, 25.0.

3. The Hoyer medium consists of (g/l): mannitol, 30.0; $(NH_4)_2SO_4$, 1.0; K_4HPO_4, 1.0; K_2HPO_4, 0.1; KH_2PO_4, 0.9; $MgSO_4 \cdot 7H_2O$, 0.25; and $FeCl_3$, 0.005.

4. The medium for testing utilization of L-amino acids as sole nitrogen sources consists of D-mannitol, 30.0 g; *d*-biotin, 0.001 g; Ca-D-pantothenate, 0.001 g; thiamine, 0.001 g; pyridoxal hydrochloride, 0.0015 g; niacin, 0.0015 g; riboflavin, 0.0015 g; *p*-aminobenzoic acid, 0.001 g; vitamin B_{12}, 0.001 g; folic acid, 0.001 g; salt solution A, 5 ml; salt solution B, 5 ml; L-amino acid, 1 g; in 1 liter of 0.2 M Tris-maleate buffer, pH 5.4. Salt solution A contains (g/l distilled water): KH_2PO_4, 10.0; and K_2HPO_4, 10.0. Salt solution B contains (g/l distilled water): $MgSO_4 \cdot 7H_2O$, 4.0; NaCl, 0.2; $FeSO_4 \cdot 7H_2O$, 2.0; $MnSO_4 \cdot H_2O$, 0.15.

TABLE BXII.γ.21. Characteristics differentiating the genera *Frateuria*, *Gluconobacter*, and *Acetobacter*[a]

Characteristics	*Frateuria*	*Gluconobacter*	*Acetobacter*
Flagellar arrangement in motile strains:			
Polar	+	+	−
Peritrichous	−	−	+
Overoxidation of ethanol	−	−	+
Oxidation of DL-lactate to CO_2 and H_2O	+	−	+
Oxidation of acetate to CO_2 and H_2O	−	−	+
Formation of brown water-soluble pigments on GYC agar	+[b]	−	−
Formation of H_2S	+	−	−

TABLE BXII.γ.22. Other characteristics of *Frateuria aurantia*[a]

Characteristic	Result or Reaction
Growth in 0.5% yeast extract broth or 0.5% peptone broth	d
Growth in Frateur's Hoyer medium with:	
Ethanol	–
Glucose	d
Mannitol	+
Growth in SM[b] containing 0.5–2% NaCl	d
Growth in SM at pH 3.6–8.1	+
Temperature range, growth in SM at:	
4°C	–
30–37°C	+
Ethanol tolerance, growth in SM containing:	
1% Ethanol	+
2–5% Ethanol	d
10% Ethanol	–
Glucose tolerance, growth in 0.5% yeast extract containing:	
20% Glucose	+
25–30% Glucose	d
35% Glucose	–
Tolerance to metals and dyes, growth in presence of:	
Malachite green, 0.001%; crystal violet, 0.0001%; brilliant green, 0.001%	+
$Cd(CH_3COO)_2 \cdot 2H_2O$, 0.01%; $CoSO_4 \cdot 7H_2O$, 0.01%	–
$HgCl_2$, 0.001%	+
CH_3COOTl	d
Vitamin requirements: *p*-aminobenzoic acid, thiamine, niacin, pantothenate	–
Final pH in D-glucose, D-xylose, or D-galactose media	4,5
Acid produced from: [c]	
Ethanol, D-ribose, D-mannose, *n*-propanol, *i*-inositol	+
m-Erythritol, D-arabinose[d], D-fructose, sucrose, *n*-butanol	d
Glycerol[d], L-rhamnose[d], L-sorbose, D-mannitol, sorbitol, D-cellobiose[d], D-lactose [d], maltose, raffinose, dextrin, starch, *n*-amyl alcohol	–
Carbon sources for growth: [e]	
Glycerol, *m*-erythritol, D-ribose, D-fructose, D-glucose, D-mannose, D-mannitol, D-sorbitol, L-arabinose, D-lyxose, L-lyxose, adonitol, *i*-inositol, acetate, glycerate, lactate	+
Ethanol, D-arabinose, D-xylose, L-rhamnose, D-galactose, L-sorbose, D-cellobiose, D-lactose, maltose, sucrose, raffinose, starch, methanol, ethanediol, L-arabitol, *m*-xylitol, oxalate, malonate, tartrate, malate, gluconate, dextrin	d
n-Propanol, dulcitol, formate, citrate	–
Amino acids as sole nitrogen source:	
Arginine, asparagine, glutamine, glutamate, isoleucine, leucine, phenylalanine	+
Alanine, aspartate, histidine, methionine, proline, serine, valine	d
Cysteine, glycine, lysine, threonine, tryptophan	–
Amino acids as sole carbon and nitrogen sources:[f]	
Alanine, aspartate, glutamate, proline	–
Antimicrobial agents (amount per disk):	
Bacitracin, 10 U; chloramphenicol, 30 μg; colistin sulfate, 10 μg; erythromycin, 10 μg; fusidic acid, 10 μg; gentamicin, 10 μg; lincomycin, 2 μg; methicillin, 10 μg; neomycin, 30 μg; nitrofurantoin, 200 μg; penicillin G, 10 U; polymyxin B, 300 U; sulfafurazole, 100 μg	R
Kanamycin, 30 μg; novobiocin, 30 μg; streptomycin, 10 μg; tetracycline, 30 μg	S
Ampicillin, 10 μg; cephaloridine, 25 μg; nalidixic acid, 30 μg	d
Catalase	+
Oxidase	–
Nitrate reduction, indole production, gelatin hydrolysis, change in litmus milk	–
Ferric chloride reaction on media containing:	
D-Glucose	d
D-Fructose	+
D-Galactose	–

[a]For symbols see standard definitions; R, resistant; S, susceptible.

[b]SM medium contains (g/l): D-glucose, 50.0; yeast extract, 5.0.

[c]Acid formation was tested in the following medium (g/l): yeast extract, 5.0; bromocresol purple, 0.02; carbon source, 10.0. A final pH below 5.9 was considered as positive for acid formation.

[d]After retesting, some corrections of our previous results (Swings et al., 1980) were necessary.

[e]Growth was tested on the following medium (g/l): carbon source, 3.0; yeast extract, 0.5; vitamin-free Casamino acids, 3.0; agar (Oxoid No. 1), 25.0.

[f]Frateur's Hoyer medium was employed, with D-mannitol omitted.

All known authentic *Frateuria* strains have been isolated in Japan.

Enrichment and Isolation Procedures

Yamada et al. (1976) used the following medium for the enrichment of *Frateuria* from raspberries (per liter of 10% potato extract): D-glucose, 10.0 g; ethanol, 5.0 ml; yeast extract, 5.0 g; peptone, 3.0 g; and acetic acid, 0.3 ml. The pH was 4.5 and the incubation temperature 30°C. Isolation of *Frateuria* is possible on a $CaCO_3$-containing medium, on which the colonies dissolve the $CaCO_3$ and thus are surrounded by a clear zone.

Maintenance Procedures

Originally *Frateuria* was grown and maintained on a medium containing (g/l of 20% potato extract): D-glucose, 5.0; glycerol, 15.0; yeast extract, 30.0; peptone, 20.0; and $CaCO_3$, 10.0. *Frateuria* can be maintained for five months at 4°C on slants of this medium contained in screw-capped vials. *Frateuria* survives lyophilization for many years.

Differentiation of the genus *Frateuria* from other genera

Frateuria resembles the genera of acetic acid bacteria in its ability to oxidize ethanol to acetic acid and to grow at pH 3.6. It resembles mostly *Gluconobacter* because of its polar flagellation; however, it oxidizes lactate, requires no vitamins, and does not produce 5-ketogluconic acid. *Acetobacter* differs from *Frateuria* by its peritrichous flagellation and its ability to oxidize acetate. *Frateuria* makes the ubiquinone Q8, whereas *Gluconobacter* possesses ubiquinone Q10 and *Acetobacter* possesses Q9 or Q10.

Frateuria can be easily distinguished from its phylogenetically nearest neighbors within the *Gammaproteobacteria* (*viz*, *Lysobacter*, *Stenotrophomonas*, *Xanthomonas*) using FAME analysis, in which it characteristically possesses $C_{12:0\ 2OH}$ and $C_{17:0\ cyclo}$ fatty acids, which are absent in *Lysobacter*, *Stenotrophomonas*, and *Xanthomonas*. The latter three genera typically display $C_{11:0\ iso}$, $C_{11:0\ iso\ 3OH}$, and $C_{15:0\ anteiso}$ fatty acids, which are absent in *Frateuria*. The presence of more than 50% $C_{15:0\ iso}$ fatty acid is characteristic for *Frateuria*.

Taxonomic Comments

When either phenotypic features or protein gel electrophoregrams of *Frateuria* strains are compared, a tight cluster is obtained, suggesting a high genetic resemblance among them. In the past, *"Acetobacter aurantius"* strains were considered as polarly flagellated acetic acid bacteria that were intermediate between *Acetobacter* and *Gluconobacter* (Asai, 1968). Yamada et al. (1976) already suspected that these strains form a separate new genus, mainly because of their typical ubiquinone Q8. The reclassification of these strains was performed by Swings et al. (1980).

DNA–rRNA hybridizations had already shown that *Frateuria* was not related to *Acetobacter* or to *Gluconobacter*, and did not belong in rRNA superfamily IV (*sensu* De Ley, 1978), of which the family *Acetobacteraceae* constitutes a separate branch (De Vos, 1980; Gillis and De Ley, 1980; Swings et al., 1980). 16S rDNA gene sequencing confirmed that *Frateuria* belongs in the *Gammaproteobacteria* (the former rRNA superfamily II *sensu* De Ley 1978). *Frateuria* is closely related to *Stenotrophomonas*, *Xanthomonas*, *Xylella*, and *Lysobacter*. 16S rRNA gene sequence similarity values of *F. aurantia* with the type strains of *Stenotrophomonas maltophilia*, *Xanthomonas campestris*, *Xylella fastidiosa*, and *Lysobacter enzymogenes* are 89.6%; 89.6%; 88.8%, and 88.8%, respectively. *Frateuria*, *Stenotrophomonas*, and *Xanthomonas* were shown to contain the polyamine spermidine (Hamana and Matsuzaki, 1993; Yang et al., 1993b).

Further Reading

Swings, J., M. Gillis, K. Kersters, P. De Vos, F. Gosselé and J. De Ley. 1980. *Frateuria*, a new genus for *"Acetobacter aurantius"*. Int. J. Syst. Bacteriol. *30*: 547–556.

List of species of the genus Frateuria

1. **Frateuria aurantia** Swings, Gillis, Kersters, De Vos, Gosselé and De Ley 1980, 555^VP^.
au.ran′ tia. L. v. *aurare* to overlay with gold; M.L. adj. *aurantius* gold colored, refers to the gold-yellow color of the strains on MYP agar.

The description of the species is as for the genus. See Tables BXII.γ.21 and BXII.γ.22 for additional characteristics.

Isolated from *Lilium auratum* and from the fruit of *Rubus parvifolius* in Japan.

The mol% G + C of the DNA is: 62–64 (T_m).

Type strain: IFO 3245, ATCC 33424, DSM 6220.

GenBank accession number (16S rRNA): AJ010481.

Genus III. **Luteimonas** *Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280[VP]*

André Lipski and Erko S. Stackebrandt

Lu.te.i.mo′ nas. M.L. adj. *luteus* yellow; Gr. n. *monas* a unit; M.L. fem. n. *Luteimonas* a yellow unit.

Rod-shaped cells 0.4–0.6 × 0.8–1.8 μm. Gram negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrite is reduced to nitrous oxide, but nitrate is not reduced. Colonies are yellow. Heterotrophic. Ubiquinone with eight isoprene units. **Iso-/anteiso-type fatty acid profile** with $C_{15:0\ iso}$ and $C_{17:1\ iso\ 9c}$ predominating. Isolated from several experimental biofilters supplied with the waste gas of an animal rendering plant.

The mol% G + C of the DNA is: 67.

Type species: **Luteimonas mephitis** Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280.

Enrichment and Isolation Procedures

All strains of the genus were isolated on thiosulfate agar from cultures for the enrichment of methyl-sulfide-degrading bacteria (Bendinger and Reichert, personal communication). However, the capability for sulfide degradation was not stable for the isolates of this genus and was lost during subcultivation (Reichert, personal communication).

Maintenance Procedures

Short-term maintenance on agar plates for several weeks at room temperature is acceptable. For long-term storage, preservation at below −70°C with 5% dimethylsulfoxide is recommended. Freezing at higher preservation temperatures results in rapid loss of viability.

Differentiation of the genus *Luteimonas* from other genera

The genus can be separated from the genera *Xanthomonas* and *Stenotrophomonas* by the absence of the fatty acid 3-hydroxy-isotridecanoic acid, and from the species *Xylella fastidiosa* by the

presence of branched-chain fatty acids. No gliding motility, which is a characteristic property of the genus *Lysobacter* (Christensen and Cook, 1978), was observed for the genus *Luteimonas*. Denitrification activity is absent in the genera *Xanthomonas*, *Stenotrophomonas*, *Xylella*, and *Lysobacter* (one *Lysobacter antibioticus* strain is positive), but present in the genus *Luteimonas*.

Taxonomic Comments

The genus is a deep-branching member of the *Xanthomonas* group of the *Gammaproteobacteria*. *Luteimonas mephitis* is remotely and approximately equidistantly related to members of *Xanthomonas*, *Pseudoxanthomonas*, *Xylella*, *Lysobacter*, and *Stenotrophomonas* (93–95% 16S rDNA similarity); members of *Schineria*, *Rhodanobacter*, *Frateuria*, and *Nevskia* are even more distantly related.

Using members of *Stenotrophomonas* as a root, analyses by RDP dendrogram (Maidak et al., 1997; De Soete, 1983), maximum-likelihood, and neighbor-joining (Felsenstein, 1993) place *Luteimonas mephitis* between *Lysobacter antibioticus* and the species *Rhodanobacter lindaniclasticus*, *Frateuria aurantia*, and *Nevskia ramosa*, which share a common ancestry with *L. mephitis*. *N. ramosa* is characterized by a significantly longer branch length than the other members of this phylogenetic cluster. Using the 16S rDNA sequence of *N. ramosa* as a root, *Frateuria aurantia* and *Rhodanobacter lindaniclasticus* are separated from *Luteimonas mephitis*, *Lysobacter antibioticus*, and members of *Xylella*, *Xanthomonas*, *Stenotrophomonas*, and *Pseudoxanthomonas*. Hence, the branching order of genera constituting the deeply branching lineages of the *Gammaproteobacteria* changes with the selection and number of sequences included in the analysis, and at present cannot be considered stable.

List of species of the genus Luteimonas

1. **Luteimonas mephitis** Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280[VP]
me.phi' tis. L. gen. fem. n. *mephitis* of harmful odor.

The characteristics are the same as those given for the genus and as listed in Table BXII.γ.23. The predominant compounds of the fatty acid profile are $C_{15:0\ iso}$, $C_{17:1\ iso\ \omega9c}$, and $C_{17:0\ iso}$. The major hydroxy fatty acid is $C_{11:0\ iso\ 3OH}$. The fatty acids $C_{17:0\ cyclo}$ and $C_{13:0\ iso\ 3OH}$ are absent. At the beginning of the stationary phase in liquid media, cells tended to clump, showing "trembling"-like behavior. Staining of flagella (Heimbrook et al., 1989) was negative. As cells from this growth phase also showed no evidence of flagella by electron microscopic observation, the type strain of *L. mephitis* is considered nonmotile. The strain showed no growth under anaerobic conditions on Caso agar (Becton Dickinson and Company, Cockeysville, MD, USA). No pathogenic activity toward humans, animals, or plants is known.

The mol% G + C of the DNA is: 67 (HPLC).
Type strain: B1953/27.1, DSM 12574.
GenBank accession number (16S rRNA): AJ012228.

Genus IV. **Lysobacter** *Christensen and Cook 1978, 372*[AL]

PENELOPE CHRISTENSEN

Lys.o.bac'ter. Gr. adj. *lysis* loosing; M.L. n. *bacter* equivalent of Gr. neut. n. *bactrum* a rod; M.L. masc. n. *Lysobacter* the loosing rod; intended to mean the lysing rod.

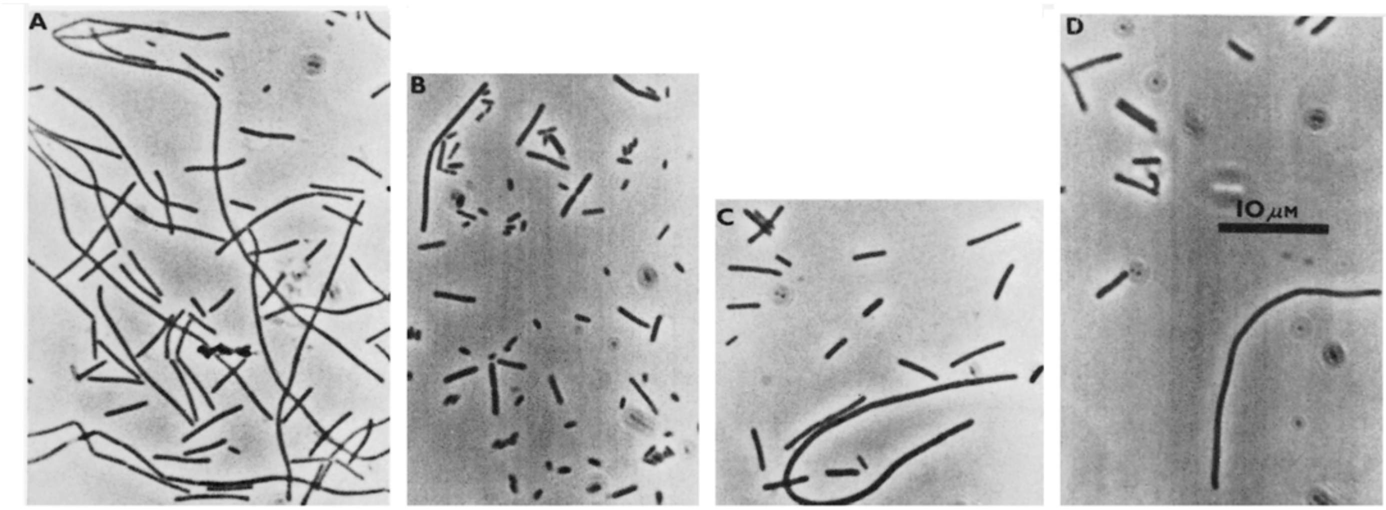
Thin rods, 0.2–0.5 × 1.0–15 (sometimes up to 70) μm, which are Gram negative, nonflagellated, **gliding, flexing,** and aerobic. **Colonies are highly mucoid, cream-colored, pink, or yellow-brown;** many strains also produce a brown, water-soluble **pigment**. **Nonfruiting; no microcysts** produced. Growth in broth culture is silky. Most strains are resistant to actinomycin D. This organism **degrades chitin** and often other polysaccharides, but it does not degrade filter-paper cellulose, and it infrequently degrades agar. Strongly proteolytic, characteristically **lysing a variety of microorganisms** (both Gram-negative and Gram-positive bacteria, including actinomycetes, blue-green and green algae, yeasts, and filamentous fungi), as well as nematodes. Habitat: soil and freshwater.

The mol% G + C of the DNA is: 65.4–70.1.

Type species: **Lysobacter enzymogenes** Christensen and Cook 1978, 374.

FURTHER DESCRIPTIVE INFORMATION

Thin, flexible, gliding, Gram-negative rods, 0.2–0.5 × 1.0–15 (sometimes up to 70) μm (Figs. BXII.γ.27, BXII.γ.28, and BXII.γ.29). Colonies are slimy or mucoid, with the rubbery type of *L. gummosus* being particularly difficult to handle, and may be white, cream-colored, yellow, pink, or brown; many strains also produce a brown, water-soluble pigment, especially in older cultures. The nature of *Lysobacter* pigments is not known, but they are not carotenoids or flexirubins (Reichenbach et al., 1981). Colonies of *L. brunescens* spread in the typical *"Cytophaga"* fashion, but those of *L. antibioticus* and *L. enzymogenes* are more mucoid, and it is believed that this quality conceals the typical spreading. All strains of the latter two species have been observed to produce a thin, advancing fringe of cells at colony edges on one or more media. However, *L. gummosus* has never been observed to spread, most likely due to both its shorter cells and the large amount of gum produced on every medium on which it has been grown.



Liquid cultures show a characteristic silkiness when gently tapped, a property correlated with the presence of longer cells. Silkiness is not often seen with *L. gummosus* cultures, which the heavy gum seems to preclude lengthy cells. Liquid cultures of all four species are somewhat viscous, and *L. gummosus* is so much so that a 2-d-old tube culture may be inverted without spillage.

Aerobic. Mesophilic. The optimum temperature for growth of these organisms is relatively high (20–40°C) as compared to most other soil and water organisms. pH range for growth: 5–10. Growth of most strains is reduced by 1% NaCl.

Chemoorganotrophic. Metabolism is usually respiratory; molecular oxygen is used as the terminal electron acceptor. NO_3^-, NH_4^+, glutamate, and asparaginate are used as sole nitrogen sources, but urea is used by only a few strains. In general, the addition of yeast extract to a salts–glucose–nitrate agar or to a chitin-only medium stimulates growth. Chitin, but not filter-paper cellulose or agar, is hydrolyzed; some species degrade alginate, pectate, starch, and/or carboxymethyl cellulose (CMC). One of the extracellular enzymes of *L. enzymogenes* strain ATCC 27796, previously known as "myxobacter Al-1", was the first enzyme with both β-1,4-gluconase and chitosanase activities to be described (Hedges and Wolfe, 1974). This enzyme attacks amorphous forms of cellulose such as CMC but does not attack crystalline cellulose. It was the first enzyme with chitosanase activity to be purified to homogeneity and could be useful for the characterization of fungal cell walls and as a tool for the classification of fungi. It has been shown to be capable of attacking some fungal cell walls to release glucosamine. The enzyme has a molecular weight of 28,900–31,000 Da and contains large amounts of the basic amino acids lysine and arginine among its 230 residues.

Strongly proteolytic. The enzymes of two strains of *L. enzymogenes* have been the subjects of intensive study. One strain, ATCC 27796, known formerly as "myxobacter AL-1," excretes a bacteriolytic enzyme, designated "AL-1 protease I", with a molecular weight of 14,300 and containing 136 amino acids. In contrast to many exocellular enzymes, this protein contains a disulfide bond, 1 mol hexose per mol protein, and a relatively high content of aromatic amino acids; the E_{280} of a 1% solution in a 1 cm cuvette is 15.8 (Jackson and Wolfe, 1968). This enzyme has been found to cleave the pentaglycine bridge in the cell wall of *Staphylococcus* and other bacteria and to remove peptide moieties from the peptidoglycan (Katz and Strominger, 1967; Tipper et al., 1967). ATCC 27796 also produces another extracellular protease ("AL-1 protease II"), which crystallizes as fine needles and has a molecular weight of 17,000 Da, with 157 amino acid residues (Wingard et al., 1972). This enzyme does not possess cell-wall lytic activity, and it has a unique specificity for lysine residues, exhibiting peptide bond cleavage on the amino side of lysine.

It was not realized at the time that the AL-1 protease reported by Jackson and Matsueda (1970) was from the same species of bacterium as the α-lytic protease described in the paper immediately following it in that publication (Whitaker, 1970). The "myxobacterium *Sorangium*"/"myxobacter 495" (now ATCC 29487) has since been classified as *L. enzymogenes*, and it was with this strain that Whitaker's group did the initial enzymological characterization of α- and β-lytic proteases (Whitaker, 1965, 1967; Whitaker et al., 1965a, b). The proteases of "495" (now ATCC 29487) have provided much fruitful work for biochemists interested in the three-dimensional structure of microbial proteases as compared with mammalian examples. Although the classification of the zinc-containing α-lytic protease is uncertain, β-lytic protease has been shown to be a serine protease with the active site amino acid sequence Asp–Ser–Gly (Whitaker et al., 1966; Whitaker and Roy, 1967). This is the same sequence as that of the mammalian pancreatic serine protease, and this enzyme was the first microbial serine protease isolated that is not a member of the Thr–Ser–Met family. The subsequent elucidation of the complete polypeptide sequence has shown 198 amino acids in a single polypeptide chain, which contains three intrachain disulfide bridges and has an overall molecular weight of 19,869 (Olson et al., 1970). In a 2.8-Å resolution crystallographic study of α-lytic protease, the three-dimensional structure of the enzyme has been determined, facilitating a detailed description of the active site. Comparisons with other microbial serine proteases (viz *Streptomyces griseus* proteases A and B) support the possibility that they arose from a common ancestral gene (Brayer et al., 1979). Sub-

sequent work has included further study of the active site and comparison with mammalian elastase (Bauer et al., 1981), investigation of the molecular structure at 1.8-Å resolution (M.N.G. James, personal communication), and D. Agard's isolation of the α-lytic protease gene, sequencing, and point-specific mutations (M.N.G. James, personal communication).

The nucleases of *L. enzymogenes* strain ATCC 29487 (formerly "myxobacter 495") have been characterized by von Tigerstrom (1980, 1981, 1983), with the two major ones being extracellular RNase and DNase. The RNase consists of one polypeptide chain with a molecular weight of 46,000–47,000 Da that is most active at pH 8.0–8.5 and in the presence of Mg^{2+}. The nonspecific nuclease has a molecular weight of 22,000–28,000 Da, is most active at pH 8.0, and requires Mg^{2+} or Mn^{2+}.

Catalase, oxidase, and phosphatase are produced; work is in progress on the phosphatases of *L. enzymogenes* (R.G. von Tigerstrom, personal communication).* The indole, methyl-red, and Voges–Proskauer tests are negative.

Lyses Gram-negative and Gram-positive bacteria, including actinomycetes, yeasts and filamentous fungi, blue-green and green algae, and nematodes. Lysobacters do not attack Gram-negative bacteria as vigorously as they do Gram-positive species; this may be a self-protective feature.

All strains known at present have been isolated from soil or freshwater habitats; no studies have been aimed at finding them elsewhere, but this would probably be a fruitful area for investigation. Their polysaccharolytic and proteolytic abilities suggest a role in the degradation of biological structural and storage materials. The significance of their lytic abilities toward other organisms has yet to be fully assessed. It is quite possible that marine members of the genus will be found or that these organisms may have medical significance.* *Lysobacter* spp. have probably been confused with "eubacteria" in the past when encountered on regular plating media; nutritionally dilute media are needed in order for lysobacters and other gliding bacteria to be recognized, since they do not exhibit spreading on plate count agar (PCA).

One species, *L. antibioticus*, elaborates a potent, wide-spectrum antibiotic named "myxin," which is a 1-hydroxy-6-methoxyphenazine (Cook et al., 1971; Behki and Lesley, 1972). It is manufactured by Hoffman and Roche, but there are two important drawbacks to its widespread medical usage: it has too wide a spectrum,

**Editorial Note:* Since the publication of this chapter in the 1st edition of *Bergey's Manual of Systematic Bacteriology*, several papers on this topic have been published. See von Tigerstrom (1984); von Tigerstrom and Stelmaschuk (1985, 1986, 1987); Au et al. (1991).

**Editorial Note:* Since the publication of this chapter in the 1st edition of *Bergey's Manual of Systematic Bacteriology*, several papers on this topic have been published. See Bonner et al. (1988), O'Sullivan et al. (1988), Harada et al. (1988), and Tymiak et al. (1989).

especially for internal use, and it is explosive when dry. Its use is restricted to topical application for resistant fungal skin problems.

Enrichment and Isolation Procedures

Lysobacters have the unusual ability to hydrolyze chitin, and their isolation is facilitated by providing chitin as a suspension, in ground mushrooms, or in autoclaved yeast cells. The simplest method is to enrich soil samples with one of the above sources of chitin, incubate it for at least 1 month, then plate it out onto yeast cell agar (Smit and Clark, 1971), which consists of 0.5% baker's yeast in a 1.5% agar medium. The number of colonies capable of lysing autoclaved yeast cells increases dramatically with such enrichment procedures (Christensen and Cook, 1978). Water samples can be plated directly onto yeast cell agar.

Maintenance Procedures

Lysobacters grow profusely on PCA (plate count agar, from, for example, Difco), SAA (skim–acetate agar: 0.5% skim milk, 0.05% yeast extract, and 0.02% sodium acetate in 1.5% agar) or broth, or CCA (Cook's *Cytophaga* agar: 0.2% tryptone in 1.0% agar) (Christensen and Cook, 1972). The more dilute the medium, the greater the expression of the spreading morphology, thus CCA is recommended for this purpose and because on this medium, organisms do not appear to lose their polysaccharolytic and proteolytic potentials. On PCA, colonies of lysobacters are

often indistinguishable from nongliding bacteria. Ordinary plating techniques are sufficient with incubation at room temperature for the species so far known; however, difficulty can occur with *L. gummosus* because of its intensely rubbery colonies, and, for this species, it is recommended that young cultures (<24 h) be used when possible. Lyophilization is successful, and cultures are readily obtainable from these preparations, which are recommended for long-term storage. Caution is advised on two aspects, however: (a) colony morphology may change slightly after freeze-drying, and (b) strains of *L. enzymogenes* do not exhibit as strong a microbial lytic action and do not maintain as high a level of certain proteolytic enzymes, after they have been maintained in the laboratory on skim milk media for some time, as do cells that have not been freeze-dried, and this may also apply to lyophilized cultures.

Procedures for Testing Special Characters

In order to differentiate lysobacters from the myxobacteria, it is necessary to demonstrate the absence of fruiting bodies. At least two methods should be attempted, such as inoculation onto sterile wild herbivore pellets in water agar (Smit and Clark, 1971) and induction of myxospores following addition of 0.5 M glycerol during exponential growth (Dworkin and Gibson, 1964).

Suitable methods for demonstration of polysaccharide degradation, antimicrobial lytic action, and susceptibility to actinomycin D have been published by Christensen (1977).

Differentiation of the species of the genus *Lysobacter*

Characteristics useful for distinguishing among the species of *Lysobacter* are given in Tables BXII.γ.24 and BXII.γ.25.

TABLE BXII.γ.24. Differential characteristics of the species of the genus *Lysobacter*[a,b,c]

Characteristics	1. *L. enzymogenes*	2. *L. antibioticus*	3. *L. brunescens*	4. *L. gummosus*
Broth culture viscous	+	+	−	+ (heavy)
Colonies:				
Type of growth	Sloppy, mucoid	Sloppy, mucoid	Spreading, thin	Pulvinate, gummy
Surface smooth	+ or −	+	+ or −	+
Opacity	Tp, Tl or Op	Tl or Op	Tp or T1	Tl or Op
Color	Dark C to deep Y-C	Pi to Br-Pi or O-Br	Y to Ch	Pale Y-G to Y-G
Brown, water-soluble pigment produced	None to moderate	Weak to heavy	Weak to heavy	−
Myxin crystals in old cultures	−	Usually +	−	−
Urea as nitrogen source	+ or −	−	−	+
Acid from:				
Cellobiose	+	+	−	+
Sucrose	+	−	−	+
Lactose	+	d	−	+
Lipase–Tween 20	+	d	−	+
Hydrolysis of:				
Alginate	+ or −	d	−	−
CMC	+	+	−	+
Pectate	+	−[d]	+	+
SYS or NBS	−	−[e]	+	−
Potato starch	+ or −	−[f]	+	−
Sheep erythrocytes	α, β, or γ	β or α	γ or −	α
H_2S produced	d	−	+	−
Citrate as sole carbon source	+	+	−	+
Growth on:				
MacConkey's	+ (colorless or −)	d (colorless)	−	−
EMB	+ (Pi)	+ (Pi)	−	+ (Pi)
Completely inhibited by 0.1% SLS	+ or −	+	+	−
Susceptible to:				
Chloramphenicol (30 μg)	d	−	+	−
Penicillin G (10 U)	−	−	d	−
Actinomycin D	d	−	+	d
Habitat	Soil	Soil	Freshwater	Soil

[a]Data are from Christensen and Cook (1978), to which the reader is referred for details of tests.

[b]Symbols: +, 90% or more of strains are positive; −, 90% or more of strains are negative; and d, 11–89% of strains are positive.

[c]Abbreviations: Br, brown(ish); C, cream-colored; Ch, chocolate; EMB, eosin methylene blue; G, gray; NBS, nutrient broth–starch; O, orange: Op, opaque; Pi, Pink(ish); SLS, sodium lauryl sulfate; SYS, salts–yeast extract–starch; Tl, translucent; Tp, transparent; and Y, yellow(ish).

[d]Growth but not liquefaction.

[e]Only one strain recorded on SYS.

[f]Only one strain recorded.

TABLE BXII.γ.25. Other characteristics of the species of the genus *Lysobacter*[a,b,c]

Characteristics	1. *L. enzymogenes*	3. *L. antibioticus*	4. *L. brunescens*	2. *L. gummosus*
Cell dimensions (μm)	0.3–0.5 × 4–50	0.4 × 4–40	0.2–0.5 × 7-70	0.4 × 2

[a]Data are from Christensen and Cook (1978), to which the reader is referred for details of tests.

[b]Symbols: +, 90% or more of strains are positive; –, 90% or more of strains are negative; and d, 11–89% of strains are positive.

[c]Abbreviations: OF, oxidation/fermentation; and SLS, sodium lauryl sulfate.

[d]Flexing, gliding, and silkiness are more readily observed with longer cells.

[e]Only one strain recorded on nutrient broth.

List of species of the genus Lysobacter

1. **Lysobacter enzymogenes** Christensen and Cook 1978, 374^{AL}
en.zy.mo′ge.nes. Gr. n. *zyme* leaven; M.L. n. *enzymum* enzyme; Gr. v. *gennaio* to produce; M.L. adj. *enzymogenes* enzyme-producing.

Two distinct colony forms are known: a dirty-white, mucoid colony and a yellowish, nonmucoid one. The mucoid colony produces nonmucoid mutants, but the yellowish, nonmucoid form does not produce revertants to the dirty-white, mucoid form. The colony descriptions given here and in Table BXII.γ.25 cover the whole range of colony forms observed. The forms are identical in other properties.

On CCA, 5-d-old colonies are dark cream-colored, with Munsell notation 2.5Y 6–8/4–8 and 5–10YR 6–8/4–8, and circular to irregular. Colonies usually have a smooth surface, but occasionally have a rough surface. Edges may be entire, undulate, lobate or erose; elevation is typically effuse with a raised or convex center, but occasionally flat. Colonies are transparent or translucent; no brown, water-soluble pigment is produced.

On SAA, 5-d-old colonies are dark cream-colored, with Munsell notation 2.5–7.5Y 6.5–8.5/4–6 and 7.5–10YR 5.5–7/5–7, and circular to irregular, with a smooth or rough surface. Edges may be entire, undulate or erose; elevation is typically effuse with a raised, convex or umbonate center, but occasionally flat. Colonies are transparent, translucent or opaque; no brown, water-soluble pigment is produced.

On PCA, 5-d-old colonies are deep yellow, cream-colored, or creamy brown, with Munsell notation 1.5–5Y 3–7/4–8, and more or less circular, usually with a smooth surface. Edges may be entire, undulate or erose; elevation is usually convex, but may be effuse with a convex or raised center or may be umbonate. Colonies are translucent or opaque; some brown, water-soluble pigment may be produced.

Older cultures of the majority of strains produce copious, dark-brown, water-soluble pigment on most media.

The mol% G + C of the DNA is: 65.4–70.1 (T_m).

Type strain: ATCC 29487, UASM 495.

Additional Remarks: Other strains: ATCC 27796 (UASM AL-1), ATCC 29488 (UASM 13B), and ATCC 29485/6 (colony types of UASM 18L).

2. **Lysobacter antibioticus** Christensen and Cook 1978, 387^{AL}
an.ti.bi.o′ti.cus. Gr. pref. *anti* against; Gr. n. *bios* life; M.L. adj. *antibioticus* against life, antibiotic.

On CCA, 5-d-old colonies are pinkish brown, with Munsell notation 1–10YR 2.5–7/4–8, and circular to irregular, with a smooth surface. Edges are usually erose, but may be entire, undulate, or filamentous. Elevation is usually flat or raised, but sometimes effuse with a convex center. Translucent or opaque; some or much brown, water-soluble pigment is produced.

On SAA, 5-d-old colonies are pinkish brown, with Munsell notation 2.5Y 7/5 and 1.5–7.5YR 3–6/4–8, and more or less circular, with a smooth surface. Edges are usually erose, but may be entire or filamentous. Elevation is usually raised, but may be effuse, flat or convex. Translucent or opaque; some or much brown, water-soluble pigment is produced or may be absent.

On PCA, 5-d-old colonies are orange-brown, with Munsell notation 1–2.5Y 4–6/3–4 and 5–10YR 2–5/2–6, and more or less circular, with a smooth surface. Edges are usually entire, but may be erose or undulate. Elevation is convex or raised. Colonies are usually opaque; weak to heavy, brown, water-soluble pigment is produced.

Older cultures on most media produce copious brown, water-soluble pigment, and deep-red crystals of the antibiotic myxin may be observed within the highly mucoid colonies.

The mol% G + C of the DNA is: 66.2–69.2 (T_m).

Type strain: ATCC 29479, UASM 3C.

GenBank accession number (16S rRNA): AB019582.

Additional Remarks: Other strains: ATCC 29480 (UASM L17) and ATCC 29481 (UASM 4045).

3. **Lysobacter brunescens** Christensen and Cook 1978, 390^{AL}
bru.nes′cens. L. v. *brunesco* to become dark brown; L. part. adj. *brunescens* becoming dark brown.

On CCA, 5-d-old colonies are brownish yellow, with Munsell notation 2.5–5Y 3–4/4–8 and 10YR 4–5/6–8, and irregular, with a rough surface. Edges are usually filamentous, but may be lobate, undulate, or erose. Elevation is effuse with an umbonate or convex center. Colonies are transparent; amounts of brown, water-soluble pigment vary from moderate to absent.

On SAA, 5-d-old colonies are yellow-brown, with Munsell notation 2.5Y 4.5/6 and 7.5–10YR 4–6/6–8. Usually irregular, but occasionally circular. Colonies usually have a rough surface. Edges are typically erose or filamentous, but may be entire, undulate, or lobate. Elevation is effuse or raised, with convex or umbonate centers. Transparent or translucent; weak to moderate amounts of brown, water-soluble pigment are produced.

On PCA, 5-d-old colonies are deep yellow-brown, with Munsell notation 1–2.5Y 3–4/4–6 and 10YR 3–4/4–6. Circular to irregular, with a smooth or rough surface. Edges are usually entire or undulate, but sometimes erose or filamentous. Elevation is either effuse with convex or umbonate centers, raised, or convex. Translucent; production of brown, water-soluble pigment is moderate to heavy.

Older cultures on all media produce copious, dark-brown, water-soluble pigment.

The mol% G + C of the DNA is: 67.6–67.8 (T_m).

Type strain: ATCC 29482, UASM D.

Additional Remarks: Other strains: ATCC 29483 (UASM 2) and ATCC 29484 (UASM 6).

4. **Lysobacter gummosus** Christensen and Cook 1978, 388^{AL}
gum.mo′sus. L. adj. *gummosus* slime (gum)-producing.

On CCA, 5-day-old colonies are pale yellowish-gray, with Munsell notation 5Y 8/2. Circular, with a smooth surface. Entire edge. Elevation pulvinate. Translucent; no water-soluble pigment produced. Gummy.

On SAA, 5-d-old colonies are pale yellowish-gray, with Munsell notation 5Y 8/2. Circular, with a smooth surface. Entire edge. Elevation pulvinate. Opaque; no water-soluble pigment produced. Very gummy.

On PCA, 5-d-old colonies are yellow-gray, with Munsell notation 5Y 7/4. Circular, with a smooth surface. Entire

edge. Elevation pulvinate. Opaque; no water-soluble pigment produced. Very gummy.

Older cultures are intensely gummy and do not produce a water-soluble pigment. In very old cultures, the viscosity of the colony may decrease dramatically, although viable cells can still be recovered from this thin slime.

The mol% G + C of the DNA is: 65.7 (T_m).

Type strain: ATCC 29489, UASM 402.

Genus V. **Nevskia** *Famintzin 1892, 484*[AL]

Hans-Dietrich Babenzien and Heribert Cypionka

Nev'ski.a. M.L. fem. n. *Nevskia* from the Neva, a river in St. Petersburg.

Cells elongated, rod shaped, usually slightly bent with **acellular hyaline stalks** (Fig. BXII.γ.30). The **stalks branch dichotomously** because of binary fission of mature cells and the preference for laterally excreted slime material (Fig. BXII.γ.31). Undisturbed and slowly growing cells form **flat, rosette-like to bush-like microcolonies** (Fig. BXII.γ.32), up to 80 μm in diameter, **on the surface of freshwater**. Faster growth results in the formation of a thin surface pellicle without distinct stalks (Fig. BXII.γ.33A) and with

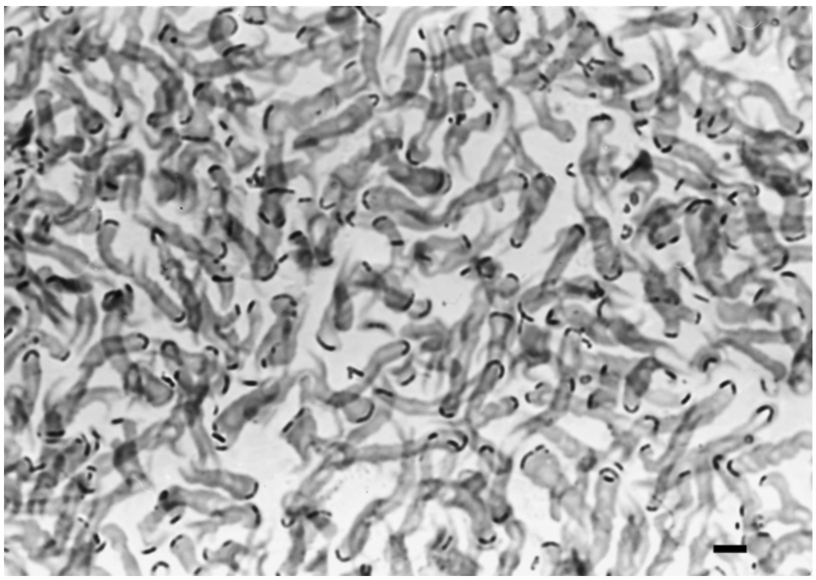

FIGURE BXII.γ.30. Enrichment culture of *N. ramosa*, thin bent rods at the tip of slime stalks. Formalin-toluidine blue. Bar = 10 μm.

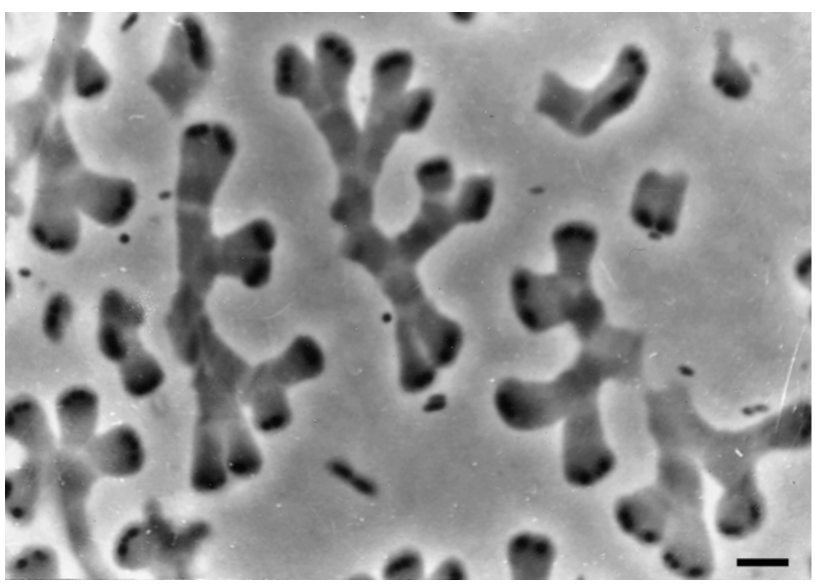

FIGURE BXII.γ.31. *Nevskia ramosa*, strain Soe 1 (DSM 11499). Dichotomously branched slime stalks with *Nevskia ramosa* cells at the tip. Phase-contrast micrograph. Bar = 10 μm.

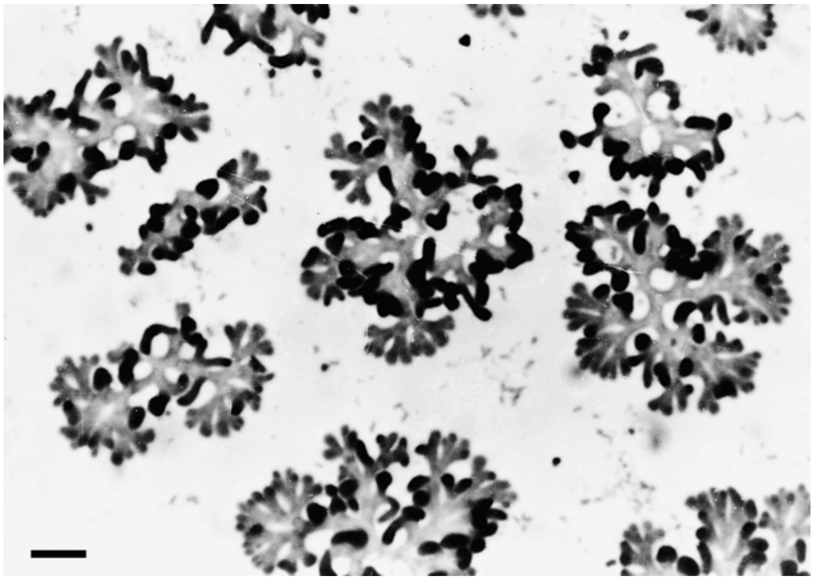

FIGURE BXII.γ.32. Habitat form of *N. ramosa*, showing the typical bush-like microcolony structure. Formalin-carbol-fuchsin. Bar = 20 μm.

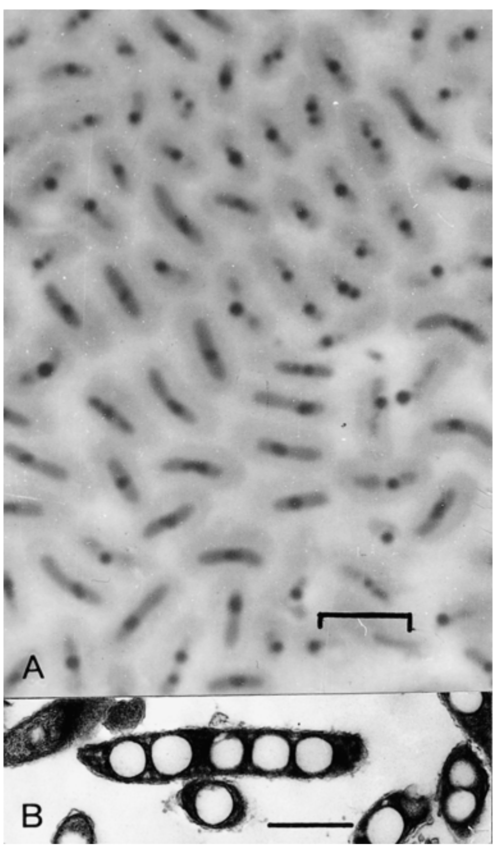

FIGURE BXII.γ.33. *Nevskia ramosa*, strain Soe 1 (DSM 11499). *A*, without distinct stalks in this growth phase. Phase-contrast micrograph. Bar = 10 μm. *B*, ultrastructure of organisms grown with Na-lactate. Cells filled with poly-β-hydroxybutyrate granules (white areas). Bar = 1 μm.

slime all around the cells. Cells filled with numerous refractile globules (Fig. BXII.γ.33B) which consist mainly of polyhydroxyalkanoates. Resting stages are not known. **Gram negative**. In young cultures, some cells are **motile** by means of a polar flagellum: they are set free from the microcolonies and can start the development of new colonies (Fig. BXII.γ.34). **Strictly aerobic.** Optimum growth temperature: 20–25°C. **Chemoorganotrophic**, with a broad range of organic compounds, having an oxidative type of metabolism. **Colorless colonies** on nutrient agar. Weak catalase activity, no cytochrome oxidase activity. Cytochromes of the *b* and *c* types are present. Originally found in the surface pellicle of an aquarium. Occur mainly on the surface of freshwater environments (neuston community).

Phylogenetic analysis of 16S rDNA sequences revealed that *N. ramosa* is a member of the phylum *Proteobacteria* and represents a deep branch of the *Gammaproteobacteria* with no known close relatives (Fig. BXII.γ.35).

The original strain described by Famintzin (1892) as the type strain was not isolated in pure culture.

The mol% G + C of the DNA is: 67.8–69.0 (HPLC), neotype strain Soe 1 (DSM 11499); 69.0, strain OL 1 (DSM 11500).

Type species: **Nevskia ramosa** Famintzin 1892, 484.

Further descriptive information

The two 16S rDNA sequences obtained have been deposited with EMBL (accession No. AJ001010 and AJ001011 for strains Soe 1 and OL 1, respectively). The 16S rDNA sequences of the two strains revealed 99.2% similarity; genomic fingerprinting by ERIC-PCR showed different banding patterns on agarose gel (Stürmeyer et al., 1998).

For *in situ* identification by hybridization, two oligonucleotide probes targeting positions 656–674 (NEV 656, 5′-CGCCTCCCTCTACCGTTT-3′) and 177–195 (NEV 177, 5′-GCTCTTGCGAGATCATGC-3′) of the 16S rRNA gene are available (Glöckner et al., 1998).

The type species was described by Famintzin (1892) as being 2–6 × 12 μm in size, but he also mentioned organisms identical to *N. ramosa* of "much smaller sizes". Henrici and Johnson (1935) described an organism practically identical to *N. ramosa* in morphology but of smaller dimensions , i.e., 1 × 3–4 μm. Babenzien (1965, 1967) isolated some strains from the surface of swamp ditches and ponds and the average size was 0.7 × 2.4–2.7 μm.

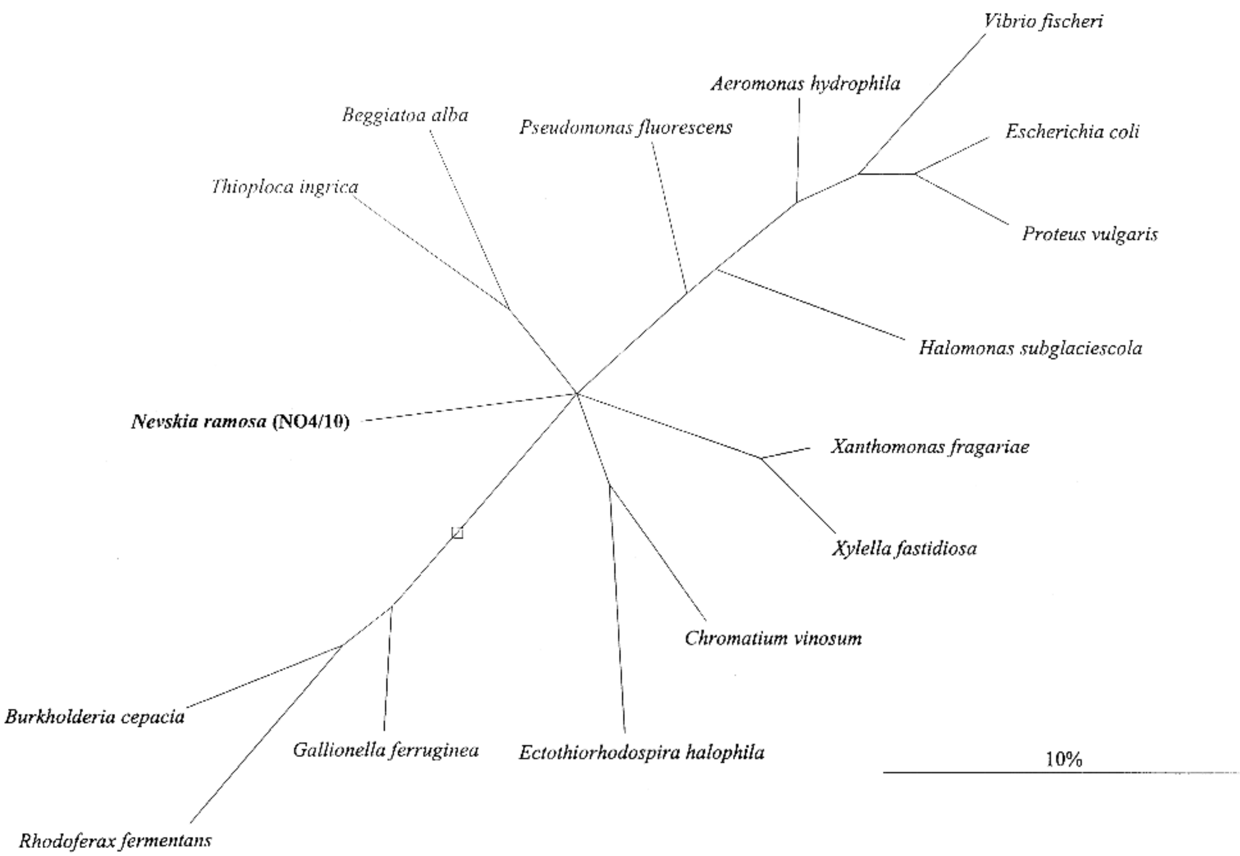

FIGURE BXII.γ.35. Phylogenetic tree, showing phylogenetic relationships between *Nevskia ramosa*, *Nevskia* clones NO4 and NO10, and closest relatives among the *Gammaproteobacteria*, based on comparative analysis of 16S rDNA. Bar = 10% estimated divergence. The open box indicates the root. (Reproduced with permission from Glöckner et al., Applied and Environmental Microbiology *64*: 1895–1901, 1998, ©American Society for Microbiology, Washington, D.C..)

Hirsch (1992) reported other *Nevskia*-like organisms also in this size range. The neotype strain DSM 11499 has a size of 0.7–1.1 × 1.4–2.3 μm during the logarithmic phase of growth and a tendency to form more elongated cells within the lag phase.

The globular bodies were thought to be composed of "etherical oils" and could be dissolved with 70% ethanol (Famintzin, 1892), whereas it was assumed by Henrici and Johnson (1935) that the vacuoles contained sulfur. According to Babenzien and

Hirsch (1974), globules contain mainly poly-β-hydroxybutyrate. Cells grown at the air-water interface typically contain 2–5 refractile globules.

In the enrichment cultures of Henrici and Johnson (1935), the bacteria were distinctly favored by the addition of sulfide, which indicated that *Nevskia* was either a sulfur bacterium or a microaerophile. As reported by Babenzien (1965) and Hirsch (1981), enrichment cultures were definitely favored by addition of 0.1% sodium lactate or acetate to lake water.

Pure cultures of *N. ramosa* have a strictly aerobic metabolism and grow with numerous substrates (Table BXII.γ.26) added to lake water or simple synthetic medium (Stürmeyer et al., 1998). No anaerobic growth with nitrate, thiosulfate, and sulfate as electron donors.

The development of a pellicle and stalk formation is primarily dependent on the availability of combined nitrogen. If ammonia, nitrate, or amino acids are supplied to the nutrient broth, the cultures grow submersed. It is assumed that the *Nevskia* biofilm in nature traps ammonia from the air before it is dissolved in the water.

By cultivating *N. ramosa* as a surface film, the fluid medium remains clear.

The slime stalks consist mainly of polysaccharides with rhamnose and small amounts of glucose and mannose, but other hydrophobic components may be present.

Nitrogenase activity was not detected.

According to numerous reports (Babenzien, 1966; Babenzien and Hirsch, 1974; Hirsch, 1981; Heldal and Tumyr, 1986; Kangatharalingam and Priscu, 1993; Stürmeyer et al., 1998), *Nevskia ramosa* is widely distributed in shallow aquatic habitats; it has never been reported from soils. Most findings have been from the water surface and, in fact, *Nevskia* appears to be a typical neuston microorganism. As indicated by the dull appearance and hydrophobicity of the biofilm, the flat rosettes live essentially outside of the water phase. While *Nevskia* cells are sensitive to UV radiation if kept in the dark after UV exposure, the isolates overcome UV damage by a very effective photorepair mechanism if incubated subsequently under light.

Enrichment and Isolation Procedures

Surface films of swamp ditches, ponds, greenhouse pools, etc. are collected with sterile glass slides, needle loops, paper strips, or foils. The samples are transferred to Petri dishes with sterile water from the same sites, supplemented with 5 mM sodium lactate, and incubated in the dark at room temperature for about 10 days. Under microscopic control, bacterial microcolonies from the water surface are then picked up with a loop and transferred repeatedly into sterile Erlenmeyer flasks containing the same medium. For dilution purposes and to obtain pure cultures, multiwell chambers are also suitable. Pure cultures were obtained by repeated streaking of diluted samples on agar plates (1% Difco agar) containing lake water medium. To obtain submersed cultures, the medium was supplemented with 5 mM NH_4Cl.

Pure cultures can also be cultivated as surface films in a synthetic medium of the following composition: sodium lactate, 5 mM; $MgSO_4 \cdot 7H_2O$, 0.2 mM; $CaCl_2 \cdot 2H_2O$, 0.1 mM; KH_2PO_4, 25 mM; trace element solution SL 9, 0.5 ml/l; and vitamin solution, 0.5 ml/l. The pH is adjusted to 7.0. Incubation temperature 20–25°C (Stürmeyer et al., 1998).

Maintenance Procedures

Stock cultures can be maintained in Erlenmeyer flasks containing liquid medium, covered with cotton plugs, with transfers every three months. The strains in the DSM (Braunschweig, Germany) are stored at −70°C and are available in lyophilized form.

Taxonomic Comments

Since the taxonomy of *N. ramosa* was based solely on morphological data, it was previously found in the section on "Phylogenetically unaffiliated bacteria" (*The Prokaryotes*, 2nd Ed.) and Section 21 "Budding and/or appendaged bacteria" (*Bergey's Manual of Systematic Bacteriology*, 1st Ed.).

It is now clear that *N. ramosa* should not be affiliated with *Caulobacterales*, *Gallionella*, *Thiobacterium*, or *Beggiatoa*.

TABLE BXII.γ.26. Utilization of organic substrates by *Nevskia ramosa*

List of species of the genus Nevskia

1. **Nevskia ramosa** Famintzin 1892, 484[AL]
ra.mo'sa. L. adj. *ramosus* branched.

The characteristics are the same as those described for the genus. A spectrum of substrates and the mode of growth are shown in Table BXII.γ.26. The neotype strain Soe 1 (DSM 11499) was isolated from a small bog lake (L. Soelkensee, Germany) and formerly designated as strain IMET 10965.

The mol% G + C of the DNA is: 67.8 (HPLC), strain Soe 1 (DSM 11499); 69.0 (HPLC), strain OL 1 (DSM 11500).

Type strain: Soe 1, DSM 11499.

GenBank accession number (16S rRNA): AJ001010.

Genus VI. **Pseudoxanthomonas** *Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280*[VP]

André Lipski and Erko S. Stackebrandt

Pseu.do.xan.tho.mo' nas. Gr. *pseudes* false; M.L. n. *Xanthomonas* a bacterial generic name; M.L. fem. n. *Pseudoxanthomonas* false *Xanthomonas*.

Rod-shaped cells. Gram negative. **Aerobic. Heterotrophic.** Colonies are yellow. Possess a ubiquinone with eight isoprene units. **The predominant fatty acids in the iso-/anteiso-type fatty acid profile are $C_{15:0\ iso}$ and $C_{15:0\ anteiso}$.**

Type species: **Pseudoxanthomonas broegbernensis** Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280.

Differentiation of the genus *Pseudoxanthomonas* from other genera

The genus can be separated from the genera *Xanthomonas* and *Stenotrophomonas* by the absence of the fatty acid 3-hydroxy-isotridecanoic acid and from the species *Xylella fastidiosa* by the presence of branched-chain fatty acids.

Taxonomic Comments

Pseudoxanthomonas broegbernensis is clearly a member of the family *Xanthomonadaceae*. The phylogenetic position within this family is not yet settled. Depending on the selection and number of reference sequences, the genus *Xanthomonas* or *Xylella* is the most closely related genus. The more precise phylogenetic relatedness of these genera must await analyses using more sequences of strains of the genus *Pseudoxanthomonas*, which is presently represented by a single sequence only.

At present, the 16S rDNA sequence of *P. broegbernensis* shares the closest relationship (97% similarity) to the sequence of an undescribed ultramicrobacterium strain 12-3 (Iizuka et al., 1998) whose accession number is AB008507.

List of species of the genus Pseudoxanthomonas

1. **Pseudoxanthomonas broegbernensis** Finkmann, Altendorf, Stackebrandt and Lipski 2000, 280[VP]
broeg.ber' nen.sis. M.L. fem. adj. *broegbernensis* pertaining to Brögbern (location near Lingen/Germany, from where the organism was isolated).

The characteristics are as described for the genus and as listed in Table BXII.γ.27. Nitrate is not reduced, but nitrite is reduced to nitrous oxide (Finkmann et al., 2000). Predominant compounds of the fatty acid profile are $C_{15:0\ iso}$, $C_{15:0\ anteiso}$, $C_{16:0}$, $C_{16:1\ \omega7c}$, and $C_{17:1\ iso\ \omega8c}$. The major hydroxy fatty acid is $C_{11:0\ iso\ 3OH}$. The fatty acids $C_{17:0\ cyclo}$ and $C_{13:0\ iso\ 3OH}$ are absent. No pathogenic potential for humans, animals, or plants known.

TABLE BXII.γ.27. Characteristics of *Pseudoxanthomonas broegbernensis*[a,b]

Characteristic	Reaction
Nitrate reduction to nitrite or N_2	–
Nitrite reduction to N_2O	+
Tween 80 hydrolysis	+
Urease, arginine dihydrolase	–
Alkalinization of citrate and malonate media	–
Lecithinase	–
Growth at 37°C	–
Acid from:	
Glucose, xylose, fructose, lactose, maltose	+
Rhamnose, sucrose	–
Hydrolysis of:[c]	
pNP-*N*-acetyl-β-glucosaminide, pNP-β-galactopyranoside	+
pNP-β-glucopyranoside, pNP-α-D-maltoside, pNP-β-xyloside	+
Bis-pNP-phosphate, pNP-phosphocholine, thymidine-5′-mono-phosphate-pNP-ester	–
Hydrolysis of:[c]	
L-Alanine-pNA, L-arginine-pNA, γ-L-glutamate-pNA, L-leucine-pNA, L-lysine-pNA	+
Glycine-pNA, L-proline-pNA, L-valine-pNA	–
Growth with:	
N-Acetylglucosamine, D-cellobiose, D-galactose, D-maltose, D-mannose, D-sucrose, D-trehalose	+
L-Arabinose, D-fructose, gluconate, D-ribose, i-inosite, D-mannite, sorbite, propionate, T-aconitate, adipate, DL-3-hydroxybutyrate, DL-lactate, L-malate, pyruvate, L-histidine, L-hydroxyproline, L-ornithine, L-proline, putrescine	–
Growth in the presence of:	
NaCl, 3%	–
Cadmium acetate, 0.001%; $ZnCl_2$, 0.01%; lead acetate, 0.01%	–
Growth in presence of antimicrobial agents (μg or U per disk):	
Erythromycin (10 μg); streptomycin (10 μg); nalidixic acid (30 μg); kanamycin (30 μg); ampicillin (10 μg); penicillin G (10 U); gentamicin (10 μg); fucidin (10 μg); tetracycline (30 μg); novobiocin (30 μg)	+
Neomycin, 30 μg	–

[a] Symbols: see standard definitions.

[b] Data from Lipski et al. (1992); Finkmann et al. (2000).

[c] pNP, *para*-nitrophenyl; pNA: *para*-nitroanilide.

The only strain of this genus was isolated from an experimental biofilter supplied with the waste gas of an animal rendering plant.

The mol% G + C of the DNA is: not known.

Type strain: B1616/1, DSM 12573.

GenBank accession number (16S rRNA): AJ012231.

Genus VII. **Rhodanobacter** *Nalin, Simonet, Vogel and Normand 1999, 22*[VP]

THE EDITORIAL BOARD

Rho.da' no.bac.ter. L. masc. n. *Rhodanus* River Rhône; M.L. masc. n. *bacter* equivalent of *bacterium* a small rod; M.L. masc. n. *Rhodanobacter* rod isolated close to the River Rhône.

Gram-negative rods. **Nonmotile**. Colonies on SMA agar plates are yellow with clean edges, 0.2–1 mm in diameter after 3 d at 30°C. Do not form spores. Branching does not occur. Aerobic; chemoorganotrophic. **Catalase and oxidase positive**. Optimum growth temperature 30°C. Based on analysis of 16S rDNA sequences, *Rhodanobacter* belongs in the class *Gammaproteobacteria*, order *Xanthomonadales*, and family *Xanthomonadaceae*.

The mol% G + C of the DNA is: 63.

Type species: **Rhodanobacter lindaniclasticus** Nalin, Simonet, Vogel and Normand 1999, 22.

FURTHER DESCRIPTIVE INFORMATION

Rhodanobacter lindaniclasticus can degrade γ-hexachlorocyclohexane (lindane; γ-HCH) under aerobic conditions. The first gene in the lindane degradation pathway, *linA*, is highly conserved (99.4%) between *R. lindaniclasticus* and the other known aerobic lindane degrading bacterium, *Sphingomonas paucimobilis* (Thomas et al., 1996b).

ENRICHMENT AND ISOLATION PROCEDURES

Thomas et al. (1996b) collected γ-HCH-contaminated soil from several wood treatment facilities and added 5 g to a mixture of 10 g each Biolyte CX80 and CX85 in 100 ml of Ringer (1/4) solution. Following 1 h on a rotary shaker and 10 min of ultrasonication, 1 ml of the resulting supernatant was used as an inoculum for the enrichment culture and added to 3 l of a mineral medium containing γ-HCH as the sole carbon and energy source. Over 18 months, γ-HCH was added and the pH adjusted as necessary, using 1 N NaOH. Aliquots were periodically plated onto SMA agar and tested for ability to utilize γ-HCH.

DIFFERENTIATION OF THE GENUS *RHODANOBACTER* FROM OTHER GENERA

Rhodanobacter can be distinguished from other members of the *Xanthomonadaceae* by its ability to utilize γ-HCH as a growth substrate. Other distinguishing characteristics are listed in Table BXII.γ.17 in the chapter on *Xanthomonas*.

List of species of the genus Rhodanobacter

1. **Rhodanobacter lindaniclasticus** Nalin, Simonet, Vogel and Normand 1999, 22[VP]

lin.da' ni.clas.ti.cus. Fr. masc. n. *lindane* commercial name of γ-HCH; Gr. adj. *clasticus* breaking, from G. part. perf. *klastos* broken; M.L. masc. adj. *lindaniclasticus* lindane-breaking.

Colonies on nutrient agar are yellow (nothoxanthin), circular, and convex, 0.2–1 mm in diameter. Growth on Milieu Base Salin (MBS) with γ-HCH as sole carbon source. Catalase, oxidase, and Tween 80 esterase positive. Urease, protease, tryptophanase, nitrate reductase, amylase, and DNase negative. Utilizes the following carbon sources: D-glucose, esculin, cellobiose, trehalose, D-xylose, lactate, caprate, malate, and citrate. Optimal growth at 30°C; also grows at 41°C; no growth at 4°C.

The type strain was isolated from soil at a wood-treatment site.

The mol% G + C of the DNA is: 63 (HPLC).

Type strain: RP5557, LMG 18385.

GenBank accession number (16S rRNA): AF039167.

Genus VIII. **Schineria** *Tóth, Kovács, Schumann, Kovács, Steiner, Halbritter and Máriageti 2001, 406*[VP]

THE EDITORIAL BOARD

Schi' ner.i.a. N.L. fem. n. *Schineria* pertaining to Schiner who first described the fly *Wohlfahrtia magnifica* in 1862.

Gram-negative nonmotile aerobic rods. Catalase positive. Major fatty acids, $C_{14:0}$, $C_{16:0}$, and $C_{18:1}$. Major polar lipids include phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylserine.

The mol% G + C of the DNA is: 42 (HPLC).

Type species: **Schineria larvae** Tóth, Kovács, Schumann, Kovács, Steiner, Halbritter and Máriageti 2001, 406.

FURTHER DESCRIPTIVE INFORMATION

The inner cell membrane forms invaginations that protrude into the cytoplasm (Tóth et al., 2001).

The *Schineria* strains studied were isolated from larvae of *Wohlfahrtia magnifica*, a dipteran that is an obligate parasite and that infects many vertebrates, including domestic livestock; it is possible that the strong chitin-degrading capability of *Schineria* strains plays a role in molting of the host larvae (Tóth et al., 2001).

Analysis of 16S rDNA sequences placed *Schineria larvae* in the *Gammaproteobacteria* (Tóth et al., 2001).

Enrichment and Isolation Procedures

Schineria larvae strains were isolated on King's B medium from homogenates of washed *Wohlfahrtia magnifica* stage 1 and stage 2 larvae (Tóth et al., 2001).

Maintenance Procedures

Schineria larvae strains were maintained on King's B medium (Tóth et al., 2001).

List of species of the genus Schineria

1. **Schineria larvae** Tóth, Kovács, Schumann, Kovács, Steiner, Halbritter and Máriageti 2001, 406[VP]
lar'vae. L. gen. fem. *larvae* pertaining to the origin of the type strain isolated from *Wohlfahrtia magnifica* maggots.

Single straight encapsulated rods (0.8–0.9 × 2.0–3.0 µm). Produce H_2S. Hydrolyze chitin and urea; do not hydrolyze casein, esculin, or gelatin. Nonhemolytic. Do not utilize citrate. Voges–Proskauer test negative. No acid produced from carbohydrates in bioMéreiux API CH50 test strips.

The mol% G + C of the DNA is: 42 (HPLC).
Type strain: L1/68, CIP 107108, DSM 13226.
GenBank accession number (16S rRNA): AF252143.

Genus IX. **Stenotrophomonas** *Palleroni and Bradbury 1993, 608[VP]**

Norberto J. Palleroni

Ste.no.tro.pho.mo'nas. Gr. adj. *stenus* narrow; Gr. n. *trophus* one who feeds; Gr. n. *monas* a unit, monad; M.L. fem. n. *Stenotrophomonas* a unit feeding on few substrates.

Straight or curved rods but not helical, 0.5 × 1.5 µm, occur singly or in pairs. Do not accumulate poly-β-hydroxybutyrate granules as intracellular reserve material. No resting stages are known. Gram negative. **Motile by two or more polar flagella. Aerobic, having a strictly respiratory type of metabolism with oxygen as electron acceptor. Nitrate is reduced but it is not used as a nitrogen source for growth.** The colonies are yellow, greenish, or gray. The yellow color is not due to carotenoids or xanthomonadins. The colonies may turn a dark brown color with age. **The major polyamines are spermidine and cadaverine.** Aside from fatty acids in common with *Xanthomonas* species, one of the species (*S. maltophilia*) **is characterized by the presence of $C_{17:0}$ cyclopropane fatty acid and ubiquinone Q8**. No growth occurs at 4 or 41°C; the optimum growth temperature is ~35°C. **Oxidase negative.** Gelatinase and catalase positive. Strong lipolytic activity, as judged by the hydrolysis of Tween 80. **Chemoorganotrophic.** One of the species (*S. maltophilia*) is widely distributed in nature and is commonly isolated from clinical materials and nosocomial infections.

The mol% G + C of the DNA is: 66.9 ± 0.8.

Type species: **Stenotrophomonas maltophilia** (Hugh 1981) Palleroni and Bradbury 1993, 608 (*Pseudomonas maltophilia* Hugh 1981, 195; *Xanthomonas maltophilia* Swings, De Vos, Van Den Mooter and De Ley 1983, 412.)

Further descriptive information

Morphological characteristics *Stenotrophomonas* cells are morphologically uniform and appear as slender straight or curved rods, single or in pairs (Fig. BXII.γ.36). No granules of reserve materials are visible under the phase contrast microscope in cells grown under various conditions. No studies on fine structure of thin sections have been reported in the literature.

The cells have two or more polar flagella (Fig. BXII.γ.37),

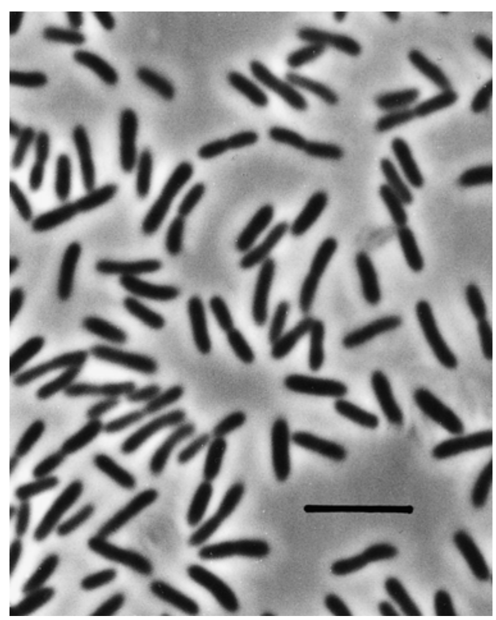

FIGURE BXII.γ.36. Cells of *Stenotrophomonas maltophilia* strain ATCC 13637[T] grown in nutrient broth. Phase contrast. Bar = 5 µm.

**Editorial Note:* The literature search for the chapter on *Stenotrophomonas* was completed in January, 2000. During the course of unavoidable publication delays, a number of new species were described or reclassified after the chapter was completed. It was not possible to include these species in the text or to include their characteristics in the comparative tables. The reader is encouraged to consult the studies listed in the Further Reading section.

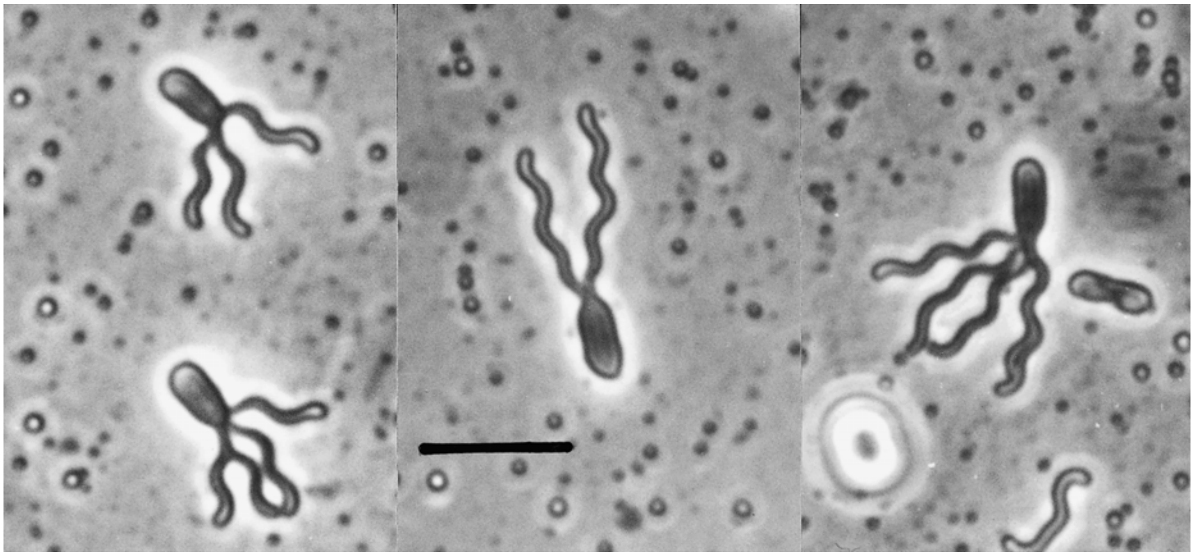

FIGURE BXII.γ.37. *Stenotrophomonas maltophilia* strain ATCC 13637^T. Leifson flagella stain. Bar = 5 μm.

whereas *Xanthomonas* species typically have only one polar flagellum per cell. A flagellin of molecular weight 33 kDa has been isolated (Montie and Stover, 1983).

Polar fimbriae occur in *S. maltophilia*, as well as in several other pseudomonads (Fuerst and Hayward, 1969). These elements may be necessary for attachment to host cells and other solid surfaces, and may also be involved in the twitching motility of the *Stenotrophomonas* cells on solid surfaces (Henrichsen, 1975).

Chemical composition Most studies on cell composition in this genus refer to *S. maltophilia*. This species is resistant to EDTA treatment, whereas *P. aeruginosa* and other species of this genus were found to be particularly sensitive, due to removal of components (metal ions, proteins, lipopolysaccharides, lipids) from the outer membrane of these organisms by the chelator (Wilkinson, 1970; Wilkinson et al., 1973).

An early report on the lipid composition of several species of *Xanthomonas* (Rietschel et al., 1975) shows a marked similarity to the lipid composition of whole cells of *S. maltophilia*, and clear differences from the composition of pseudomonads of other phenotypic groups (Moss et al., 1972, 1973), in agreement with the taxonomic relationships shown by rRNA–DNA hybridization experiments (Palleroni et al., 1973). Both *S. maltophilia* and *Xanthomonas* have a lipid A composition based on glucosamine (Hase and Rietschel, 1976), and similarities in the LPS composition include a high content of rhamnose, the presence of D-galacturonic acid, the absence of a heptose, and a low KDO content (Neal and Wilkinson, 1979, 1982). The major fatty acids of the outer membrane of *S. maltophilia* include 9-methyl-decanoic, 2-hydroxy-9-methyldecanoic, 3-hydroxy-9-methyldecanoic, 3-hydroxydodecanoic, and 3-hydroxy-11-methyldecanoic acids (Wilkinson et al., 1983b).

An interesting feature of the LPS of *S. maltophilia* is the presence of a pentose derivative identified as 3-*O*-methyl-L-xylose, which is also found in unrelated species such as *Rhodopseudomonas viridis* (Weckesser et al., 1974). Other observations on the LPS structure and a possible basis for the serological cross-reaction between *Stenotrophomonas* and *Brucella* have been reported (Di Fabio et al., 1987), as well as details of the synthesis of the tetrasaccharide repeating unit of *Stenotrophomonas* LPS (Liptak et al., 1986). A specific extraction procedure has been described for the study of outer membrane proteins (Chin and Dai, 1990), which participate in the antibiotic susceptibility of *S. maltophilia* strains isolated from clinical species (Cullmann, 1991; Lecso-Bornet et al., 1992; Wilcox et al., 1994).

By transfer to a medium containing carbenicillin and polyvinyl pyrrolidone, Pease et al. (1989) were able to induce the formation of cell-wall-deficient forms in various stages, which were demonstrated using scanning electron microscopy. Induction of rapid reversion to normal bacterial forms has been attributed to plasmids by the authors. This rapid reversion makes it difficult (although not impossible) to maintain cell-wall-deficient strains in media containing carbenicillin.

The efficiency of solute diffusion through the outer membrane of *S. maltophilia* is roughly 3–5% of that of *E. coli*. This low value in *S. maltophilia* is attributed to the low copy number of porins rather than to differences in the size of the channels (Yamazaki et al., 1989).

No hopanes have been found in *S. maltophilia* cells (Rohmer et al., 1979). *Stenotrophomonas maltophilia* contains spermidine and cadaverine as the major polyamine components (Auling et al., 1991; Yang et al., 1993b).

The whole cell fatty acid composition of *Stenotrophomonas* will be discussed under Taxonomic Comments.

Pigmentation The colonies of *S. maltophilia* strains on various complex and chemically defined media are often yellowish. The color, which does not diffuse into the medium, is not due to carotenoid pigments but perhaps to flavins (Stanier et al., 1966; Palleroni and Bradbury, 1993). Although characterization of the pigment is still tentative, it is probably not a xanthomonadin (the pigment characteristic of *Xanthomonas*) or a closely related compound (Starr et al., 1977).

According to a published description (Hugh and Gilardi, 1980), the colonies of *S. maltophilia* characteristically appear lavender-green in color on blood agar media. A greenish discoloration of erythrocytes develops in the area of confluent growth, but there are no signs of hemolysis around isolated colonies. *S. africana* forms faint fluorescent green colonies on Trypticase soy agar and gray colonies on sheep blood agar and on MacConkey

agar at both 30 and 37°C. (Drancourt et al., 1997). No information on the chemical nature of the pigment(s) is available.

Some strains of *S. maltophilia* develop a brown discoloration in agar media—in fact this was the basis for the name *"Pseudomonas melanogena"* (Iizuka and Komagata, 1963a; Komagata et al., 1974)—which may be due not to water-soluble melanin but to a secondary chemical reaction on some extracellular products (Hugh and Gilardi, 1980). The intensity of this brown color is enhanced after growth at 42°C.

Nutrition and growth conditions Many strains of *Stenotrophomonas* require the addition of growth factors (methionine or cystine plus glycine) for growth on chemically defined media (Iizuka and Komagata, 1964b; Hugh and Gilardi, 1980). Methionine-independent strains, however, have been known for many years (Ikemoto et al., 1980). As suggested elsewhere in this chapter, they may represent a different species of *Stenotrophomonas*.

Even though *Stenotrophomonas* species are able to reduce nitrate, this anion is not a nitrogen source for growth. This lack of growth is a useful characteristic for the differentiation of this genus from most other groups of aerobic pseudomonads (Stanier et al., 1966).

A strong ammonia odor develops after growth on blood agar medium (Hugh and Gilardi, 1980). This property is absent from *S. africana* (Drancourt et al., 1997).

Studies on the nutrition of *S. maltophilia* have shown that this species is not as nutritionally versatile as other species of aerobic pseudomonads of the genus *Pseudomonas* and other species formerly assigned to this genus (Stanier et al., 1966). This restricted nutritional capacity was the basis for the proposed new generic name (*Stenotrophomonas*) (Palleroni and Bradbury, 1993). Typically, strains of the two species of this genus utilize some disaccharides (maltose, cellobiose, lactose) as sole carbon and energy sources (Hugh and Ryschenkow, 1961; Stanier et al., 1966; Drancourt et al., 1997). These substrates are rarely utilized by other pseudomonads. Growth on lactose is poor, perhaps because of the fact that the cells do not use galactose.

The strong lipolytic activity of *S. maltophilia* is due, at least in part, to the presence of an esterase in the outer membrane. The esterase may play a role in the utilization of esters as substrates for growth (Debette and Prensier, 1989). The membrane-bound non-specific esterases of many strains have been analyzed by polyacrylamide gel electrophoresis and isoelectric focusing, and the relationship of these observations to the distribution of selected phenotypic properties of the strains supports the idea that species names such as *Pseudomonas beteli* and *P. hibiscicola* should be considered synonyms of *S. maltophilia* (Singer et al., 1994), as suggested by Van Den Mooter and Swings (1990).

A micromethod for the nutritional screening of strains of *S. maltophilia* has been described (Freney et al., 1983). In the earlier study by Stanier et al. (1966), 23 strains of *S. maltophilia* were subjected to an extensive nutritional screening (see the description of this species later in this chapter). No simple alcohols, polyalcohols or glycols, aromatic compounds, amines, various nitrogenous compounds, or paraffin hydrocarbons were utilized by the great majority of strains. Of the 145 substrates tested, only 23 supported growth of all or most strains. The strains tested in this study—provided by Dr. P. Thibault of the Pasteur Institute—had been isolated from various materials of clinical origin. However, later isolations from different natural habitats have resulted in the identification of strains of *S. maltophilia* capable of degrading sulfonic-aromatic compounds (Lee and Clark, 1993), the herbicide Dicamba (3,6-dichloro-2-methoxybenzoic acid) (Yang et al., 1994; Wang et al., 1997), toluene and xylenes (Su and Kafkewitz, 1994), benzoate (Liu et al., 1996b), or chitin (Andreeva et al., 1996; Wiwat et al., 1996). *S. maltophilia* has been isolated from enrichments with kerosene and crude oil, inoculated with soil from petroleum regions in Japan. Although the isolates used hydrocarbons, they rapidly lost this capacity after subculture under laboratory conditions (Iizuka and Komagata, 1964b).

Some of these properties place *Stenotrophomonas* species among those of interest for applications in biotechnology and for bioremediation of contaminated environments. However, it is important to keep in mind that organisms reputed to be opportunistic human pathogens should be used under strictly controlled conditions in large-scale biotechnological projects.

Metabolism Studies on many basic aspects of metabolism and metabolic pathways in this group of bacteria are rather fragmentary. The strains of *Stenotrophomonas* species give a negative oxidase reaction, which is correlated with the lack of cytochrome *c* (Stanier et al., 1966). Neither an α-band at 551–554 nm nor a β-band at 522–524 nm was seen in the spectra. The oxidase reaction was mistakenly recorded as positive by Palleroni and Bradbury (1993), following the report of Van Den Mooter and Swings (1990) who recorded a positive reaction for the majority of their strains. Some strains gave at most a faint positive oxidase reaction.

The metabolism of fructose involves the participation of a phosphoenol-pyruvate (PEP) phosphotransferase system (Sawyer et al., 1977b). *S. maltophilia* is able to use lactose for growth, a property very rare in other aerobic pseudomonads. As mentioned above when dealing with the nutritional aspects of this species, growth on this disaccharide, however, is rather poor, which may be related to the fact that the cells do not use galactose as a carbon source.

In the tyrosine biosynthetic pathway, both *Pseudomonas* and *Stenotrophomonas* strains have a prephenate activity linked to NAD; this activity is sensitive to feedback inhibition in *Stenotrophomonas* but not in *Pseudomonas*. The latter genus also has an arogenate dehydrogenase linked to NAD, an enzyme that is lacking in *Stenotrophomonas* (Byng et al., 1980). Studies on the regulatory pattern of prephenate and arogenate dehydratase activities in the phenylalanine biosynthetic pathways have suggested that *Stenotrophomonas* be classified in the same group as the fluorescent species of *Pseudomonas* (Whitaker et al., 1981b).

In spite of the fragmentary biochemical information that is available, various reports on the isolation and properties of a number of enzymes are found in the literature. These refer to proteases (Debette, 1991; Margesin and Schinner, 1991; Singer and Debette, 1993), peptidases (Stevens et al., 1990; Suga et al., 1995; Kabashima et al., 1996), cocaine esterase (Britt et al., 1992a), a secondary alcohol dehydrogenase that has little activity on primary and aromatic alcohols (Britt et al., 1992b), deoxyribonuclease (Scally and Winder, 1991), and enzymes involved in ADP ribosylation (Edmonds et al., 1989), a mechanism of action found in important bacterial toxins. The peptidyl dipeptidase activity of *S. maltophilia* appeared to be the most active among those of 24 different bacterial species examined (Stevens et al., 1990).

Studies on the *S. maltophilia* β-lactamases will be mentioned in the section on antibiotic susceptibility.

As stated elsewhere, *S. maltophilia* is unable to use nitrate as a nitrogen source, but it can reduce this anion to nitrite (Iizuka

and Komagata, 1964b; Stanier et al., 1966). The nitrate reductase of some strains has been characterized (Woodward et al., 1990; Ketchum and Payne, 1992). A membrane-bound methyl viologen nitrate reductase and a soluble molybdopterin have been described in a study on 23 strains of *S. maltophilia* (Woodward et al., 1990).

The above studies point to the fact that in the reduction of nitrate to nitrite, the former can act as an electron sink when the organisms are growing under semiaerobic conditions. In a study of utilization of toluene and xylenes by a strain of *S. maltophilia*, these aromatic substrates were used under low oxygen and anoxic conditions in the presence of nitrate (Su and Kafkewitz, 1994). For strains with nitrite and nitrate reductase activity, see the note at the end of the list of species.

Phages and plasmids The information available on these subjects is scanty and fragmentary. The sensitivity of *Xanthomonas* showed a major overlap with the sensitivity of *S. maltophilia* among the various species then assigned to the genus *Pseudomonas* (Starr, 1981). This finding is a further confirmation of the phylogenetic relationship between *Xanthomonas* and *Stenotrophomonas* as members of the *Gammaproteobacteria*.

It has to be admitted, however, that the practical application of phage sensitivity as a diagnostic tool frequently fails to fulfill expectations. As stated by Billing and Garrett (1980) with reference to problems of identification of plant pathogenic bacteria, "phages potentially useful in diagnosis have been found in some cases, but all too often in other cases they have proved nonspecific or too specific." However, there are instances in which phage sensitivity may become an important piece of evidence pointing to basic phylogenetic relationships. For example, a phage lytic for *Pseudomonas* species, both fluorescent and nonfluorescent, but not for *S. maltophilia*, was isolated from sewage and described in detail (Kelln and Warren, 1971). On the other hand, the isolation of a temperate phage capable of plaque formation on both *P. aeruginosa* and *S. maltophilia* has been described (Moillo, 1973).

Some factors required for phage nucleic acid replication may be conserved through evolution in some groups of Gram-negative bacteria. One of the elements required for *in vitro* replication of sex-specific single stranded RNA coliphage Qβ is the so-called host factor (HF), which is a heat-resistant RNA-binding protein of molecular weight 12,000, usually present in *E. coli* as a hexamer (Franze de Fernández et al., 1972). A component able to cross-react with an *E. coli* HF antiserum was detected in the extracts of a number of species of aerobic pseudomonads, among them, *S. maltophilia* (DuBow and Ryan, 1977). Cell extracts of members of rRNA similarity groups I and V (*Pseudomonas*, *Xanthomonas*, and *Stenotrophomonas*) had HF activity after heat treatment. Heat-treated extracts of species of pseudomonads belonging to different branches of *Proteobacteria* did not stimulate replication of Qβ RNA and, in addition, they inhibited the activity of systems containing saturating amounts of *E. coli* HF, in other words, they contained a heat-resistant inhibitor.

The promiscuous IncP-1 plasmid R18 was analyzed by means of Tn7 insertion mutations in the Tra1 region, involved in conjugational transmissibility from *P. aeruginosa* to other species, including *S. maltophilia* (Schilf and Krishnapillai, 1986).

From a collection of 18 strains of *S. maltophilia*, 5 were shown to harbor plasmids, of which one was studied in some detail. Its molecular weight is 4.4×10^6 daltons, and the presence of several single restriction sites makes it promising as a cloning vector (Shen et al., 1992).

Antigenic properties A 30 kDa immunoglobulin binding protein was isolated from *S. maltophilia* (Grover et al., 1991a) and later partially characterized (Grover and Odell, 1992). The protein binds IgGs of various subclasses and IgA at their Fc regions. A substantial number of reports on the composition of several antigens in the outer membrane of *S. maltophilia* by Prof. Wilkinson and collaborators can be found in the literature (Winn et al., 1995, 1996; Winn and Wilkinson, 1995, 1996, 1997).

A serological classification of *S. maltophilia* strains based on the heat-stable O antigens has been proposed, extending the 15 serotypes defined by antisera in previous investigations (Hugh and Ryschenkow, 1961) to a total of 26 (Schable et al., 1989).

The isolation of a membrane protein capable of cross-reacting with the β subunit and carboxyl tail of human pregnancy chorionic gonadotropin (hCG), was described (Grover et al., 1991b, 1993b; Carrell et al., 1993). The partial sequence of the receptor soon followed (Grover et al., 1993a). A complete sequence of the gene encoding the *S. maltophilia* gonadotropin-like protein is now available (Grover et al., 1995). Exposed sites on *S. maltophilia* cells bind both hCG and the native hCG-like ligand with equal affinity (Carrell and Odell, 1992).

Antibiotic sensitivity The high frequency of detection of *S. maltophilia* as an opportunistic pathogen and isolation from materials of clinical origin, has prompted numerous studies on the susceptibility of the strains to various antibiotics, as well as the intrinsic and exogenous conditions that affect such sensitivity (Cullmann, 1991; Lecso-Bornet et al., 1992; Sader et al., 1994; Wilcox et al., 1994; Poulos et al., 1995; Rahmati-Bahram et al., 1995, 1996; Vanhoof et al., 1995; Alonso and Martínez, 1997). The conditions for laboratory tests have also been examined (Yao et al., 1995).

S. maltophilia is resistant to most β-lactam antibiotics, and the aminoglycosides and quinolones have a modest activity (García-Rodríguez et al., 1991). However, some quinolones have been found to be quite active (Furet and Pechere, 1991), in particular, clinafloxacin (Visalli et al., 1997). In a Japanese study on *S. maltophilia* strains isolated from clinical materials, high sensitivity to minocycline was observed. The sensitivity did not show the yearly changes recorded for *P. aeruginosa* (Tabe and Igari, 1994). *S. africana* has an antibiotic susceptibility restricted to netilmicin, ciprofloxacin, trimethoprim-sulfamethoxazole, and colimycin (Drancourt et al., 1997).

A report on the transmission of antibiotic resistance from *S. maltophilia* to *Pseudomonas aeruginosa* calls attention to the combined danger that these two species represent as the most common Gram-negative opportunistic pathogens in the hospital environment (Babalova et al., 1995). Laboratory experiments with a strain of *S. maltophilia* have shown the possibility of transferring to other species its multiple resistance to drugs (which included amikacin and cephalosporins) coded for by genes in an R plasmid (Krcmery et al., 1985). Interestingly, antibiotic and heavy metal resistance genes of Gram-positive origin, also detected in *Staphylococcus aureus*, have been identified in a *S. maltophilia* strain of clinical origin (Alonso et al., 2000).

Among the resistance factors of *S. maltophilia*, β-lactamases have received much attention (Paton et al., 1994; Felici and Amicosante, 1995; Bonfiglio et al., 1995; Kelly and Mortensen, 1995). Sequence studies on the L1 metallo-β-lactamase have discovered significant differences from similar enzymes present in *Aeromonas hydrophila* and *Bacillus cereus*, which resulted in the addition of a new subclass of this type of enzymes to the ones already known (Walsh et al., 1994). The L1 penicillinase *blaS* gene of *S. malto-*

philia was cloned in *E. coli*, where it could express its capacity for imipem hydrolysis (Dufresne et al., 1988).

A recent study of the L2 serine β-lactamase from *S. maltophilia* has demonstrated that this enzyme is a clavulanic acid-sensitive cephalosporinase related to a β-lactamase from *Yersinia enterocolitica* (Walsh et al., 1997a).

A number of antibiotics have been tested against *S. africana* using the disk diffusion technique (Drancourt et al., 1997). This species appeared to be susceptible to netilmicin, ciprofloxacin, trimethoprim-sulfamethoxazole, and colimycin.

An antifungal compound, maltophilin, is produced by *S. maltophilia*. It is active against human and plant pathogenic fungi (Jakobi et al., 1996).

Relationships to plants A predominance of *S. maltophilia* over other pseudomonads has been observed in the rhizosphere of several cultivated plants, such as cabbage, rape, mustard, corn, and beet (Debette and Blondeau, 1980). Some of these plants have proteins of high sulfur content, and the abundance of *S. maltophilia*, which requires S-containing amino acids like methionine, may be due to excretion of such compounds by the roots. However, methionine could not be detected in significant amounts in the rhizosphere.

In the rhizosphere of oilseed rape, *S. maltophilia* is able to interfere with growth of plant pathogenic fungi (Berg et al., 1996). The antifungal compound maltophilin (Jakobi et al., 1996) may be involved in this activity. Use of chitinolytic strains of *S. maltophilia* has been proposed for biological control of summer patch on turf grass (Kobayashi et al., 1995).

S. maltophilia has been found on the surface of leaves of the grass *Lolium perenne*, although at a low frequency in comparison to other aerobic pseudomonads (Austin et al., 1978).

Pathogenicity for humans *S. maltophilia* has been implicated as a direct agent of disease and as the cause of secondary infections that aggravate various human pathological conditions. It has been identified in cystic fibrosis (Gladman et al., 1992; Denton et al., 1996), cancer (Khardori et al., 1990; Elsner et al., 1997), meningitis (Nguyen and Muder, 1994; Papadakis et al., 1997), soft tissue infections (Vartivarian et al., 1994), septic bursitis (Papadakis et al., 1996), urinary tract infections (Vartivarian et al., 1996), bacteremia (Muder et al., 1996), endophthalmitis following surgical procedures (Kaiser et al., 1997), and pneumonia (Elsner et al., 1997). The literature records concern for the emergence of the species as a dangerous opportunistic pathogen (Marshall et al., 1989), and for the role of anti-pseudomonadal antibiotics in this process.

A method based on the PCR technique for the detection of *Pseudomonas aeruginosa*, *Burkholderia cepacia*, and *S. maltophilia* in sputum of cystic fibrosis patients has been described, but the specificity is low for *S. maltophilia*, which may be due to improper PCR conditions (Karpati and Jonasson, 1996). It is interesting to mention here that strains of *S. maltophilia* do not produce alginate, and that genetic studies have demonstrated failure to transfer a plasmid carrying the gene *algT* from *P. aeruginosa* to *S. maltophilia*. The studies also failed to identify sequences homologous to this gene in samples examined by Southern analysis (Goldberg et al., 1993).

The type strain of *S. africana* was isolated from an HIV patient who exhibited primary meningoencephalitis (Drancourt et al., 1997).

Ecology The variety of materials from which *S. maltophilia* can be isolated is truly remarkable. A list compiled by Hugh and Gilardi includes raw and pasteurized milk; well, stagnant, and river waters; sewage; frozen fish; feces of snakes, lizards, frogs, and rabbits; rotten eggs; and soil in petroleum zones. It has been isolated from the internal tissue of banana pseudostem, decaying banana sucker, cotton seed, bean pod, and tobacco seedling (Hugh and Gilardi, 1980). Strains similar to *Xanthomonas* and *Stenotrophomonas* have been frequently isolated from biofilms for waste gas treatment (Lipski et al., 1992; Lipski and Altendorf, 1997). Some strains have been assigned to a new species, *Stenotrophomonas nitritireducens* (Finkmann et al., 2000) (see note at the end of the list of species). From a soda lake, an alkaliphilic strain was studied by Duckworth et al. (1996).

For years, the species has been associated with a variety of infections in humans (Sutter, 1968; Gilardi, 1971), and it could be found in "contaminated tissue culture, streptomycin solution, distilled water, incubator reservoirs, respirators, nebulizers, and evacuated blood collection tubes" (Hugh and Gilardi, 1980). As mentioned above, strains of the species have been isolated from the rhizosphere and aerial parts of plants. These organisms may represent a very high proportion of the non-fermentative, Gram-negative bacteria in the soil microflora (Debette and Blondeau, 1977), and they have been isolated in large numbers from manured soils in Japan (Katoh and Suzuki, 1979) (cited by Ikemoto et al., 1980). The isolation of three strains similar to *S. maltophilia*, from gut and feces of the arthropod *Folsomia candida* was reported by Duckworth et al. (1996).

The distribution of *S. africana* in nature is not known.

Enrichment and Isolation Procedures

Strains of *S. maltophilia* have been isolated from a bewildering variety of materials (Hugh and Gilardi, 1980) and they are second only to *P. aeruginosa* in the frequency of isolation in hospitals and clinical laboratories. Because the nutritional spectrum of the species is so restricted, it is not possible to design effective enrichment procedures based on carbon sources specifically used by strains of *S. maltophilia*. As mentioned elsewhere (Table BXII.γ.28), some carbon sources (maltose, lactose, cellobiose) are used by *S. maltophilia* strains and not by strains of other species of aerobic pseudomonads. However many other organisms found in natural samples are capable of using these substrates, which conspires against the effectiveness of enrichment procedures based on their use by *S. maltophilia*. The fact that so many strains have been isolated using traditional bacteriological procedures is indicative of their wide occurrence in appreciable numbers in many natural materials. In view of the fact that many strains require growth factors (methionine or other amino acids), direct isolation is best performed by streaking plates of any of several

TABLE BXII.γ.28. General characteristics of *S. maltophilia*

complex media (Difco Nutrient Agar, Trypticase Soy, Brain Heart Infusion, etc).

Maintenance Procedures

As with most aerobic pseudomonads, *S. maltophilia* can be maintained in slants of common complex culture media, with transfers every one or two months. Although there is no information about *S. africana*, the above considerations might also apply to this species. *S. maltophilia* tolerates freeze-drying well, although freezing of cell suspensions at $-20°C$ or lower after addition of a cryo-protecting agent like glycerol (5–10% final concentration) may be the most reliable method for long-term preservation, since some strains do not revive from freeze-dried preparations.

Procedures for Testing Special Characters

Screening for nutritional properties Details of the methodology for determination of the nutritional spectra of aerobic pseudomonads are available (Stanier et al., 1966; Palleroni and Doudoroff, 1972; Palleroni, 1984). A simple minimal medium that does not include strong chelating compounds (Palleroni and Doudoroff, 1972)[1] gives better results than that of earlier formulations (Terry et al., 1991). Methionine (50 μg/ml) should be added from a sterile stock solution after the medium has been autoclaved. Good heterotrophic growth can be obtained by adding to the medium a single organic compound as carbon and energy source to a final concentration of 0.1%. Some compounds may be toxic at this concentration, but even if this is reduced to 0.0125%, visible growth above the level of the control without substrate can be obtained. Precautions and useful suggestions can be found in the above-mentioned papers.

Acid production from carbohydrates The recommended medium (Hugh and Leifson, 1953)[2] gives clear and reproducible results. It contains a small amount of peptone, and ammonification does not interfere with the acid production. As mentioned by Palleroni and Doudoroff (1972), the results do not necessarily correlate with utilization of the substrates for growth. There may be redundancy in some of the results, since a single dehydrogenase may cause acid production from different sugars.

Hydrolysis of Tween 80 The test devised by Sierra (1957) for the detection of lipolytic activity is very simple and the results are clear. Sierra's medium[3] contains Tween 80 and calcium chloride, and opacity formation around the patches of growth or the individual colonies indicates precipitation of calcium salts of the fatty acids liberated by lipases (Sierra, 1957).

Nitrate reduction Reduction of nitrate to nitrite can be tested according to Lelliott et al. (1966).

Oxidase reaction A description of this test can be found in the paper by Stanier and collaborators (Stanier et al., 1966).

Gelatinase Of the several techniques that have been proposed, the one described by Skerman (1967) is most convenient.

Egg yolk reaction The egg yolk test has been used for many years to detect lecithinase production (Esselman and Liu, 1961). However, the reaction is quite complex, although the results are in most cases clear and reproducible. The test can be performed according to published procedures (Lelliott et al., 1966; Stanier et al., 1966).

Catalase reaction The presence of catalase is simply tested by placing a drop of a hydrogen peroxide solution on top of a colony and observing the formation of bubbles of free O_2. The observation may be facilitated by using a dissecting microscope. In cases where the reaction is very weak, the use of an oxygen electrode may be advisable (Auling et al., 1978).

Nucleic acid hybridization Several methods are in use. In some of them, one of the DNA partners is immobilized on a membrane (Johnson, 1994a; Ballard et al., 1970; Palleroni et al., 1972). More stringent conditions are obtained by hybridization in solution followed by hydrolysis of single strands using S1 nuclease (Johnson and Palleroni, 1989; Johnson, 1994a). rRNA–DNA hybridization, as originally applied (Palleroni et al., 1973), has been largely replaced by sequence studies of PCR-amplified genes (Johnson, 1994b).

Fatty acid analysis Although several analytical procedures based on similar principles are in use, the method described by Stead (1992) can be recommended for the pseudomonads.

Differentiation of the genus *Stenotrophomonas* from other genera

Stenotrophomonas can be easily differentiated from other genera of aerobic pseudomonads. The salient characteristics of *Stenotrophomonas* include the requirement for growth factors (mainly methionine), the inability to use nitrate as a nitrogen source, and the restricted range of substrates that can be used as sole carbon and energy sources. A clear differentiation of *S. maltophilia* from species of various genera of aerobic pseudomonads is possible using the small group of selected characteristics shown in Table BXII.γ.28. When the occurrence of these characters is scored for various other groups of pseudomonads, a clear separation is evident (Table BXII.γ.29). As stated elsewhere (Stanier et al., 1966), these organisms constitute the most isolated group among the aerobic pseudomonads. Useful phenotypic characteristics for the differentiation of *S. maltophilia* and *S. africana* from some species of aerobic pseudomonads are given in Table BXII.γ.30. *S. nitritireducens* could not be included in the table since no pertinent phenotypic details are given in the characterization of this species.

Taxonomic Comments

Strains of *S. maltophilia* were included in the phenotypic study of Stanier et al. (1966), and their phenotypic characteristics were precisely defined. Later studies by Palleroni et al. (1973) separated this species from all other species of *Pseudomonas* and allocated it to rRNA similarity group V, together with the species of the genus *Xanthomonas*. Based on these results, Swings et al. (1983) proposed the transfer of *P. maltophilia* to the genus *Xanthomonas*, a decision that did not receive universal approval. In a study on numerical taxonomy and protein gel electrophoresis patterns as tools for the differentiation of pseudomonads, van Zyl and Steyn (1990) showed that *S. maltophilia* and *Pseudomonas hibiscicola* constituted a cluster that was not significantly close to

1. Medium of Palleroni and Doudoroff (1972) (g/l of 0.33 M Na-K phosphate buffer, pH 6.8): NH_4Cl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; ferric ammonium citrate, 0.05; and $CaCl_2$, 0.005. The first two ingredients are added to the buffer and sterilized by autoclaving. The ferric ammonium citrate and $CaCl_2$ are added aseptically from a single stock solution that has been sterilized by filtration.

2. Hugh and Leifson medium (g/l): peptone 2.0; NaCl, 5.0; K_2HPO_4, 0.3; agar, 3.0; brom thymol blue, 0.03; carbohydrate, 10.0; pH 7.1.

3. Sierra's medium (g/l): Bacto-peptone (Difco), 10.0; NaCl, 5.0; $CaCl_2 \cdot H_2O$, 0.1; and agar, 17.0. Tween 80 is sterilized separately and added to the medium after autoclaving to give a final concentration of 10 g/l.

[a]Each figure in the table represents the number of strains positive for a given number of the characteristics listed in Table BXII.γ.28.

the *Xanthomonas* group, and the authors found it reasonable to accept the suggestion of Palleroni (1984) for the creation of a new genus name for the strains, which were at the time labeled *Xanthomonas maltophilia*. In fact, a later paper by the same authors (van Zyl and Steyn, 1992) clearly highlighted the differences between *X. maltophilia* and the xanthomonads, and presented compelling evidence that culminated in the proposal of the new genus *Stenotrophomonas* by Palleroni and Bradbury (1993).

Xanthomonas has been classically defined as a group of plant-pathogenic organisms and, from what we know about *Stenotrophomonas*, the pathogenic propensities of the two species assigned to the genus seem to be directed to human hosts. We know very little about the relationship of *S. maltophilia* with plants, but, as indicated in an earlier section of this chapter, the association seems to be a beneficial one. But even if we discard the value of these qualifications as part of a genus definition, various other characteristics have been invoked elsewhere to support allocating *(Xanthomonas) maltophilia* to a different genus (Palleroni and Bradbury, 1993). Additional evidence supporting this criterion is summarized in the following paragraphs.

Restriction analysis of PCR-amplified 16S rRNA genes, performed on a collection of *Xanthomonas* and *Stenotrophomonas* strains, resulted in the definition of 19 restriction fragment length polymorphism (RFLP) groups, which subsequently could be subdivided into two main clusters, one containing all the *Xanthomonas* species, and the other, *S. maltophilia*. An examination of the relationship between the DNA similarities as determined by hybridization methods, and the nucleotide substitution rate in the small rRNA subunit, confirmed the differentiation of the two genera (Nesme et al., 1995). A rapid method of classification based on PCR has demonstrated the production of DNA fragments in *S. maltophilia* extracts different from those obtained from the *Xanthomonas* strains tested (Maes, 1993).

S. maltophilia was included in a study using the AFLP (amplified fragment length polymorphism) technique (Janssen et al., 1996). As in the case of RFLP, this promising method has resulted in dendrograms that confirm relationships derived from other molecular approaches (Janssen et al., 1996; Rademaker et al., 2000).

Analysis of fatty acid composition for a large collection of strains of the genus *Xanthomonas* by Yang et al. (1993d) revealed the presence of nine fatty acids in more than 99% of the *Xanthomonas* strains. Three of the acids ($C_{11:0\ iso}$, $C_{11:0\ iso\ 3OH}$, and $C_{13:0\ iso\ 3OH}$), are characteristic for the genus and therefore are taxonomically important to differentiate it from related genera. *S. maltophilia* strains contained the nine typical fatty acids, but, in addition, they were characterized by the presence of the fatty acid $C_{17:0}$ cyclopropane, which was absent from *Xanthomonas* species, with the exception of *X. campestris* pathovar *hyacinthi*. There was great uniformity in the fatty acid composition of the *S. maltophilia* strains, although they had been isolated from very diverse materials, but the DNA homology values among them ranged from 37 to 100% according to Ikemoto et al. (1980).

In a study of a large collection of *S. maltophilia* strains isolated from environmental and clinical sources, Hauben et al. (1999b) found a striking phenotypic uniformity but considerable genomic heterogeneity, and ten genomic groups were observed. However, the lack of conventional phenotypic traits by which the various groups could be identified has prevented the authors from proposing a subdivision of *S. maltophilia* into different species.

Ikemoto et al. (1980) reported the results of studies on *Pseudomonas maltophilia* strains that do not require methionine. Strains of this new biovar (biovar II) differ from *S. maltophilia* (biovar I) in phenotypic properties, fatty acid composition, DNA composition, and requirement for methionine as an organic growth factor. DNA–DNA hybridization studies also point to DNA sequence differences between the two groups. Subsequently, Ha and Komagata (1984) extended the studies to the electrophoretic behavior of six enzymes, with results confirming the differences between the biovars.

Singer et al. (1994), in a comparison between phenotypic properties and esterase electrophoretic polymorphism, included another group of strains not requiring methionine, and confirmed the differences from *S. maltophilia* observed by the Japanese workers. At this point, sufficient evidence is available to suggest that biovar II of *S. maltophilia*, defined by Ikemoto et al. (1980), should be assigned to a new species of the genus. The observed differences in general properties and in DNA–DNA hybridization values clearly support this suggestion.

As previously mentioned, the phage isolated from sewage by Kelln and Warren (1971) was lytic for species of *Pseudomonas* but did not lyse *S. maltophilia* or strains of species of homology groups other than group I. The phylogenetic significance of this finding became apparent after demonstration of the genomic heterogeneity of the genus *Pseudomonas*, as classically defined.

List of species of the genus Stenotrophomonas

1. **Stenotrophomonas maltophilia** (Hugh 1981) Palleroni and Bradbury 1993, 608[VP] (*Pseudomonas maltophilia* Hugh 1981,195; *Xanthomonas maltophilia* Swings, De Vos, Van Den Mooter and De Ley 1983, 412.)
mal.to.phi' li.a. Anglo-Saxon n. *malt* Gr. n. *philia* friend; M.L. fem. n. *maltophilia* friend of malt.

Straight or slightly curved rods, 0.5 × 1.5 μm, occurring singly or in pairs. Motile by means of polar multitrichous flagella. Do not accumulate PHB as an intracellular reserve material. Colonies may be yellow or greenish yellow. The yellow color is not due to carotenoid pigments or xanthomonadins. Reduction of nitrate to nitrite is positive, but denitrification does not occur. The oxidase reaction is negative. Strongly lipolytic. Gelatinase reaction positive. Ammonia odor can be produced by colonies on blood agar. Methionine or cystine is required for growth, although strains lacking this requirement may be isolated (Ikemoto et al., 1980).

Limited in its nutritional spectrum. Individual strains used between 24 and 28 of 146 organic compounds tested as main carbon and energy sources (Stanier et al., 1966). The utilizable compounds were: glucose, mannose, sucrose, trehalose, maltose, cellobiose, lactose, salicin, acetate, propionate, valerate, malonate, succinate, fumarate, L-malate, lactate, citrate, α-ketoglutarate, pyruvate, L-alanine, D-alanine, L-glutamate, L-histidine, and L-proline. A variable number of strains also used fructose, isobutyrate, aconitate, and *n*-propanol. Under aerobic conditions, acid is readily produced in complex media with maltose but not with glucose (Hugh and Ryschenkow, 1960). Nitrate is not used as a nitrogen source.

No growth at 4°C or 41°C. Optimum growth temperature, 35°C. Many strains can be isolated from various natural materials, and frequently from clinical specimens. According to Hugh and Gilardi (1980), *S. maltophilia* is the second most frequently isolated aerobic pseudomonad, after *P. aeruginosa*, in the clinical laboratory. Strains of the species appear to be opportunistic human pathogens. Also found in water, milk, frozen foods, and many other sources. Debette and Blondeau (1980) were able to isolate more strains of *S. maltophilia* than of any other pseudomonad from the rhizosphere of some cultivated plants. Ikemoto et al. (1980) defined two biovars of this species and further studies perhaps will demonstrate that one of them (biotype II) deserves independent species status within the genus *Stenotrophomonas*.

The mol% G + C of the DNA is: 66.9 ± 0.8 (Bd) (Mandel, 1966).

Type strain: ATCC 13637, Hugh 810-2, DSM 50170, ICPB 2648-67, IMET 10402, NCIB 9203, NCTC 10257, NRC 729, RH 1168.

GenBank accession number (16S rRNA): M59158, X95923, AB008509.

2. **Stenotrophomonas africana** Drancourt, Niel and Raoult 1997, 162[VP]
a.fri.ca' na. L. adj. *africana* from Africa.

Curved rods, 0.5 × 1.5 μm. Motile by means of two polar flagella. Colonies are gray to green. No ammonia odor is produced on blood plates. Indole and oxidase reactions are negative. Catalase positive. Basic phenotypic properties are similar to those of *S. maltophilia*, among them the basic biochemical characteristics, except for the failure to assimilate *cis*-aconitate. A total of 24 of 1377 16S rDNA base positions are different from those of *S. maltophilia*, and the DNA–DNA similarity between the two species is 35%. Isolated from the cerebrospinal fluid of a patient testing positive for HIV antibodies and exhibiting primary meningoencephalitis (Drancourt et al., 1995, 1997).

The mol% G + C of the DNA is: not known.

Type strain: MGB, CIP 104854.

GenBank accession number (16S rRNA): U62646.

3. **Stenotrophomonas nitritireducens** Finkmann, Altendorf, Stackebrandt and Lipski 2000, 281[VP]
ni.tri.ti.re.du' cens. M.L. *nitritis* nitrite; L. *reducere* to reduce; L. part. pres. *reducens* reducing; M.L. part. pres. *nitritireducens* reducing nitrite.

The following description is transcribed in its entirety from the original publication by Finkmann et al. (2000). Predominant fatty acids are $C_{15:0\ iso}$, $C_{17:0\ iso\ \omega7c}$, $C_{16:0\ iso}$, $C_{14:0\ iso}$, and $C_{15:0\ anteiso}$. $C_{17:0\ cyclo}$ and $C_{13:0\ iso\ 3OH}$ are present. The strains reduce nitrite to nitrous oxide, nitrate is not reduced, and nitrous oxide is the end product. Esculin is not hydrolysed and lecithin is not degraded. The strains grow in the presence of 0.01% $ZnCl_2$. The strains are resistant to fucidin, tetracycline, and novobiocin, but susceptible to streptomycin, nalidixic acid, and kanamycin. The strains show strong hydrolytic activity for *p*-nitrophenyl N-acetyl-β-D-glucosaminide. The strains were isolated from experimental biofilters supplied with artificial waste gases containing ammonia or ammonia and dimethyl disulfide. One strain (B1910/29.1) was isolated from an experimental biofilter supplied with the waste gas of an animal-rendering plant.

The mol% G + C of the DNA is: not known.

Type strain: L2, DSM 12575.

GenBank accession number (16S rRNA): AJ012229.

An examination of the properties reported in the above description clearly shows that a comparison of *S. nitritireducens* with *S. maltophilia* and *S. africana* is not possible, in view of the disparity of criteria used for characterization. Therefore, with the exception of nucleic acid similarity data, there is no phenotypic information that may account for assignment of *S. nitritireducens* to the genus *Stenotrophomonas*, and this species has been excluded from Table BXII.γ.30.

Genus X. **Thermomonas** *Busse, Kämpfer, Moore, Nuutinen, Tsitko, Denner, Vauterin, Valens, Rosselló-Mora and Salkinoja-Salonen 2002, 480*[VP]

Ewald B.M. Denner, Peter Kämpfer and Hans-Jürgen Busse

Ther.mo.mo'nas. Gr. n. *therme* heat; *monas* a unit, monad; M.L. fem. n. *Thermomonas* a thermophilic monad.

Gram-negative filamentous rods (1.0–12.5 × 0.5–0.75 μm). Motile by means of polar monotrichous flagellation or nonmotile. **Aerobic**. Endospores are not formed. **Moderately thermophilic**; temperature range for growth is 18–50°C, with an **optimum between 37 and 50°C**. **Catalase and oxidase positive**. Chemoorganotrophic. **Carbohydrates are usually not utilized**. Indole, Voges–Proskauer, methyl red, and Simmons citrate tests are negative. Urea is hydrolyzed. **Nitrate is not reduced to nitrite or nitrogen**; H_2S is not produced. **Ubiquinone Q-8** is the major respiratory lipoquinone system. The main component in the cellular polyamine content is **spermidine**. Polar lipid fingerprints are characterized by the presence of diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylglycerol. Cellular fatty acids are predominantly **iso-branched** with $C_{15:0\ iso}$ and $C_{16:0\ iso}$ as major components; other characteristic fatty acids are $C_{11:0\ iso}$, $C_{11:0\ iso\ 3OH}$, and $C_{17:1\ iso\ \omega9c}$. Based on 16S rRNA gene sequence data, *Thermomonas haemolytica* currently forms **a separate line of descent within the *Xanthomonadaceae* related to the genera *Xanthomonas*, *Pseudoxanthomonas*, *Luteimonas*, *Stenotrophomonas*, and *Xylella*.**

The mol% G + C of the DNA is: 67.1–68.7.

Type species: **Thermomonas haemolytica** Busse, Kämpfer, Moore, Nuutinen, Tsitko, Denner, Vauterin, Valens, Rosselló-Mora and Salkinoja-Salonen 2002, 480.

Further descriptive information

Currently, the genus contains only a single species, *T. haemolytica*. The four strains (A50-7-3[T], B50-7-1, B50-8-1, and D50-7-1) of the only species yet described characteristically show a marked β-hemolysis on blood agar. Cells of *T. haemolytica* are rod-shaped with a typical Gram-negative cell wall structure and have a tendency to form filaments (Fig. BXII.γ.38). *T. haemolytica* is motile by means of a polar flagellum. While tumbling can be frequently noticed, directed movement is only rarely observable. Motility of the cells is most pronounced at 37°C and higher. The flagellation of the cells can be visualized by the staining procedure of Kodaka et al. (1982), but has not yet been observed by electron microscopy.

T. haemolytica grows well on standard bacteriological media such as Tryptone soy agar (TSA), Luria–Bertani (LB) medium, or nutrient agar. Colonies on standard media are circular, smooth, and convex with an entire edge. At 50°C colonies are whitish/translucent, and at 37°C, transparent. After prolonged incubation (2–3 d) on TSA at 50°C, *T. haemolytica* produces a diffusible brownish discoloration of the medium and a characteristic ammonium-like odor. The temperature range for growth is 18–50°C; no growth occurs at 14 or 53°C.

Cellular fatty acid analyses indicate that with increasing growth temperature, over a range of 23–50°C, the proportion of unsaturated fatty acids in *Thermomonas haemolytica* decreases from 24% to 2.7% (mean of the four strains) of total fatty acids, mainly due to a decrease in the content of $C_{17:1\ iso\ \omega9c}$. The relative amount of $C_{17:0\ iso}$ remains constant in cells growing over the whole temperature range. This may indicate that the adaptation to growth at high temperatures by *Thermomonas haemolytica* does not occur by increasing the ratio of $C_{17:0\ iso}$ to $C_{17:1\ iso\ \omega9c}$. Instead, the relative proportion of the major fatty acid, $C_{15:0\ iso}$, increases with increasing growth temperature. Interestingly, the relative amounts of short chain fatty acids, $C_{11:0\ iso}$ and $C_{11:0\ iso\ 3OH}$, also increase slightly at 50°C (Busse et al., 2002).

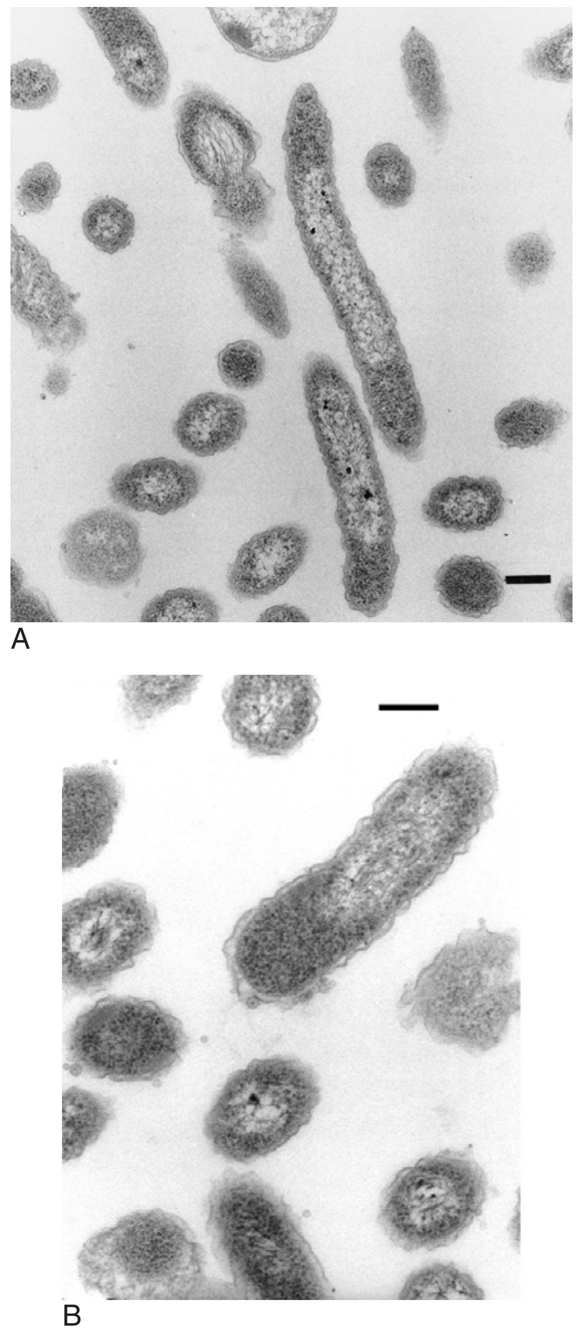

FIGURE BXII.γ.38. Electron micrographs of ultrathin sections of cells of *T. haemolytica* A50-7-3[T] showing (*A*) the filamentous and (*B*) rod-shaped forms. Bars = 200 nm. (Reprinted with permission from H.-J. Busse et al., International Journal of Systematic and Evolutionary Microbiology *52:* 473–483, 2002, ©International Union of Microbiological Societies.)

T. haemolytica also grows well on R2A agar, a low-nutrient complex medium developed previously for the enumeration and subculture of heterotrophic bacteria in potable water (Reasoner and Geldreich, 1985). *T. haemolytica* does not grow on the chemically defined yet simpler Czapek–Dox medium, which contains only sodium nitrate as inorganic source of nitrogen and sucrose as sole source of carbon.

As tested on selective/differential media, *T. haemolytica* is not able to grow in the presence of bile salt–neutral red (MacConkey agar) or in the presence of the cationic detergent cetyl trimethylammonium bromide (cetrimide agar). *T. haemolytica* is susceptible to amoxycillin/clavulanic acid, ampicillin, cephalexin, chloramphenicol, colistin sulfate, erythromycin, fusidic acid, gentamicin, kanamycin, neomycin, penicillin G, polymyxin B, streptomycin, and tetracycline, but is resistant to lincomycin, nitrofurantoin, and sulfamethoxazole/trimethroprim.

T. haemolytica characteristically uses only a limited number of organic acids and amino acids as a single source of carbon, whereas *T. haemolytica* A7-3-1^{T} is the most versatile strain and B50-8-1 the most inactive strain of the four *T. haemolytica* strains (Table BXII.γ.31). Strain B50-8-1 is also somewhat distinct from the other three *T. haemolytica* strains, on the basis of mol% G + C content of DNA (67.1); however, by DNA–DNA similarity, riboprint patterns, and AFLP profiles strain B50-8-1 is univocally a strain of *T. haemolytica* (Busse et al., 2002).

Enrichment and Isolation Procedures

The four strains of *T. haemolytica* were isolated at different times from papermaking chemicals (kaolin and pigment slurries) that were plated onto Plate Count Agar (Difco) with subsequent incubation at 50°C (Väisänen et al., 1998).

TABLE BXII.γ.31. Physiological and biochemical characteristics of the *Thermomonas haemolytica* strains[a]

Characteristic	A50-7-3^{T}	B50-7-1	D50-7-1	B50-8-1
Assimilation of:				
Acetate	+	−	+	−
Propionate	+	+	−	−
cis-Aconitate	+	+	−	−
L-Malate	+	−	−	−
Mesaconate	+	+	−	−
Oxoglutarate	+	−	−	−
Pyruvate	+	+	+	−
L-Alanine	+	+	−	−
L-Aspartate	+	+	−	−
L-Phenylalanine	+	−	−	−
L-Proline	−	+	−	−
L-Serine	+	−	−	−
Hydrolysis of:				
Gelatin	+	+	−	+

[a]All *Thermomonas haemolytica* strains assimilate DL-3-hyroxybutyrate, and L-leucine, whereas none of the strains assimilate *N*-acetyl-D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-mannose, D-maltose, α-D-melibiose, L-rhamnose, D-ribose, sucrose, salicin, D-trehalose, D-xylose, adonitol, *i*-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, fumarate, glutarate, itaconate, DL-lactate, suberate, β-alanine, L-histidine, L-ornithine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, or phenylacetate. *p*NP-α-D-glucopyranoside, *p*NP-phenylphosphonate, 2-deoxythymidine-5′-*p*NP-phosphate, L-alanine-*p*NA, L-glutamate-γ-3-carboxy-*p*NA, and L-proline-*p*NA are hydrolyzed, but esculin, *p*NP-β-D-galactopyranoside, *p*NP-β-D-glucuronide, *p*NP-β-D-glucopyranoside, bis-*p*NP-phosphate, and *p*NP-phosphoryl-choline are not. Enzymatic tests for urease, alkaline phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, chymotrypsin, phosphatase acid, and naphthol-AS-BI-phosphohydrolase are uniformly positive.

Maintenance Procedures

Slant cultures grown on standard bacteriological media should not be held for longer than 1 week at 4°C. Cells may also stored at −70°C in broth media, e.g., nutrient or LB broth containing 15–20% glycerol as cryoprotectant or under liquid nitrogen.

Differentiation of the genus *Thermomonas* from other genera

Thermomonas can be clearly differentiated from other genera of the *Xanthomonadaceae* on the basis of 16S rRNA gene sequence, cellular fatty acid composition, and several physiological and bio-

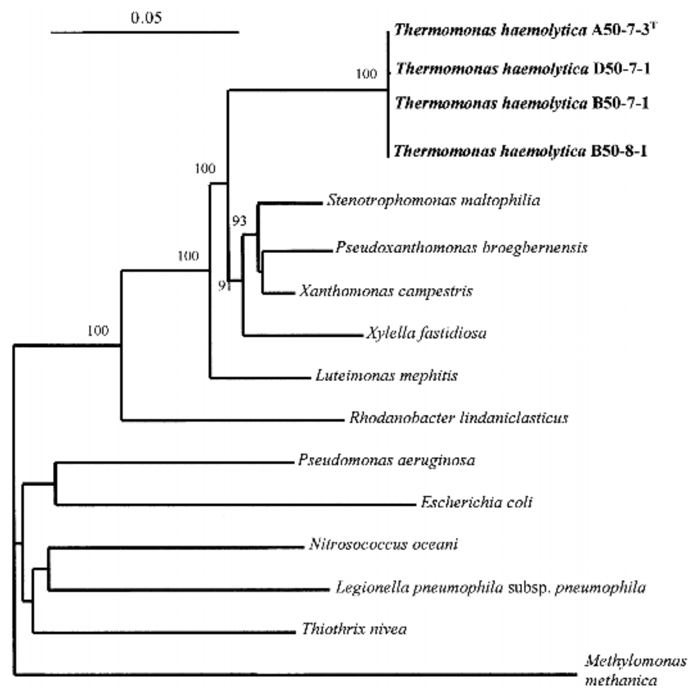

FIGURE BXII.γ.39. Phylogenetic position of *Thermomonas haemolytica* to related genera of the *Xanthomonadaceae*, and species representing distinct lineages within the *Gammaproteobacteria*. The dendrogram was generated from evolutionary distances, calculated from pair-wise dissimilarities, using the FITCH program contained in the PHYLIP package (Felsenstein, 1993). Bootstrap estimates of confidence, derived from 1000 resamplings, are shown for branchings with values greater than 80%, within the *Stenotrophomonas–Xanthomonas–Xylella* phylogenetic lineage. The topography of the branching order of the lineage within the dendrogram was supported by identical branching orders generated using an alternative treeing algorithm of maximum-likelihood (FastDNAml, version 1.0) (data not shown) and by estimated high bootstrap proportions of confidence for the respective branchings. GenBank/ EMBL/DDBJ accession numbers: *Escherichia coli*, M24836; *Legionella pneumophila* subsp. *pneumophila*, M59157; *Luteimonas mephitis*, AJ012228; *Methylomonas methanica*, M95660; *Nitrosococcus oceani*, M96395; *Pseudomonas aeruginosa*, Z76651; *Pseudoxanthomonas broegbernensis*, AJ012231; *Rhodanobacter lindaniclasticus*, AF039167; *Stenotrophomonas maltophilia*, X95923; *Thermomonas haemolytica*, A50-3-7^{T} (AJ300185); *Thermomonas haemolytica*, B50-7-1, AJ300186 (partial sequence, see Busse et al., 2002); *Thermomonas haemolytica* B50-8-1, AJ300188 (partial sequence, see Busse et al., 2002); *Thermomonas haemolytica* D50-7-1, AJ300189 (partial sequence, see Busse et al., 2002); *Thiothrix nivea*, L40993; *Xanthomonas campestris*, X95917; *Xylella fastidiosa*, AF192343. Bar = 5 substitutions at any nucleotide position per 100 nucleotide positions (estimated evolutionary distance from the point of divergence of the 16S rRNA gene sequences).

chemical characteristics (Table BXII.γ.32). In particular, *Thermomonas* species exhibit a higher temperature optimum of 37–50°C.

Taxonomic Comments

Comparative evolutionary distance analysis of the 16S rDNA sequence shows that the genus *Thermomonas* represents a separate line of descent within the *Gammaproteobacteria*. The nearest phylogenetic relatives, albeit relatively distant (16S rDNA sequence similarities <95%), are species of the genera *Xanthomonas*, *Pseudoxanthomonas*, *Stenotrophomonas*, *Luteimonas*, and *Xylella* (Fig. BXII.γ.39).

Very recently, an isolate SGM-6 was obtained from a hot spring at Sao Gemil in central Portugal, showing a 16S rDNA gene sequence similarity of 97.4% to *T. haemolytica* A50-7-3 [T] and able to grow at temperatures as high as 55°C. This isolate may represent another species of the genus *Thermomonas*, or at least a novel strain of *T. haemolytica* (M. Da Costa and F. Rainey, personal communication). Meanwhile, a second *Thermomonas* species has been described Alves et al., 2003a.

Differentiation of the species of the genus *Thermomonas*

Only one species, *Thermomonas haemolytica*, is currently known.

List of species of the genus Thermomonas

1. **Thermomonas haemolytica** Busse, Kämpfer, Moore, Nuutinen, Tsitko, Denner, Vauterin, Valens, Rosselló-Mora and Salkinoja-Salonen 2002, 480[VP]
hae.mo.ly′ti.ca. Gr. n. *haema* blood; Gr. adj. *lyticus* dissolving; M.L. fem. adj. *haemolytica* blood dissolving.

Morphological, physiological, biochemical, and chemotaxonomic characteristics are the same as those described for the genus. Other characteristics are listed in Tables BXII.γ.31 and BXII.γ.32. Isolated from kaolin slurry used in the papermaking industry.

The mol% G + C of the DNA is: 67.1–68.7 (HPLC); type strain, 68.5.

Type strain: A50-7-3, DSM 13605, LMG 19653.

GenBank accession number (16S rRNA): AJ300185.

Additional Remarks: Reference strains include B50-71 (DSM 13598, LMG 19655; GenBank accession number AJ300186), B50-8-1 (DSM 13599, LMG 19654; GenBank accession number AJ296318), D50-7-1 (DSM 13610, LMG 19656; GenBank accession number AJ296319).

Genus XI. **Xylella** *Wells, Raju, Hung, Weisburg, Mandelco-Paul and Brenner 1987, 141*[VP]

Gerard S. Saddler and John F. Bradbury

Xy.lel′la. Gr. n. *xylon* wood; M.L. dim. ending *-ella*; M.L. fem. n. *Xylella* a small wood.

Single, straight rods, 0.25–0.35 × 0.9–3.5 µm, that can form long filamentous strands under some cultural conditions. Gram negative. **Nonmotile**, lacking flagella. Endospores not produced. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Colonies are cream to white.** Two colonial variants are frequently encountered: convex to pulvinate, smooth, opalescent with entire margins; and umbonate, rough with finely undulated margins. **Oxidase negative and catalase positive.** Optimum temperature for growth, 26–28°C; optimum pH for growth, 6.5–6.9. Nutritionally fastidious. Found mainly in the xylem of plant tissue.

The mol% G + C of the DNA is: 51.0–52.4 (T_m); 52–53.1 (Bd).

Type species: **Xylella fastidiosa** Wells, Raju, Hung, Weisburg, Mandelco-Paul and Brenner 1987, 141.

Further descriptive information

Cell morphology Long filamentous strands can be observed in many strains, but filaments are encountered more frequently when sampling from smooth colonies; rough colonial variants tend to exhibit only single rods (Wells et al., 1987). Flagella are not present and motility has not been observed. Cells exhibit rounded ends, though tapering can be observed at one end only. Irregular ridges or folds in the cell surface can be seen. Fibril-like structures are evident and, although peritrichous, predominate at the poles. There is some evidence of morphological heterogeneity, because strains of *X. fastidiosa* causing phony peach disease are thought to be slightly shorter (0.35 × 2.3 µm) and exhibit more pronounced ridges, or rippling of the cell wall when compared against strains causing Pierce's disease (Nyland et al., 1973). Staining with methylene blue is effective for the visualization of citrus variegated chlorosis strains *in planta* (De Lima et al., 1997).

Cell wall composition The major fatty acid components present are: pentadecanoic acid ($C_{15:0}$), hexadecanoic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$) and heptadecanoic acid ($C_{17:0}$) (Wells and Raju, 1984; Wells et al., 1987). The hydroxy fatty acids 2-hydroxydecanoic ($C_{10:0\ 2OH}$) and 3-hydroxydodecanoic ($C_{12:0\ 3OH}$) acids are reported to be present (Wells et al., 1987).

Fine structure The cell wall shows periodic, spiral, or annulated structural arrangement with the thickness varying from 25 to 35 nm in the furrows to 45–55 nm around the ridges (Nyland et al., 1973; Chagas, et al., 1992). The wall consists of an outer, an inner (each comprised of 3-layered unit membrane structure), and a middle peptidoglycan layer. Progressive changes in the cell wall occur with age; initially the inner and outer layer are thin, becoming denser with time, the outer layer increasing in density first (Mollenhauer and Hopkins, 1974). As the cells age, the cell wall structure can be more difficult to visualize and this is particularly true when examining senescent or dead cells. Cell content consists of DNA threads, ribosomes, and osmophilic granules of unknown function (Chagas et al., 1992). The distribution of cell constituents alters with age, with ribosomes aggregating along the periphery of aging cells. Fibril-like structures can also be observed.

Colonial characteristics Two colony types can be observed: smooth and rough, both are circular and opalescent. When grown on BCYE[1] medium, colonies are small, 0.6 mm in diameter after 10 days at 27°C, expanding to 1.5 mm after 30 days. On this medium, rough colonies exhibit green or red margins when viewed under reflected light. Cell replication is by binary fission (Wells et al., 1987; Chagas et al., 1992).

Nutrition, metabolism, and metabolic pathways Strains are aerobic, chemoorganotrophic, and use oxygen as the terminal electron acceptor. Many strains are nutritionally fastidious and require specialized media such as BCYE and PW[2] for growth (Wells et al., 1987). Little information on enzymic activity exists; however, protease activity has been determined by growing both virulent and weakly virulent strains of *X. fastidiosa* on PD3[3] medium (Davis et al., 1981c) amended with gelatin (Fry et al., 1994). Detailed study revealed the presence of at least two proteases, designated P1 and P2, of 54 and 50 kDa, respectively. Production reached a maximum with onset of the stationary phase, P2 becoming more, and P1 becoming less, predominant over time.

Genetics, mutants and plasmids The genetics of this genus have attracted limited interest thus far. The production of a cosmid clone bank (Goodwin, 1989), and evidence for the lack of homology between the *hrp* gene cluster of *Xanthomonas vesicatoria* and DNA from *Xylella fastidiosa*, (Leite et al., 1994b) have contributed to what limited information exists. The reader is directed towards the Bioinformatics Laboratory at the University of Campinas* for details of a project to sequence the entire genome of *X. fastidiosa* (Setubal, personal communication).

Plasmids have been observed in some strains of *X. fastidiosa* (Chen et al., 1992a). A restriction map has been generated for plasmid pXFPW1, which is 1.3 kb in size and was isolated from an *X. fastidiosa* strain causing periwinkle wilt disease. A copy number of 60 was estimated, and restriction analysis demonstrated a high degree of homology with two other plasmids from strains of Pierce's disease and mulberry leaf scorch disease. In contrast, a cryptic plasmid from *X. fastidiosa* ATCC 35868 was found in only one other strain of *X. fastidiosa*—ATCC strain 35878—and further searches revealed some nucleotide sequence homology with plasmid pNKH43 from *Stenotrophomonas maltophilia* (Pooler et al., 1997a).

Molecular data Restriction fragment length polymorphism (RFLP) analysis has been used to study diversity within *X. fastidiosa* by examining 24 strains from eight different hosts (Chen et al., 1992b). Two genomic libraries were constructed in pUC18 from a PD strain and a plum leaf scald strain. By studying 24 probe-enzyme combinations, 67 characters could be determined and PD strains, in particular, exhibited a high degree of uniformity. Subsequent studies produced similar results, this time using RAPD fingerprinting with 14 random primers on 17 different strains of *X. fastidiosa* (Chen et al., 1995); again, a high degree of similarity among the PD strains was evident, although clear differences between this group and *Quercus* leaf scorch, plum leaf scald strains, and a periwinkle wilt strain indicates a high degree of heterogeneity within the species overall. Analogous results were obtained by Albibi et al. (1998), using two random primers; OPA-03 and OPA-11 (Operon Technologies Inc.). With this method, PD strains could be distinguished from other strains of *X. fastidiosa* (citrus variegated chlorosis, mulberry leaf scorch, periwinkle wilt, plum leaf scald, and phony peach), as well as strains of *Xanthomonas campestris* pathovar *vesicatoria* and *Escherichia coli*. The use of RAPD markers has been further refined to develop a detection method, as demonstrated by Pooler and Hartung (1995b). Primers were developed for the specific detection of strains of citrus variegated chlorosis (CVC). A CVC-specific region of the *X. fastidiosa* genome that contains a 28-nucleotide insertion was identified, and single base changes that distinguish CVC from other *X. fastidiosa* strains. This method was used to develop a sensitive and specific assay for detecting *X. fastidiosa* in potential insect vectors, by the prior selection of the bacterium using immunomagnetic separation (Pooler et al., 1997b).

Infraspecific heterogeneity within *X. fastidiosa* has also been observed using other markers, such as PCR amplification with tRNA consensus primers (Beretta et al., 1997). With this method, it is possible to distinguish between CVC strains and mulberry leaf scorch strains. Further, a 7.4-kb *Eco*R1 fragment of genomic DNA of the type strain of *X. fastidiosa*, ATCC 35879, has been used as a probe and found to be conserved in 18 other strains (Minsavage et al., 1994). PCR primers developed from a 1.0-kb internal *Eco*RV portion of the fragment allowed the differentiation of the species into two groups or "pathovars". A PCR assay has been developed for the specific detection of *X. fastidiosa* strains from a wide variety of hosts, through the amplification of a 400-bp product for the variable regions V1 and V6 of the 16S rDNA sequence (Firrao and Bazzi, 1994).

Antigenic structure Polyclonal antibodies have been used in conjunction with ELISA and immunofluorescence for the detection of *X. fastidiosa* strains (Sherald and Lei, 1991; Zaccardelli et al., 1993; Hartman et al., 1995). However, not all strains in the species can be detected using this method. In a further refinement, polyclonals were successfully obtained by screening for unique protein bands of PD strains of *X. fastidiosa* (Bazzi et al., 1994b). The antibodies directed against the two best-suited protein bands (20.7 kDa and 19.8 kDa) did not show any cross-reaction in a Western blot, a solid phase ELISA, or using indirect fluorescent antibody staining, when tested against other bacteria commonly found on grapevine. Using these "monospecific" antibodies in conjunction with indirect ELISA, the detection limit was found to be 8.3×10^5 cells/ml. Similar levels of detection (3×10^5 cells/ml) using a series of 10 monoclonal antibodies specific to pear leaf scorch (PLS) strains of *X. fastidiosa*, also by indirect ELISA (Leu et al., 1998), have been reported. The monoclonals proved highly specific: 9 of the 10 did not cross-react with 14 other bacterial strains belonging to 9 genera. In Western blot analysis, all the monoclonal antibodies recognized a 46.9-kDa polypeptide in all 12 *X. fastidiosa* strains, and a specific 21.5 kDa polypeptide in PLS strains.

1. BCYE medium (Wells et al., 1981) (g/l distilled water): yeast extract, 10.0; activated charcoal, 2.0; L-cysteine HCl·H_2O, 0.4 (filter sterilized [0.2 µm pore size] and added after autoclaving); ferric pyrophosphate (soluble), 0.25 (filter sterilized [0.2 µm pore size] and added after autoclaving); ACES buffer, 10.0; agar, 17.0.

2. PW medium (Davis et al., 1981b) (g/l distilled water): Phytone peptone (BBL), 4.0; trypticase peptone (BBL), 1.0; hemin chloride, 0.01; $MgSO_4 \cdot 7H_2O$, 0.4; K_2HPO_4, 1.2; KH_2PO_4, 1.0; phenol red, 0.02; L-glutamine, 4.0 (filter sterilized [0.2 µm pore size] and added after autoclaving); bovine serum albumin fraction V, 6.0 (filter sterilized [0.2 µm pore size] and added after autoclaving); agar, 12.0.

3. PD3 medium (Davis et al., 1981c) (g/l distilled water) Tryptone (Difco), 4.0; Soytone (Difco), 2.0; trisodium citrate, 1.0; disodium succinate, 1.0; hemin chloride, 0.01 (10 ml of 0.1% w/v solution in 0.05N NaOH); potato starch (soluble) 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; K_2HPO_4, 1.5; KH_2PO_4, 1.0; Bacto agar (Difco), 15.0.

**Editorial Note:* The website for the Bioinformatics Laboratory at the University of Campinas is http://www.lbi.dcc.unicamp.br/.

Antibiotic and drug sensitivity Data from *in vitro* studies have shown that different disease strains of *X. fastidiosa* exhibit a differential response to carbenicillin, penicillin G, and gentamycin when these antibiotics are added to CS-20[4] medium (Hopkins, 1988b). Data from *in vivo* studies of leaf scorch of pear trees (*Pyrus pyrifolia*) in the low-altitude areas of central Taiwan (Leu and Su, 1993) have shown that symptom remission can be achieved by injection of oxytetracycline.

Pathogenicity and ecology Symptoms produced in host plants vary, the most characteristic being a necrosis of interveinal leaf tissue, producing a characteristic scorching effect in a wide range of woody plants. Of primary importance is Pierce's disease of grapevine, which can cause 100% destruction in some vineyards, but which is normally not a serious pathogen (Goodwin and Meredith, 1988). The bacteria block xylem vessels and cause water stress, leading to leaf scorch symptoms, but no wilting is observed as leaf stomata close. Although transpiration is reduced, diseased leaves remain water stressed and various functions are impaired, resulting in carbohydrate imbalance, loss of chlorophyll and disruption of cell membranes. Physiological changes associated with water stress and senescence have been compared between leaves of healthy grapevines (*Vitis vinifera* cv. Chardonnay) and grapevines infected with the PD strains (Goodwin et al., 1988a, b). Vegetative growth of diseased vines was less than that of healthy vines under natural vineyard conditions. Although stomatal resistance of diseased leaves with marginal necrosis was similar to that of healthy leaves during early morning, the stomatal resistance of diseased leaves increased greatly later in the day, while that of healthy leaves remained relatively constant. The diurnal patterns of transpiration and photosynthesis demonstrated that these processes were inhibited by PD strains. The reduced photosynthesis of diseased leaves was at least partly due to inhibition of nonstomatal-related aspects of CO_2 fixation. Compared with healthy leaves, diseased leaves had higher concentrations of abscisic acid, glucose, fructose, Ca^{2+} and Mg^{2+}, but a lower concentration of K^+. Sucrose accumulated in green tissue of a diseased leaf, but the concentrations of sucrose and starch were lower in diseased chlorotic tissue than in diseased green or healthy leaf tissue. Chlorophyll reduction in diseased leaves was also associated with increases in electrolyte leakage, lipid peroxidation, and superoxide anion. Based on these physiological changes, it was proposed that the symptoms of PD were the result of relatively mild but prolonged water stress accelerating leaf senescence. Subsequent studies have demonstrated that PD strains were responsible for the production of occlusions in xylem vessels of susceptible hosts (Fry and Milholland, 1990).

Pierce's disease of grapevine can be transmitted by xylem-feeding leafhoppers (Hill and Purcell, 1997). Acquisition of PD strains has been demonstrated in the blue-green sharpshooter (*Graphocephala atropunctata*) after four days' incubation with infected grapes. Subsequent transmission to healthy plants can be achieved after 10 days. Previous studies have demonstrated that harvested fruit clusters from diseased grapes did not serve as inoculum sources for *G. atropunctata* (Purcell and Saunders, 1995). Only when *G. atropunctata* was given access to diseased grapevines did it subsequently transmit PD strains to healthy grapevine. Transmission efficiency by *G. atropunctata* remained high at seven days' post-acquisition and beyond (Hill and Purcell, 1995a). Bacterial population size in the heads of the inoculative vectors also increased up to day seven, but did not consistently increase further. Studies on grapevine (*Vitis vinifera*) alongside other *G. atropunctata* host plants (*Rubus discolor*, *Artemisia douglasiana*, *Echinochloa crusgalli*, and *Cynodon dactylon*) showed that distal movement from the inoculation site could only be detected in grapevine and *Rubus discolor* (Hill and Purcell, 1995b). These findings highlight the epidemiological importance of the diseased host as a reservoir for further dissemination and, in addition, agree with earlier work, which showed that strains isolated from natural hosts such as *Rubus* spp. could induce symptoms in grapevine (Hopkins, 1988a).

Similar results were obtained by studying CVC strains of *X. fastidiosa* in citrus nurseries in Brazil (Garcia et al., 1997) where the increases in vector populations of *Dilobopterus costalimai*, *Acrogonia terminalis*, and *Oncometopia facialis* and disease incidence were found to be linked. CVC strains, as well as PD strains, appear to be systemic, because xylem vessels of diseased plant petioles harbor large numbers of cells (Hartung et al., 1994).

The significance of disease reservoirs, such as weeds, has also been studied. Weeds collected from plum orchards infested with leaf scald were examined, and the presence of the pathogen was confirmed by isolation and by DAS-ELISA in *Brachiaria plantaginea*, *Digitaria* sp., *Facelis retusa*, *Hypochoeris brasiliensis*, *Leonurus sibiricus*, *Lolium multiflorum*, *Paspalum urvillei*, *Pennisetum clandestinum*, *Richardia* sp., *Taraxacum officinale*, and *Vernonia* sp. (Leite et al., 1997). Phony peach disease strains can be detected in symptomatic or asymptomatic hosts (Aldrich et al., 1992). Populations of *X. fastidiosa* in the root xylem fluid of symptomatic peach trees were high and the distribution of these bacteria was uniform both along the length of roots and among roots within the root ball; in contrast, distribution of the bacteria within asymptomatic trees was discontinuous.

Enrichment and Isolation Procedures

It has long been considered that *X. fastidiosa* is fastidious and unable to grow on standard bacteriological media, despite reports that Nutrient Agar can support growth (Chang et al., 1990; Fry et al., 1990). More commonly, a range of media have been used successfully to culture *X. fastidiosa*, namely CS20, PD1,[5] PD2,[6] PD3, and PW.

Maintenance Procedures

Lyophilization and storage on silica gel at −20°C are effective long-term storage methods (Sleesman and Leben, 1978; Hopkins, 1988b). Long-term culturing of *X. fastidiosa* frequently re-

4. CS-20 medium (Chang and Schaad in Hopkins, 1988b) (g/l distilled water): Tryptone, 2.0; Soytone, 2.0; $(NH_4)_2HPO_4$, 0.85; hemin chloride, 15 ml (0.1% w/v solution in 0.05N NaOH); KH_2PO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 0.4; L-glutamine, 6.0; dextrose, 1.0; potato starch (soluble), 2.0; L-histidine, 1.0; phenol red, 5.0 ml (0.2% solution prepared by dissolving 0.2 g in 30 drops 5N NaOH then making the volume to 100 ml in H_2O); agar, 12.0.

5. PD1 medium (Davis et al., 1980) (g/l distilled water): Tryptone (Difco), 7.0; Soytone (Difco), 3.0; disodium succinate, 1.0; hemin chloride, 0.01 (10 ml of 0.1% w/v solution in 0.05N NaOH); $MgSO_4 \cdot 7H_2O$, 1.0; $FeCl_3 \cdot 6H_2O$, 0.002; $MnSO_4 \cdot 4H_2O$, 0.002; $(NH_4)_2SO_4$, 1.0; Bacto agar (Difco), 15.0; bovine serum albumin fraction V, 2.0 (10 ml of 20% v/v, added after autoclaving to medium held at 45–50°C).

6. PD2 medium (Davis et al., 1980) (g/l distilled water): Tryptone (Difco), 4.0; Soytone (Difco), 2.0; trisodium citrate, 1.0; disodium succinate, 1.0; hemin chloride, 0.01 (10 ml of 0.1% w/v solution in 0.05N NaOH); $MgSO_4 \cdot 7H_2O$, 1.0; K_2HPO_4, 1.5; KH_2PO_4, 1.0; Bacto agar (Difco), 15.0; bovine serum albumin fraction V, 2.0 (10 ml of 20% v/v added after autoclaving to medium held at 45–50°C).

sults in the loss of virulence, e.g., after 18 months of weekly culturing on PD2 medium (Hopkins, 1984).

Differentiation of the genus *Xylella* from other genera

Characteristics useful for differentiating *Xylella* from other members of the family *Xanthomonadaceae* are listed in Table BXII.γ.17 in Genus *Xanthomonas*. In addition, a technique for identifying *X. fastidiosa* involving direct isolation of endophytic bacteria from propagation material, combined with one-dimensional SDS-PAGE of the total soluble proteins of the bacterial cell envelope, is described by Bazzi et al. (1994a). The gel electrophoretic pattern of this pathogen is characterized by a constant distribution of 14 major diagnostic bands.

Taxonomic Comments

Analysis of 16S rRNA gene sequence data placed this genus in the *Gammaproteobacteria*, related to *Xanthomonas campestris* and *Stenotrophomonas maltophilia* (Wells et al., 1987). Similar findings have been presented by Kersters et al. (1996). In a subsequent study, an average sequence similarity of 94.7% was reported between *X. fastidiosa* and seven type strains of the genus *Xanthomonas*; the sequence similarity with *S. maltophilia* was 94.1% (Moore et al., 1997). Results obtained from restriction maps of PCR-amplified 16S rRNA genes of *Xylella*, *Xanthomonas*, and *Stenotrophomonas* strains highlighted relationships between the three genera (Nesme et al., 1995). Nineteen restriction fragment length polymorphisms (RFLPs) were distinguished and strains were recovered in two main clusters, one of which contained *Xanthomonas* spp., the other *Stenotrophomonas* spp. The genera *Xanthomonas* and *Stenotrophomonas* formed a coherent group, with the genus *Xylella* recovered as a single member cluster and clearly more distantly related.

X. fastidiosa is a heterogeneous species producing a variety of symptoms on many hosts of economic significance: Pierce's disease of grapevine, citrus variegated chlorosis, phony peach, periwinkle wilt; alfalfa dwarf; ragweed stunt; and almond, coffee, elm, maple, mulberry, oak, plum, and sycamore leaf scorch. Differences between pathogenic populations can be observed using traditional methods (Table BXII.γ.33), RAPDs, (Chen et al., 1995; Pooler and Hartung, 1995a, b; Albibi et al., 1998), RFLP (Chen et al., 1992b), and monoclonal antibodies (Leu et al., 1998). Evidence from these data suggests that a pathovar structure may be appropriate to circumscribe infraspecific variation within *X. fastidiosa*, but clearly further work is required.

List of species of the genus Xylella

1. **Xylella fastidiosa** Wells, Raju, Hung, Weisburg, Mandelco-Paul and Brenner 1987, 141[VP]

fas.tid.i.o′ sa. M.L. fem. adj. *fastidiosa* highly critical; referring to the nutritional fastidiousness of the organism, particularly on primary isolation.

The characteristics are those described for the genus. Gelatin is hydrolyzed and gelatinase is produced. Many strains produce β-lactamase. β-galactosidase, coagulase, lipase, amylase, and phosphatase negative; indole and H_2S are not produced.

Differential characteristics of some pathogenic strains of *Xylella fastidiosa* are listed in Table BXII.γ.33.

The mol% G + C of the DNA is: 51.0–52.4 (T_m) and 52–53.1 (Bd).

Type strain: PCE-RR, ATCC 35879, DSM 10026, ICMP 11140.

GenBank accession number (16S rRNA): AF192343.

Order IV. **Cardiobacteriales** *ord. nov.*

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Car.di.o.bac.te.ri.a' les. M.L. neut. n. *Cardiobacterium* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Cardiobacteriales* the *Cardiobacterium* order.

The order *Cardiobacteriales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the order contains the family *Cardiobacteriaceae*.

Description is the same as for the family *Cardiobacteriaceae*.

Type genus: **Cardiobacterium** Slotnick and Dougherty 1964, 271[AL].

Family I. **Cardiobacteriaceae** Dewhirst, Paster, La Fontaine and Rood 1990, 431[VP]

FLOYD E. DEWHIRST AND BRUCE J. PASTER

Car.di.o.bac.te.ri.a' ce.ae. M.L. neut. n. *Cardiobacterium* type genus of the family; *-aceae* ending to denote a family; M.L. fem. pl. n. *Cardiobacteriaceae* the family of *Cardiobacterium*.

Straight rods, 0.5–1.7 × 1–6 μm, with rounded ends. Cells occasionally occur in pair, chains, or rosettes. Gram negative but with a tendency to resist Gram decolorization. Nonmotile, as cells do not possess flagella, but may possess type IV pili and exhibit twitching motility. Aerobic and oxidase positive except for members of the anaerobic genus *Dichelobacter*. Catalase negative. Urease negative. Fermentative type of chemoorganotrophic metabolism except for members of the genus *Dichelobacter*, which are arginine chemoorganotrophs. Acid but not gas is produced from glucose, sucrose, maltose, mannose, and fructose in the fermentative species. Nitrates are not reduced. H_2S is produced (as determined by the lead acetate method). No growth occurs on MacConkey agar. Species in the family possess the following rare or unique signatures in their 16S rRNAs: uracil at positions 18, 1051, 1400; cytosine at positions 1124 and 1253; and adenine at position 917 (*E. coli* numbering). The family is composed of three genera—the type genus *Cardiobacterium* and the genera *Suttonella* and *Dichelobacter*.

The mol% G + C of the DNA is: 45–60.

Type genus: **Cardiobacterium** Slotnick and Dougherty 1964, 271.[AL]

Differentiation from other taxa Based on 16S rRNA sequence analysis, it was recognized that *Kingella indologenes* and *Bacteroides nodosus* were taxonomically misplaced and that they were most closely related to *Cardiobacterium hominis* (Dewhirst et al., 1990). A neighbor-joining phylogenetic tree based on 16S rRNA sequence comparisons is shown in Fig. BXII.γ.40. The three organisms form a monophyletic group in the *Gammaproteobacteria*. *Bacteroides nodosus* clearly differs from *C. hominis* and *K. indologenes* in that it is an asaccharolytic anaerobe. It was therefore placed in its own genus as *Dichelobacter nodosus*. *Cardiobacterium hominis* and *K. indologenes* are quite similar phenotypically, but the mol% G + C content of their DNA differs by 11%, and *K. indologenes* was placed in its own genus as *Suttonella indologenes*. Strains for two additional *Cardiobacterium* species have been isolated, but not formally named (see Fig. BXII.γ.40). These three genera were placed in the family *Cardiobacteriaceae* based upon their forming a closely related (92% similarity) monophyletic group. The *Cardiobacteriaceae* cluster is supported in 100% of 200 bootstrap resamplings. The family branches deeply in the *Gammaproteobacteria*, being less than 87% similar to any other taxa. The most closely related organisms are *Thiobacillus neapolitanus*, *Halothiobacillus hydrothermalis* (shown on tree) and *T. halophilus*. However, these species clearly belong in a separate family because they have a chemolithotrophic metabolism, possess none of the 16S rRNA base signatures of the *Cardiobacteriaceae*, and have less than 87% 16S rRNA sequence similarity. Table BXII.γ.34 shows phenotypic traits that differentiate *Cardiobacteriaceae* genera from other genera.

Genus I. **Cardiobacterium** *Slotnick and Dougherty 1964, 271[AL]*

BRUCE J. PASTER AND FLOYD E. DEWHIRST

Car.di.o.bac.te' ri.um. Gr. n. *cardia* heart; Gr. n. *bakterion* small rod; M.L. neut. n. *Cardiobacterium* bacterium of the heart.

Straight rods 0.5–0.75 × 1.0–3.0 μm, with rounded ends. Occasional long filaments, 7.0–35.0 μm may occur. **Pleomorphic.** Cells are arranged singly, in pairs, in short chains, and in rosette clusters. Gram negative, but retention of crystal violet may occur in the swollen ends or central portions of cells. Nonmotile. **Facultatively anaerobic.** CO_2 is required by some strains on isolation. Aerobic growth is scant unless humidity is elevated. Growth in candle jars or under anaerobic conditions is not dependent on an elevated humidity. Optimum temperature, 30–37°C. Colonies on blood agar are smooth, convex, and opaque. **Chemoorganotrophic, having a strictly fermentative type of metabolism.** Acid but not gas is produced from fructose, glucose, mannose, sorbitol, mannitol, and sucrose. Lactic acid is the major product of glucose fermentation; smaller amounts of pyruvate, formate, and propionate are formed. Oxidase positive. **Catalase negative.** Small amounts of **indole** are formed. **Nitrates are not reduced.** No growth occurs on MacConkey agar. Urease negative. Ornithine decarboxylase (ODC) negative. Occur in nasal flora of humans; isolated from the blood of humans with bacterial endocarditis.

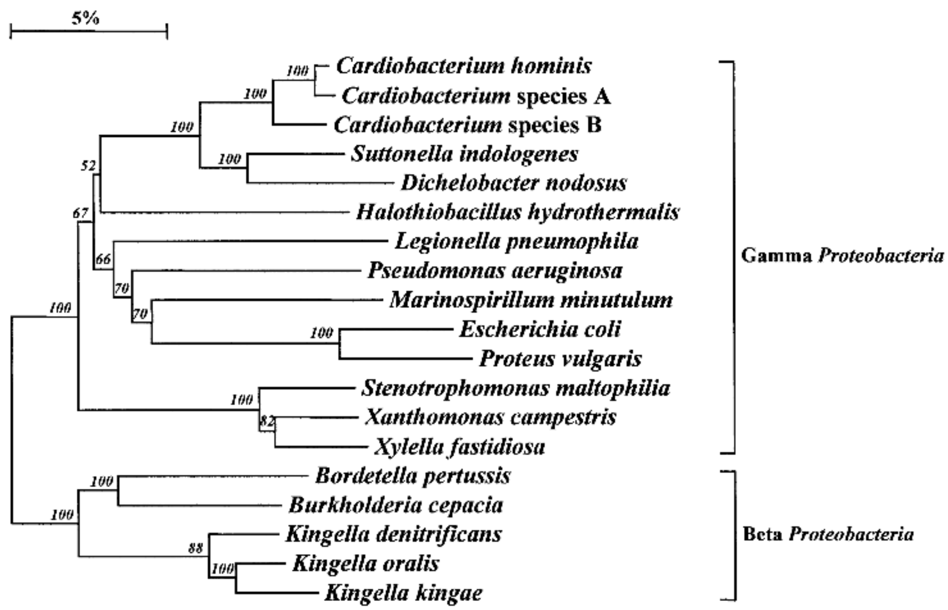

FIGURE BXII.γ.40. Phylogeny of *Cardiobacteriaceae*. The phylogenetic relationships of the three genera, namely *Cardiobacterium*, *Suttonella*, and *Dichelobacter*, of the family *Cardiobacteriaceae*, compared to other members of the *Betaproteobacteria* and *Gammaproteobacteria*. Bar = 5% difference in nucleotide sequences. The neighbor-joining method was used for tree construction. Two hundred bootstrap trees were generated, and bootstrap confidence levels (shown as percentages above the nodes) were determined. GenBank accession numbers for sequences of members of the *Cardiobacteriaceae*: *Cardiobacterium hominis*, M35014; *Cardiobacterium* sp. A, AF144697; *Cardiobacterium* sp. B, AF144696; *Suttonella indologenes*, M35015; *Dichelobacter nodosus*, M35016. Accession numbers for the sequences of the other species (all type strains) are available in GenBank.

TABLE BXII.γ.34. Phenotypic traits that differentiate *Cardiobacteriaceae* genera from other genera[a]

Characteristic	*Cardiobacterium*	*Dichelobacter*	*Suttonella*	*Bacteroides*	*Eikenella*	*Kingella*	*Moraxella*	*Pasteurella*	*Porphyromonas*

[a]For symbols see standard definitions; nd, not determined.

The mol% G + C of the DNA is: 59–60.

Type species: **Cardiobacterium hominis** Slotnick and Dougherty 1964, 271.

Further descriptive information

Cells of *Cardiobacterium* grown on tryptose blood agar (containing 5% human blood) are pleomorphic and have rounded ends. The usual cell dimensions are ~0.5–0.6 × 1.0–2.2 µm. Occasionally filaments are formed, which vary in length from 7.0–35.0 µm. Teardrop-shaped cells may occur. One or both ends of *Cardiobacterium* cells are frequently enlarged, and the crystal violet of the Gram stain tends to be retained in these areas. Other cells may show crystal violet retention in the central portions (Slotnick and Dougherty, 1964).

The degree of pleomorphism is apparently influenced by the medium on which *Cardiobacterium* is grown. Pleomorphism has been reported in cultures grown on agar media, which do not contain yeast extract. On yeast extract-containing media, the cells have been found to be generally uniform Gram-negative rods that are 0.5 × 2.0 µm (Savage et al., 1977).

Sudanophilic bodies and metachromatic granules have been reported with the use of the Sudan Black B and Albert's stain, respectively (Slotnick and Dougherty, 1964). However, Midgley et al. (1970) were unable to confirm these observations.

The cell wall is of the Gram-negative type with distinct layers—a dense outer layer, a unit membrane, and a dense inner layer. The substructure of the crystalline surface layer (S-layer) consists of closely packed units, which are nearly spherical and have an average diameter of about 3.5 nm (Reyn et al., 1971). Cells have 20–40 nm thick polar caps consisting of a dense, tuft-like material. In the periphery of the cytoplasm, numerous unit membrane profiles have been observed and are thought to be intrusions of the plasma membrane (Reyn et al., 1971).

After incubation for 24 h at 37°C on tryptose blood agar (containing 5% human blood), colonies are punctiform. After 48 h the maximum size is 1–2 mm. The colonies are circular,

convex, smooth, moist, glistening, opaque, and butyrous, and have an entire edge. No clear zones of hemolysis are formed around the colonies (Slotnick and Dougherty, 1964).

Strains of *C. hominis* may be grown in a defined medium[1] described by Slotnick and Dougherty (1965). Essential components of the medium are pantothenate, niacinamide, thiamine, threonine, proline, leucine, histidine, glycine, and arginine. Biotin, pyridoxine, tyrosine, valine, and glutamate are not required but must be included for optimum growth. Glucose is not an essential carbon source or the sole energy source, but it is fermented and does increase the growth yield. The major end product of glucose fermentation is lactic acid (Slotnick and Dougherty, 1964). Maltose, sucrose, fructose, and mannose are also fermented and can be substituted effectively for glucose in the medium. Lactose, arabinose, and galactose are not fermented or utilized for growth. Low concentrations (~1.5–2.0 μg/ml) of riboflavin or flavin mononucleotide inhibit the growth of *C. hominis*. This inhibitory effect is neutralized by the presence of excess leucine in the medium.

Growth at 30°C and 37°C is equally good. Growth at 25°C is sporadic and light. No growth occurs above 42°C or at 22°C (Slotnick and Dougherty, 1964; Midgley et al., 1970).

The optimal pH range for growth is 7.0–7.2. *C. hominis* grows poorly in air unless the humidity is increased by a method such as placing filter paper strips, saturated with water, in a closed container. In a candle jar or under anaerobic conditions, it is not necessary to increase the humidity. The optimal atmosphere contains 3–5% CO_2 (Slotnick and Dougherty, 1964). Midgley et al. (1970) found that three of four strains grew equally well in a candle jar and in a sealed jar without increased CO_2. The fourth strain grew less well in the sealed jar than in the candle jar.

Slotnick and Dougherty (1964) produced antisera to four strains. All of the strains reacted to a high titer in each of the unabsorbed sera; however, by absorption studies the four strains were shown not to be antigenically identical. No antigenic relationship was demonstrated to members of the genera *Brucella*, *Pasteurella*, *Bordetella*, *Moraxella*, *Haemophilus*, *Streptobacillus*, *Corynebacterium*, *Bacteroides*, *Neisseria*, *Escherichia*, or *Lactobacillus*.

Savage et al. (1977) tested five strains and found the minimum inhibitory concentrations for all strains to be less than 2 μg/ml for ampicillin, carbenicillin, cephalothin, chloramphenicol, penicillin, tetracycline, streptomycin, kanamycin, gentamicin, and colistin.

In humans, *C. hominis* is a relatively rare cause of bacterial endocarditis. Dental caries and periodontal disease have been suggested as predisposing factors (Berbari et al., 1997; el Khizzi et al., 1997). A single case of abdominal abscess and bacteremia due to *Cardiobacterium hominis* and *Clostridium bifermentans* has been reported (Rechtman and Nadler, 1991). Tucker et al. (1962) found no evidence of infection in mice, guinea pigs, rabbits, hamsters, or pigeons after injection of 10^7–10^8 viable organisms intravenously, intraperitoneally, or subcutaneously.

C. hominis is apparently part of the normal nasal and pharyngeal flora of humans. It was isolated from the nose or throat of 68 of 100 individuals examined by Slotnick et al. (1964). The organism was also isolated from cervical and vaginal cultures obtained from 2 of 159 subjects examined (Slotnick, 1968).

Enrichment and Isolation Procedures

Cardiobacterium hominis has been isolated from blood in several different media under both aerobic and anaerobic conditions. Media that have been used successfully are brain heart infusion broth containing sodium polyanetholsulfonate (SPS) and *p*-aminobenzoic acid, casein soy broth with SPS, thioglycolate broth with SPS, and glucose broth (Midgley et al., 1970; Savage et al., 1977).

Slotnick et al. (1964) isolated *C. hominis* from the nose and throat of humans on trypticase soy agar plates containing 5% human blood. The plates were incubated at 37°C for 48–72 h in candle jars. Because of difficulty in recognizing the colonies of *C. hominis*, smears of selected areas of the plates were stained with fluorescent antibody. Isolation of strains was accomplished by subculturing from the areas that showed positive fluorescent staining reactions.

Maintenance Procedures

Strains of *C. hominis* may be preserved by lyophilization. Freezing also may preserve them. Cells from 18–24 h old agar cultures suspended in defibrinated rabbit blood have survived for more than 15 years at −50°C.

Procedures for Testing Special Characters

Indole formation is an important characteristic for the identification of *C. hominis*. Indole production, however, may be weak and may not be detected by test procedures that do not first concentrate the indole by xylene extraction.

Tryptone broth and heart infusion broth are suitable media for the indole test. A portion of broth culture should be tested after incubation of 18–24 h. If the reaction is negative, the remaining portion of the broth culture should be tested after incubation for an additional 24 h. To perform the test, add approximately 0.5–1 ml of xylene to 3–4 ml of broth culture. Shake vigorously to extract the indole. After the xylene layer has formed at the surface, add either Ehrlich's or Kovacs' reagent, allowing the reagent to flow down the side of the slightly tilted tube.

Differentiation of the genus *Cardiobacterium* from other genera

Characteristics by which *C. hominis* can be distinguished from other Gram-negative rod-shaped organisms that have similar physiological characteristics have been described by Bruun et al. (1984b) and are shown in Table BXII.γ.34 of the chapter *Cardiobacteriaceae*. The cellular fatty acid composition of *Cardiobacterium hominis* differs from *Eikenella corrodens*, *Kingella denitrificans*, and *Kingella kingae* by the absence of 3-hydroxylauric ($C_{12:0\ 3OH}$) acid, from *Suttonella indologenes* by the presence of 3-hydroxypalmitic ($C_{16:0\ 3OH}$) acid, and from *E. corrodens* by the presence of 3-hydroxymyristic ($C_{14:0\ 3OH}$) acid (Wallace et al., 1988). *Kingella denitrificans* and *Kingella kingae* contained myristic ($C_{14:0}$) and palmitic ($C_{16:0}$) acids as major acids, whereas *cis*-vaccenic ($C_{18:1\ \omega7c}$) and palmitic acids were the major acids in *Suttonella indologenes*, *C. hominis*, and *E. corrodens*.

Taxonomic Comments

Cardiobacterium hominis is the only named species in the genus; however, two unnamed *C. hominis*-like species have been described (see Other Organisms). Based on 16S rRNA sequence

1. Defined medium has the following composition (per liter of distilled water): $MgSO_4 \cdot 7H_2O$, 0.4 g; $MnSO_4 \cdot H_2O$, 3 mg; NaCl, 50 mg; Na_2HPO_4, 2.84 g; KH_2PO_4, 2.72 g; $ZnSO_4 \cdot 7H_2O$, 4.43 mg; $FeSO_4 \cdot 7H_2O$, 4 mg; $CuSO_4 \cdot 5H_2O$, 0.5 mg; glucose, 5.0 g; arginine, 160 mg; glutamic acid, 200 mg; glycine, 176 mg; histidine, 126 mg; leucine, 426 mg; proline, 100 mg; threonine, 276 mg; valine, 185 mg; tyrosine, 35 mg; calcium pantothenate, 10 mg; niacinamide, 10 mg; pyridoxine hydrochloride, 20 mg; thiamine hydrochloride 10 mg; and biotin, 1 mg. Final pH is 7.0.

analysis, the genera *Cardiobacterium*, *Suttonella*, and *Dichelobacter* compose the family *Cardiobacteriaceae* (Dewhirst et al., 1990). The family branches deeply in the *Gammaproteobacteria* at the juncture of the *Gammaproteobacteria* and *Betaproteobacteria*. Neighboring families include *"Xanthomonadaceae"*, *"Piscirickettsiaceae"*, and *"Francisellaceae"*. A phylogenetic tree including *Cardiobacterium hominis* and related bacteria is shown in Fig. BXII.γ.40 in the *Cardiobacteriaceae* chapter.

List of species of the genus Cardiobacterium

1. **Cardiobacterium hominis** Slotnick and Dougherty 1964, 271[AL]

ho′ mi.nis. L. gen. n. *hominis* of man.

The characteristics are as described for the genus.

Occurs in nasal and oral flora of humans; isolated from the blood of humans with endocarditis.

The mol% G + C of the DNA is: 59–60 (T_m).

Type strain: 6573, ATCC 15826, DSM 8339, NCTC 10426.

GenBank accession number (16S rRNA): M35014.

Other Organisms

Strains potentially representing two additional *Cardiobacterium* species have been described (Rothenpieler et al., 1986). These species are shown as *Cardiobacterium* sp. A and *Cardiobacterium* sp. B in Fig. BXII.γ.40 in the *Cardiobacteriaceae* chapter. *Cardiobacterium* sp. A is represented by the singe strain SSI AB2167 (FsK 3118; M. Kilian, human dental plaque; Denmark, 1985). This strain has been called *Suttonella indologenes*-like and has 97% 16S rRNA sequence similarity with *C. hominis*. *Cardiobacterium* sp. B is represented by at least two strains: CCUG 13150 (SSI AB 2102; G. Dahlen; human periodontitis; Sweden, 1982) and CCUG 31207 (SSI AB 2168; FsK3120; M. Kilian; human dental plaque; Denmark, 1985). These strains have also been called *Cardiobacterium hominis*-like and were designated by Enevold Falsen as EF Group 18 strains (Culture Collection, University of Gøteborg). There are additional EF Group 18 strains in the CCUG collection. *Cardiobacterium* sp. B has 95% 16S rRNA sequence similarity with *C. hominis*. The phenotypic traits differentiating these strains from *C. hominis* are shown in Table BXII.γ.35. Further characterization of strains in the genus *Cardiobacterium* is needed prior to naming strains these additional species. Inclusion of *Cardiobacterium* spp. A and B would necessitate modification of genus description to include indole-negative and alkaline phosphatase-positive species.

TABLE BXII.γ.35. Differentiation of unnamed *Cardiobacterium* species from *C. hominis*

Characteristic	*Cardiobacterium hominis*	*Cardiobacterium* sp. A	*Cardiobacterium* sp. B	*Suttonella indologenes*
Ferments D-mannitol or D-sorbitol	+	−	+	−

Genus II. **Dichelobacter** *Dewhirst, Paster, La Fontaine and Rood 1990, 430*[VP]

Julian I. Rood, David J. Stewart, Jill A. Vaughan and Floyd E. Dewhirst

Di.che′ lo.bac.ter. Gr. adj. *Dichelos* cloven hoofed; N.L. n. *bacter* a rod; N.L. masc. n. *Dichelobacter* cloven-hoofed rod, because this organism is the rod-shaped bacterium that causes footrot in sheep, goats, and cattle.

Large straight or slightly curved rods, 3–6 × 1.0–1.7 µm, with rounded ends. **Freshly isolated cells often have terminal swellings**, this feature is less pronounced after subculture. **Gram negative** but with a tendency to resist decolorization. Organisms stained with Loeffler methylene blue have prominent polychromatic granules toward the poles and at intermediate sites within the cells. **Grows slowly only under strictly anaerobic conditions but is not rapidly killed by exposure to oxygen.** The cells have large numbers of thin polar fimbriae or pili that vary in number according to changes in colony morphology. The pili belong to the type IV or *N*-methylphenylalanine family; consequently, **the cells exhibit the twitching motility and spreading of colonies that is characteristic of cells with type IV pili**. **The organism also produces extracellular serine proteases that are relatively heat stable.** Ammonia is produced from arginine, asparagine, serine, and threonine. Positive for ornithine decarboxylase, phosphatase (weak), H_2S production, selenite reduction, and proteolytic activity on gelatin, casein, and albumin. **Negative for acid or gas production from carbohydrates**; ammonia production from phenylalanine, cysteine, citrulline, and ornithine; starch hydrol-

ysis; esculin hydrolysis; indole production; nitrate reduction; growth in 0.1% bile; hemolysis; arginine decarboxylase; catalase; oxidase; urease; DNase; coagulase; lipase; lecithinase; and hyaluronidase. The genus contains a single species, *Dichelobacter nodosus*. Further details on the properties of the genus are available elsewhere (Beveridge, 1941, Cato et al., 1979, Holdeman et al., 1984a, Skerman, 1989; Dewhirst et al., 1990).

The mol% G + C of the DNA is: 45.

Type species: **Dichelobacter nodosus** (Beveridge 1941) Dewhirst, Paster, La Fontaine and Rood 1990, 426 (*Bacteroides nodosus* (Beveridge 1941) Mráz 1963, 85; *Fusiformis nodosus* Beveridge 1941, 23.)

Further descriptive information

Dichelobacter is one of three genera that compose the family *Cardiobacteriaceae*. Based on 16S rRNA sequence data the members of this family are placed as deeply branching members of the *Gammaproteobacteria*. The 16S rRNA sequences of these genera, *Cardiobacterium*, *Suttonella*, and *Dichelobacter*, have approximately 93% identity (Dewhirst et al., 1990).

Little is known about the composition of the cell wall. The lipopolysaccharide (LPS) of *D. nodosus* is similar to enterobacterial LPS in that it contains 2-keto-3-deoxyoctonic acid (KDO), glucose, galactose, and heptose. The LPS is not highly toxic, although it does exhibit some characteristic endotoxin properties (Stewart, 1977). It is not immunoprotective (Stewart, 1978). Virtually nothing is known about the genes involved in LPS biosynthesis, although one gene, *lpsA*, whose product appears to interact with the acidic inner LPS core, has been identified (Billington et al., 1995).

The predominant fine structural feature is the presence of polar fimbriae or pili. These long filamentous structures are ~6 nm in diameter and up to 10 µm in length (Stewart, 1973; Walker et al., 1973). The fimbriae consist of identical subunits of a 17-kDa protein that has the typical sequence and structure of pilins belonging to the type IV pilin family (Elleman, 1988; Mattick, 1989). Several genes that appear to be involved in fimbrial biogenesis have been cloned and analyzed, including the gene encoding the prepilin peptidase (Johnston et al., 1995, 1998).

The organism is relatively slow growing and after 2–6 d of anaerobic growth on agar media produces flat spreading colonies 1–3 mm in diameter that are circular, concave, semiopaque, and slightly mottled, with a shiny, bumpy surface, and a pitted edge. Large colonies have concentric circles with the inner circle pitting the agar (Cato et al., 1979). However, there is considerable variation in colonial morphology, depending on both the isolate and the growth medium. Colonies may have a highly papilliated or beaded central zone overlying a pit-like depression etched into the agar surface, producing a sunken appearance, a pale, granular mid-zone surrounded by a peripheral zone with a ground glass texture, and a fimbriate edge. Changes in colony type within a strain can occur with subculturing (Skerman, 1989). Variations in the basic features of colony morphology by different strains are described (Stewart et al., 1986).

D. nodosus does not ferment carbohydrates but catabolizes arginine, a property that has been used in the formulation of the growth medium TAS (Skerman, 1989). Maximum growth requires trypticase and 0.02–0.05 M arginine. Serine also enhances growth, and in some strains so does lysine (Skerman, 1975). The organism is routinely grown in rich medium and little is known about its specific growth requirements or its metabolism. Growth is most rapid at 37°C and within a pH range of 6.8–7.8 (optimal range 7.2–7.8). In broth cultures, growth is evenly dispersed with a light, turbid, or silky texture and is usually visible within 24–48 h. The organism hydrolyses gelatin, produces ammonia from amino acids, and has ornithine decarboxylase activity (Skerman, 1989). *D. nodosus* isolates are susceptible *in vitro* to a wide range of antimicrobial agents.

The organism is naturally transformable with 7 of 17 strains that have been tested able to be transformed with plasmid DNA preparations. Natural transformation can be used to make chromosomal mutants by allelic exchange (Kennan et al., 1998, 2001). The genome of *D. nodosus* strain VCS1703A is currently being determined (see http://www.tigr.org/). The genome of the reference *D. nodosus* strain A198 (198A, VCS1001, or ATCC 27521) has been mapped; it consists of a 1.54-Mb circular chromosome that has three rRNA operons (La Fontaine and Rood, 1996). Key features are that the putative virulence genes are not localized to one region of the genome and that the genome contains a large 27-kb virulence-related locus, the *vrl* region (Billington et al., 1999), which has a markedly different distribution of *Eag*I and *Stu*I restriction sites. Only one extrachromosomal element, the 10-kb plasmid pJIR896, has been identified. This plasmid carries a copy of another virulence-associated locus, the *vap* region, as well as the insertion sequence IS*1253*, which is also found on the *D. nodosus* chromosome (Billington et al., 1996b).

The primary antigenic determinants are the type IV fimbriae. *D. nodosus* isolates can be divided into nine major serogroups (A to I) based on their ability to react with antisera prepared against purified fimbriae (Claxton, 1989). The serogroups can be further divided into two major classes based on their fimbrial subunit structure and the genetic organization of the fimbrial subunit gene region (Elleman, 1988; Hobbs et al., 1991; Mattick et al., 1991). Class I isolates (serogroups A, B, C, E, F, G, and I) have a single gene *fimB* located between the fimbrial subunit gene *fimA* and the *clpB* gene. By contrast, in the same genomic position, class II isolates (serogroups D and H) have three genes, *fimC*, *fimD*, and *fimZ*. Mutation of the fimbrial subunit gene, *fimA*, has shown that production of fimbrial subunits is essential for fimbrial biogenesis, twitching motility, natural competence, protease secretion, and virulence in sheep (Kennan et al., 2001). These studies also showed that the *fimB* gene was not required for fimbrial biogenesis or virulence.

D. nodosus is the essential causative agent of footrot in ruminants, especially in sheep, goats, cattle, and deer. The ovine disease manifests as a continuum from virulent through intermediate to benign footrot. The severity of the disease depends on both the climatic conditions, being optimal under warm, moist conditions, and the virulence of the *D. nodosus* isolates. Clinical isolates are therefore often referred to as being virulent, intermediate, or benign. The only virulence factor that has been shown to be essential for virulence is the fimbrial subunit (Kennan et al., 2001). However, the production of extracellular serine proteases and the presence of the *vrl* genomic island have also been postulated to be involved in virulence (Billington et al., 1996a). The role of these and other virulence factors in the disease process remains to be determined.

Confirmed isolates of *D. nodosus* have been obtained only from ruminants such as sheep, goats, cattle, and deer (Egerton, 1989; Stewart, 1989). The organism does not survive for longer than 14 d in feces, soil, or pasture (Stewart, 1989). Although there have been instances of *D. nodosus* supposedly being isolated from other sources, such as human specimens, these strains were not

confirmed as *D. nodosus* (Cato et al., 1979; Holdeman et al., 1984a).

Enrichment and Isolation Procedures

Specimens are collected with a cotton-tipped swab, wooden applicator stick, or scalpel blade, by scraping active footrot lesions containing exudate. The specimens are then deposited into a variety of transport media (Skerman, 1989) and promptly sent to the laboratory within 24–48 h of collection where they are inoculated onto hoof agar (Thomas, 1958), trypticase arginine serine (TAS) agar (Skerman, 1975), or modified TAS agar incorporating hemoglobin-HEPES solution (Depiazzi et al., 1990) containing 4% agar. The plates are incubated at 37°C for 2–4 d in anaerobic jars containing CO_2/H_2 (10:90). A selective blood Eugonagar medium, using lincomycin, also has been devised (Gradin and Schmitz, 1977). Primary cultures can be inoculated by heavy surface streaking with lines 10 mm apart onto well-dried plates (Skerman, 1989) or by stab inoculation (Depiazzi et al., 1990). Surface colonies grow as translucent flat granular colonies, often with concentric zones with a fimbriate edge (Thorley, 1976). In the streaking method, colonies are picked off each primary plate with a sterile straight wire and subcultured onto a 4% hoof agar, TAS agar, or blood Eugonagar plate to obtain pure colonies and then incubated anaerobically for 3–4 d at 37°C. In the stab inoculation method, an agar section is cut from the isolation plate with the aid of a stereo microscope and using a nichrome bent, spatula-shaped wire. The agar then is placed colony side down onto the surface of a modified TAS maintenance agar plate and incubated anaerobically for 2 d at 37°C. The addition of hoof particles to modified TAS agar enhances the growth of spreading colonies and facilitates the isolation of *D. nodosus.* Small Petri dishes (55 mm) are used instead of conventional plates (90 mm), which enables less culture medium to be used and three times as many agar plates to be incubated in each anaerobic jar. If a pure colony is not obtained after incubation of the primary isolation plate, then with a sterile spatula the agar is flipped upside down into the lid so that the underside colony can be sampled and subcultured (Depiazzi et al., 1990). Alternatively, a sterile microscope cover glass, dipped into a bacterial suspension of a contaminated bacterial colony and rinsed to remove nonadherent bacteria, can be used to purify *D. nodosus* colonies. The cover glass is moved in a zigzag manner over the agar surface to inoculate the adherent *D. nodosus* cells. These modifications enable the time interval between submission and final reporting to be reduced to 8 d.

Maintenance Procedures

For routine maintenance of *D. nodosus* cultures under anaerobic conditions, either hoof agar, TAS agar, modified TAS agar, or blood Eugonagar (Gradin and Schmitz, 1977) can be used. For anaerobic broth cultures, TAS broth, HEPES TAS broth, or modified Eugonbroth (BBL) is recommended. To facilitate prompt growth in liquid medium from agar cultures, the broth can be inoculated with an aqueous vortexed suspension of pure colonies or a small portion of agar. Although *D. nodosus* is an anaerobe, fully grown plate cultures can tolerate exposure to air for up to 12 h on the laboratory bench (Skerman, 1989). Cultures will remain viable in anaerobic jars for several weeks at room temperature (Skerman, 1975). For long-term storage of cultures, *D. nodosus* may be preserved by lyophilization of 3–4-d-old cells suspended in horse serum containing 7.5% (w/v) glucose, skim milk, 0.25 M sucrose, or TAS broth, or alternatively by adding 20% glycerol to TAS broth suspensions and freezing at −70°C. Cryopreserved preparations are known to survive for more than 20 years.

Procedures for Testing Special Characters

Ovine footrot lesions differ in severity according to the virulence of the strain of *D. nodosus* involved; the two major clinical forms are termed virulent and benign footrot (Stewart, 1989). There are also strains of *D. nodosus* that are intermediate in virulence. However, for purposes of uniformity in footrot diagnosis, footrot is described as virulent or benign, with strains of intermediate virulence being regarded as effectively virulent. Because the extent of disease expression is also influenced by the host (e.g., the breed of sheep), the season, and the environment, laboratory diagnosis is increasingly being used to assist the clinical diagnosis of virulent or benign footrot. Although there is a correlation between virulence of wild-type isolates and colony type, this distinction is not sufficiently reliable as a laboratory test for differentiating virulent and benign isolates. The gelatin gel test is the recommended laboratory diagnostic test for differentiating virulent and benign footrot (Palmer, 1993); it measures the thermostability of proteases in 2–4-d-old broth cultures. In general, isolates of *D. nodosus* capable of producing virulent footrot produce proteolytic enzymes that are stable to heating at 67°C, whereas proteases from benign isolates are inactivated at this temperature. Proteolytic activity is detected by clearing of a gelatin substrate incorporated into agarose plates. The gelatin gel test has now superseded the elastase test because the latter may take 7–28 d for a definitive result. Virulent isolates cause digestion of elastin particles beneath the streak line in elastin TAS agar plates, whereas benign isolates do not produce clearing (Stewart, 1979). In the alternative zymogram protease test, the electrophoretic pattern of the protease isoenzymes is determined in a nondenaturing polyacrylamide slab gel electrophoresis system followed by detection with a gelatin/agarose contact overlay assay. Benign and virulent strains have different and characteristic profiles (Every, 1982; Kortt et al., 1983; Palmer, 1993). There is a range of different zymogram patterns for isolates with either stable (S) proteases or unstable (U) proteases, with the predominant pattern being the S1 and U1 pattern, respectively (Palmer, 1993). The zymogram test may be useful for classifying isolates where there are anomalous results with the gelatin gel test and virulence assessment.

More recently, two new technologies have become available for footrot diagnosis. These are the protease monoclonal antibody (Mab) ELISA (Stewart et al., unpublished) and the gene probe/PCR-based assay (Katz et al., 1991; Liu, 1994; Rood et al., 1996). The virulent and benign Mabs are able to distinguish antigenic differences between the proteases produced by virulent and benign strains, and there is a high level of agreement between the results for the gelatin gel test and the protease Mab ELISA. This difference in epitope specificity may result from a single amino acid change in one of the virulent and benign acidic proteases (Riffkin et al., 1995). The gene probe or PCR tests detect virulence-associated genomic DNA unrelated to the protease genes. The DNA probes, which specifically detect the *vrl* and *vap* gene regions, divide *D. nodosus* isolates into three major categories (1, 2, and 3). The PCR test is based on specific oligonucleotide primers for the *vrl* and *vap* specific plasmids, pJIR314B and pJIR318, respectively (Rood et al., 1996). The PCR test further divides isolates in gene probe categories 1 and 2 into groups L and H. Isolates in all three categories can belong to

probe category + or − depending on the presence or absence of an additional gene region. It is recommended that rapid Mab tests for the proteases be used for differentiation of virulent and benign footrot and that the PCR assay should be used for molecular epidemiological studies.

Differentiation of the genus *Dichelobacter* from other genera

Dichelobacter nodosus, previously *Bacteroides nodosus*, can be differentiated from members of the genera *Bacteroides*, *Prevotella*, and *Porphyromonas* by fatty acid analysis. *D. nodosus* possesses $C_{16:1\ \omega7c}$, $C_{18:1\ \omega7c}$, and $C_{16:0}$ fatty acids, while the genera in the phylum *"Bacteroidetes"* contain large amounts of the methyl branched-chain fatty acids $C_{15:0\ iso}$ and $C_{15:0\ anteiso}$. Genera in the *"Bacteroidetes"* also possess sphingolipids. *D. nodosus* contains type IV pili, which have been found only in *Proteobacteria*. *D. nodosus* can be differentiated from other genera in the family *Cardiobacteriaceae* in that it is anaerobic, oxidase negative, indole negative, and ornithine decarboxylase positive.

Taxonomic Comments

Dichelobacter nodosus is the only species in the genus *Dichelobacter*. The genera *Dichelobacter*, *Suttonella*, and *Cardiobacterium* compose the family *Cardiobacteriaceae*. The family branches deeply in the *Gammaproteobacteria* at the juncture of the *Gammaproteobacteria* and *Betaproteobacteria*. Neighboring families include *"Xanthomonadaceae"*, *"Piscirickettsiaceae"*, and *"Francisellaceae"*. A phylogenetic tree including *Dichelobacter nodosus* is shown in the *Cardiobacteriaceae* chapter.

List of species of the genus Dichelobacter

1. **Dichelobacter nodosus** (Beveridge 1941) Dewhirst, Paster, La Fontaine and Rood 1990, 426^{VP} (*Bacteroides nodosus* (Beveridge 1941) Mráz 1963, 85; *Fusiformis nodosus* Beveridge 1941, 23.)
no.do′sus. L. adj. *nodosus* full of knots, refers to the shape of the cells.

The characteristics are as described for the genus. The organism is found on the hooves and interdigital skin of ruminants, especially sheep and cattle. The growth of most strains on an appropriate medium, such as TAS medium, is more luxurious than that of ATCC 25549. The genome of strain A198 is circular, 1.54 Mb in size, and has three rRNA operons (La Fontaine and Rood, 1996). The GenBank accession number of the 16S rRNA molecule from the reference strain A198 is M35016 (Dewhirst et al., 1990). There is no 16S rDNA sequence available from the type strain.

The organism is the essential causative agent of footrot in sheep and other ruminants (Stewart, 1989). The fimbriae are the major protective antigens; immunization of sheep with purified recombinant fimbriae will protect against infection but only by members of the homologous serogroup (Egerton et al., 1987; Stewart and Elleman, 1987). The major virulence antigens appear to be the type IV fimbriae and the extracellular serine proteases produced by the organism. Virulent isolates produce four extracellular acidic serine proteases (V1–V3, V5), pI 5.2–5.6, and a basic protease (BprV), pI.~9.5. The benign protease isoenzymes, B1–B4, have distinctly different electrophoretic mobilities and pIs, elastolytic activity, and heat stability, but are very similar to V1–V3 from virulent strains in amino acid composition, and peptide profiles, and apparent M_r proteases V5 and B5 are identical. Benign strains secrete a distinct basic protease BprB), pI 8.6, that is very closely related to the virulent basic protease. In summary, there are three distinct types of *D. nodosus* proteases, V5/B5, V1–V3/B1–B4, and the basic protease. The gene sequences for the two acidic protease genes, *apr*V5 and *apr*V2/B2, and the basic protease genes, *bpr*V/bprB, have been determined. These serine proteases are members of the subtilisin family of proteases and presumably arose by gene duplication from an ancestral precursor gene. They show significant sequence similarity to the extracellular serine protease of *Xanthomonas campestris*, a plant pathogen. In addition, there is a 27-kb genomic region, the *vrl* locus, that appears to be preferentially associated with more virulent isolates. An additional integrated region, the *vap* locus, is found in all isolates that carry the *vrl* region, and in other isolates (Billington et al., 1996a). The genome of *D. nodosus* strain VCS1703A is currently being sequenced by the Institute for Genomic Research (TIGR). The genome has been assembled into 264 contigs and can be searched using BLAST at TIGR (http://www.tigr.org/) or NCBI (http://www.ncbi.nlm.nih.gov/blast/).

The mol% G + C of the DNA is: 45.

Type strain: ATCC 25549.

Additional Remarks: The reference strain is ATCC 27521 (A198, 198A, or VPI5731-1).

Genus III. **Suttonella** *Dewhirst, Paster, La Fontaine and Rood 1990, 429*[VP]

Floyd E. Dewhirst and Bruce J. Paster

Sut.ton.el′la. L. dim. ending *-ella*; N.L. fem. n. *Suttonella* named after R.G.A. Sutton.

Large straight rods, 1.0 × 2–3 μm, with rounded ends. Cells occasionally occur in pair, chains, or rosettes. Gram negative but with a tendency to resist Gram decolorization. Nonmotile as determined by normal tests, but may be fimbriated (i.e., have pili) and exhibit twitching motility. Aerobic. Aerobic growth is enhanced by high humidity and CO_2, which makes the organism appear to be facultatively anaerobic. **Oxidase positive** (when tested with tetramethyl-*p*-phenylene diamine). **Catalase negative**. **Indole positive** (activity may be weak). Urease negative. DNase negative. Ornithine and lysine decarboxylase negative. **Alkaline phosphatase positive**. Trypsin (*N*-benzoyl-DL-arginine-2-naphthylamide) negative. Phosphohydrolase (naphthyl-AS-B1-phosphate) negative. Chemoorganotrophic, having a fermentative type of metabolism. Acid but not gas is produced from fructose, glucose, maltose, D-mannose, and sucrose. The maltose reaction is weak and delayed (positive at 28 d), but is negative as determined by rapid (4–24 h) protocols. **Nitrates are not reduced**. Nitrites are reduced by some strains. Resazurin is reduced. H_2S is produced (as determined by the lead acetate method, but not by the triple sugar iron method). No growth occurs on MacConkey agar.

The mol% G + C of the DNA is: 49.

Type species: **Suttonella indologenes** (Snell and Lapage 1976) Dewhirst, Paster, La Fontaine, and Rood 1990, 430 (*Kingella indologenes* Snell and Lapage 1976, 456.)

Further descriptive information

Initial isolates of *Suttonella indologenes* were considered novel *Moraxella* strains (van Bijsterveld, 1970; Sutton et al., 1972; Bøvre et al., 1974). Snell and Lapage (1976) placed these saccharolytic and indole producing strains in the genus *Kingella* as the novel species *Kingella indologenes*. DNA–DNA hybridizations (Rothenpieler et al., 1986) and 16S rRNA sequence analysis (Dewhirst et al., 1990) demonstrated that *Kingella indologenes* was not related to other *Kingella* species in the family *Neisseriaceae*, but rather branched between the *Betaproteobacteria* and *Gammaproteobacteria* (rRNA homology groups I and II) with *Cardiobacterium hominis*. Subsequent 16S rRNA sequence analysis demonstrated that *Bacteroides nodosus* also clustered with these species. These three species were placed in the family *Cardiobacteriaceae*, and *Kingella indologenes* and *Bacteroides nodosus* were renamed *Suttonella indologenes* and *Dichelobacter nodosus*, respectively (Dewhirst et al., 1990).

Suttonella grows slowly and after 24 h colonies are 0.1–0.5 mm in diameter. After 72 h, colonies are 1–1.5 mm. Pitting of media or spreading edges has been seen in fresh colonies, but may be lost on storage (Snell and Lapage, 1976).

The major cellular fatty acids are as follows: $C_{18:1\ \omega7c}$ (27%), $C_{16:0}$ (26%), $C_{16:1\ \omega7c}$ (19%), $C_{14:0}$ (11%), $C_{12:0}$ (5%), and $C_{12:0\ 3OH}$ (2%) (Wallace et al., 1988).

Ultrastructure has not been examined, but related genera *Cardiobacterium* and *Dichelobacter* both possess crystalline surface layers and intrusive membranes (Reyn et al., 1971; Stewart and Egerton, 1979). *Suttonella indologenes* possesses *N*-methylphenylalanine, or type IV pili.

Growth and biochemical characteristics from several references were summarized by Bruun et al. (1984b) and by Weyant et al. (1996). Growth at 22, 30, and 37°C. Acid is produced from dextrin, fructose, glucose, maltose, D-mannose, and sucrose. Growth in the presence of 4% NaCl. Production of acid phosphatase, γ-glutamyltransferase, indole, and hydrogen sulfide (by lead acetate paper). Hydrolysis of casein, Tween 20, and Tween 40. No growth at 5, 40, 42, or 45°C, or in the presence of 6% NaCl, 10% or 40% bile. No acid is produced from D-adonitol, L-arabinose, cellobiose, dulcitol, ethanol, D-galactose, glycerol, *i*-inositol, lactose, D-mannitol, melibiose, raffinose, L-rhamnose, salicin, starch, D-sorbitol, trehalose, or D-xylose. No liquefaction of gelatin or serum. No production of β-galactosidase, urease, ornithine decarboxylase, lysine decarboxylase, or trypsin. No citrate utilization or growth on hydroxybutyrate. No hydrolysis of esculin, starch, Tween 80, or arginine. No reduction of nitrate.

Currently, the only genetic information in GenBank for *Suttonella indologenes* is the 16S rRNA sequence under accession number M35015. The closely related organism *Dichelobacter nodosus* has been much more extensively studied, and over 60 sequences are in GenBank (see the chapter on the genus *Dichelobacter*). This sequence information should be extremely useful in seeking homologous genes in *Suttonella indologenes*.

Little is known regarding the pathogenicity of *Suttonella indologenes*. It has been isolated from patients with eye infections and endocarditis (van Bijsterveld, 1970; Sutton et al., 1972; Jenny et al., 1987).

Enrichment and Isolation Procedures

No particular methods have been developed specifically for isolation of *S. indologenes*. Strains have been recovered on standard blood plates grown under microaerophilic conditions.

Maintenance Procedures

Strains of *S. indologenes* may be preserved by lyophilization.

Procedures for Testing Special Characters

Indole formation may be weak and should be determined using extraction with xylene or chloroform and detection with Ehrlich's reagent (*p*-dimethylaminobenzaldehyde). The spot indole reagent *p*-aminocinnamaldehyde may fail to detect weak indole production.

Differentiation of the genus *Suttonella* from other genera

See Table BXII.γ.34 in the chapter on the family *Cardiobacteriaceae*. *Suttonella* may be distinguished from *Cardiobacterium* by a positive reaction for alkaline phosphatase, and negative reactions for D-sorbitol and D-mannitol fermentation. *Suttonella* may be distinguished from *Eikenella* and *Kingella* by indole production and γ-glutamyltransferase activity. *Suttonella* may be distinguished from many other genera by the unusual combination of being oxidase and indole positive and catalase and nitrate reduction negative.

Taxonomic Comments

Suttonella indologenes is the only species in the genus *Suttonella*. The genera *Suttonella, Dichelobacter*, and *Cardiobacterium* compose the family *Cardiobacteriaceae*. The family branches deeply in the *Gammaproteobacteria* at the juncture of the *Gammaproteobacteria*

and *Betaproteobacteria*. Neighboring families include *"Xanthomonadaceae"*, *"Piscirickettsiaceae"*, and *"Francisellaceae"*. A phylogenetic tree including *Suttonella indologenes* can be seen in Fig. BXII.γ.40.

Rosettes of trichomes typically but not always produced. Only rosette-forming strains

produce gonidia. Resting stages not known. Flagella absent, but a tuft of monopolar fimbriae may be present.

Aerobic or microaerophilic. Facultatively autotrophic, chemoorganotrophic, and mixotrophic species; the latter requiring any of several small organic compounds, e.g., acetate, lactate, propionate, pyruvate, succinate, fumarate, and oxalacetate, as well as a reduced inorganic sulfur source. **Sulfur globules deposited** within invaginations of the cytoplasmic membrane of cells grown in the presence of a reduced inorganic sulfur compound. **By light microscopy, sulfur globules appear to be internal.**

Found in sulfide-containing flowing water and in activated-sludge wastewater treatment systems.

The mol% G + C of the DNA is: 44–52.

Type species: **Thiothrix nivea** (Rabenhorst 1865) Winogradsky 1888, 39 (*Beggiatoa nivea* Rabenhorst 1865, 94.)

Further descriptive information

Advances have occurred in the taxonomy of the genus *Thiothrix* since the last edition of the *Manual* and it is no longer possible to rely on morphology alone to positively identify *Thiothrix* spp., especially, the polymorphic *T. eikelboomii* and *T. defluvii*. Notwithstanding dimensional differences, cells of *Thiothrix* spp. exhibit geometries that are typically cylindrical (Fig. BXII.γ.41a) as for *T. nivea*, *T. unzii*, and *T. fructosivorans*, and variously cuboidal, barrel-shaped, discoid, and bead-like (Fig. BXII.γ.41d and e) with respect to *T. eikelboomii* and *T. defluvii*. Trichomes are rigid in most *Thiothrix* species; however, *T. eikelboomii* and *T. defluvii* trichomes can form distinct loops or knots (Fig. BXII.γ.42), suggesting flexibility in the filaments. Several species do not contain ensheathed trichomes; however, when present, the sheath (Fig. BXII.γ.43) appears to be made up of several layers (Fig. BXII.γ.44a) and extends the full length of the trichome (Fig. BXII.γ.41c). Base to tip differentiation in cells of trichomes (Fig. BXII.γ.45) is prominent in some species. The cell wall is typically Gram negative (Fig. BXII.γ.44b), although, *T. eikelboomii* may demonstrate Gram stain variability and the formation of transverse septa in the process of cell division (Fig. BXII.γ.41e). Sulfur globules are deposited within invaginations of the cytoplasmic membrane (Fig. BXII.γ.46) and are therefore external to the cytoplasm, as in *Beggiatoa*. Poly-β-hydroxybutyrate (PHB; Fig. BXII.γ.41b and f) and polyphosphate intracellular inclusions (Fig. BXII.γ.47) may be produced. Larkin (1989) reported unconfirmed nitrogen fixation by several JP strains, including the neotype strain of *T. nivea*. Rosettes of trichomes are observed in all freshly isolated species but the property may not be stable upon repeated subculture in the laboratory. Rosettes may form from outgrowth of gonidia collected at the tip of a preexisting trichome or aggregated in the suspending fluid (Fig. BXII.γ.48). Initial attachment of the gonidia involves fimbriae (Fig. BXII.γ.49), with holdfast material being produced after attachment (Fig. BXII.γ.47). A life cycle is proposed by Larkin and Shinabarger (1983) and Larkin (1989).

Isolates of *Thiothrix* spp. develop visible colonies on LT agar after 2–3 d incubation at 28°C. Colonies are less than 2 mm in diameter, white to off-white, hard to the touch, flat to slightly raised with rough to slightly wavy or thread-like margins (Fig. BXII.γ.50). Liquid cultures are turbid to flocculent depending on species and contain freely dispersed gonidia and small rosettes. In addition, length of trichomes appears affected by culture conditions with shorter (<200 μm) trichomes occurring in shaken cultures and long (500 μm) trichomes present in static cultures.

Winogradsky (1888) first described *Thiothrix nivea* and suggested the possible presence of autotrophy within the genus *Thiothrix*. Present evidence for autotrophic potential in *Thiothrix* spp. includes ribulose biphosphate carboxylase/oxygenase (RubisCo) activity (Unz and Williams, 1989; Odintsova et al., 1993) and carbon dioxide fixation (Strohl and Schmidt, 1984; McGlannan and Makemson, 1990). Chemolithoautotrophic growth is reported for *"Thiothrix ramosa"* (Odintsova et al., 1993) and *Thiothrix* strain CT3 (Tandoi et al., 1994) and *in situ* measurements of the physiology of *Thiothrix* cells in activated sludge further implicates autotrophy for these organisms (Nielsen et al., 2000). *T. nivea* has not been cultured chemolithoautotrophically or shown to fix carbon dioxide although DNA probes have detected genes encoding for RubisCo in the organism (Shively et al., 1986).

Thiothrix spp. are found in flowing sulfide-containing waters of circumneutral pH (Bahr and Schwartz, 1956; Brigmon et al., 1994) and low oxygen tension (Bahr and Schwartz, 1956; Bland and Staley, 1978) and in activated sludge systems treating septic or sulfide-bearing wastewaters (Farquhar and Boyle, 1971; Williams and Unz, 1985b; Unz and Williams, 1988). It may be the dominant filamentous sulfide-oxidizing organism in suitable waters (Lackey et al., 1965; McGlannan and Makemson, 1990). *Thiothrix* spp. have been observed in symbiotic (Brigmon and De Ridder, 1998) and epiphytic (Larkin et al., 1990) association with aquatic animals. The ability of *Thiothrix* spp. to attach to objects and to itself undoubtedly allows it to remain situated in a suitable location in flowing water.

Enrichment and Isolation Procedures

Several methods have been reported for the enrichment of *Thiothrix* spp. In the procedure of Larkin (1989), fine-tipped forceps may be used to select tufts of suspected *Thiothrix* trichomes from *Thiothrix*-containing material contained in a Petri dish while under observation with a dissecting microscope and transmitted light. Bundles of trichomes are transferred to a second Petri dish containing about 5–10 ml of a salt solution (SS)[1] (Strohl and Larkin, 1978b), agitated with the forceps, and then transferred to another Petri dish containing the SS solution. The procedure is repeated through four or five transfers. A few drops from each dilution are transferred with a Pasteur pipette to either MP agar (SS plus 0.0001% sodium acetate, 0.03% Na_2S and 1.5% agar; Strohl and Larkin, 1978b) or MY agar (SS plus 0.01% each of sodium acetate, nutrient broth powder, and yeast extract, plus 0.03% Na_2S, and 1.5% agar; Larkin, 1980) in separate Petri dishes. Each dish is held on an angle so that the drops will flow across the agar surface. The excess is then withdrawn from the other side with the pipette. The dishes are incubated at about 25–30°C and are examined daily under transmitted light with the aid of a dissecting microscope. Colonies with a hairy or filamentous edge are transferred with sterile toothpicks to fresh media and are restreaked until pure.

Williams and Unz (1985a) transferred 1 ml amounts of activated sludge mixed liquor to standard test tubes containing 5 ml of solid media (0.15% glucose and/or 0.06% $Na_2S\cdot 9H_2O$ plus 2.0% Bacto-agar) and an overlay of 15 ml of a mineral salts-vitamin solution (MSV).[2] Tubes are incubated at 22–25°C. Sur-

1. Salt solution contains: NH_4Cl, 0.02%; K_2HPO_4, 0.001%; $MgSO_4$, 0.001%; $CaSO_4$, 20 ml/l of a saturated solution; and trace element solution, 5 ml/l. pH is about 7.5. (Trace element solution contains: $ZnSO_4\cdot 7H_2O$, 0.001%; $MnSO_4\cdot 4H_2O$, 0.002%, $CuSO_4\cdot 5H_2O$, 0.00000005%; H_3BO_3, 0.001%; $Co(NO_3)_2$, 0.0001%; Na-molybdate, 0.0001%; EDTA, 0.02%; and $FeSO_4\cdot 7H_2O$, 0.07%.)

2. Mineral salts solution contains (per liter): $(NH_4)_2SO_4$, 0.5 g; $MgSO_4\cdot 7H_2O$, 0.1 g; $CaCl_2\cdot 2H_2O$, 0.05 g; K_2HPO_4, 0.11 g; KH_2PO_4, 0.085 g; $FeCl_3\cdot 6H_2O$, 0.002 g; EDTA, 0.003 g; and vitamin mix (Eikelboom, 1975), 1.0 ml. pH is about 7.5.

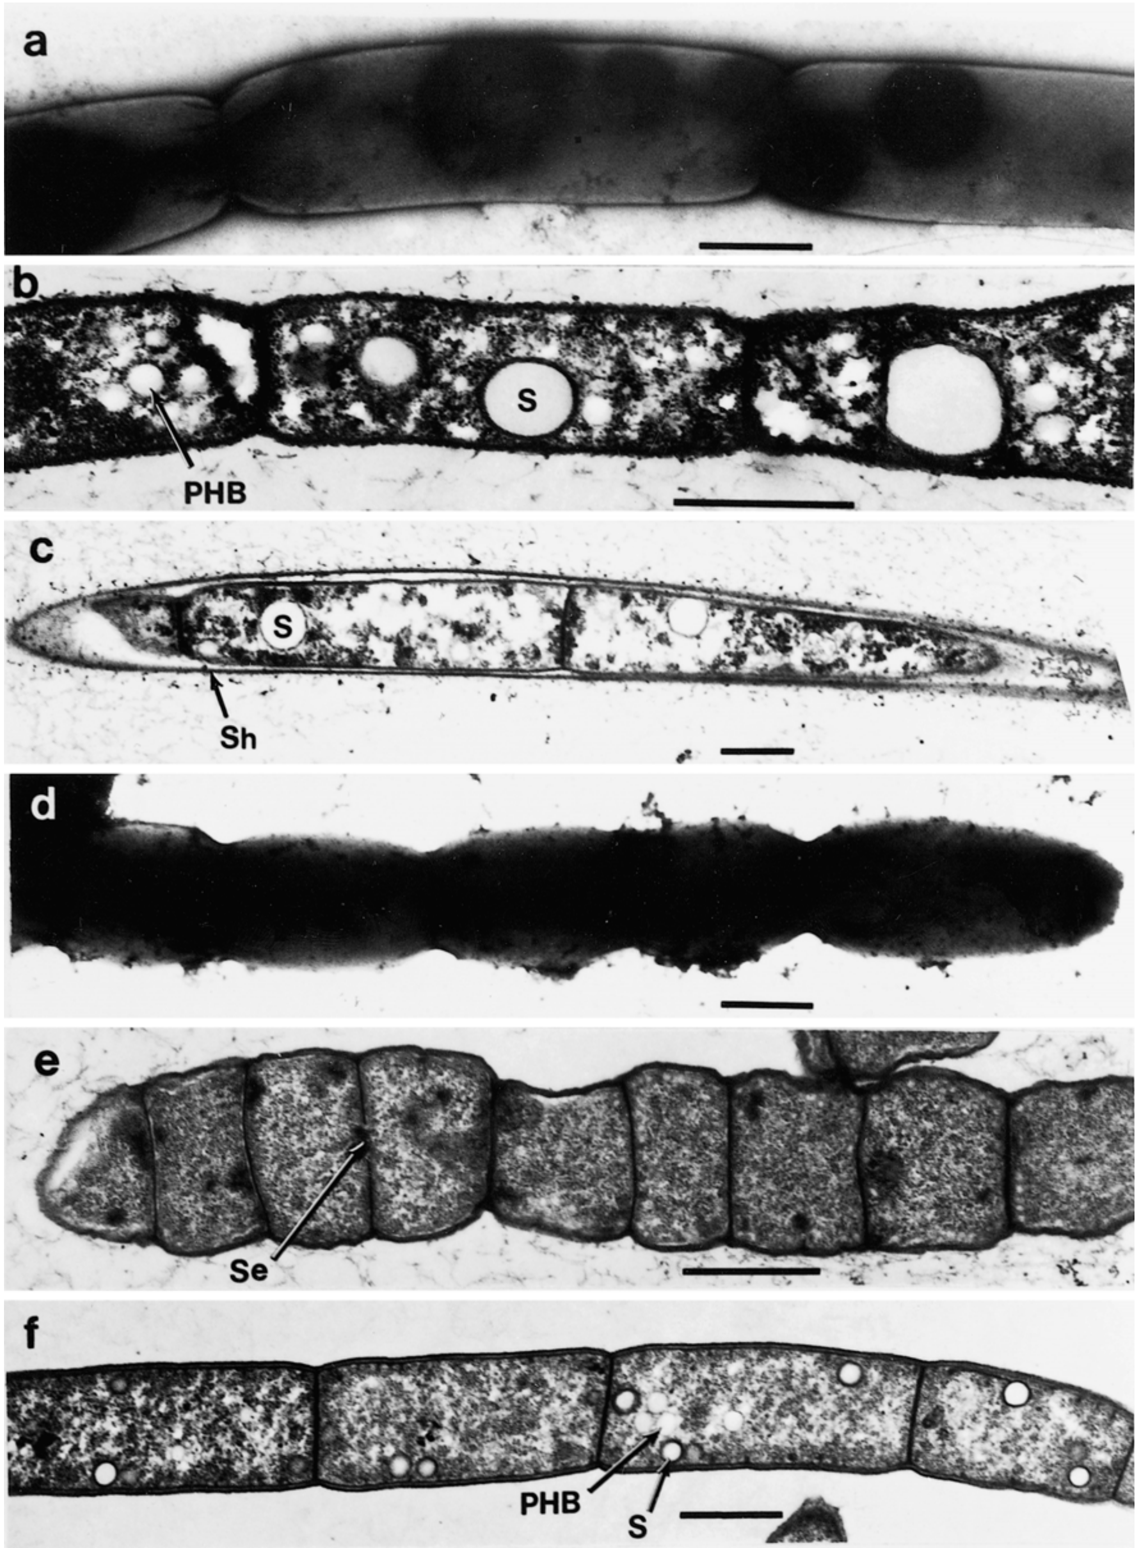

FIGURE BXII.γ.41. General ultrastructural characteristics of trichomes of *Thiothrix* species. *Thiothrix unzii* (*a*, whole cell; *b*, thin section); *Thiothrix fructosivorans* (*c*, thin section); *Thiothrix eikelboomii* (*d*, whole cell; *e*, *f*, thin section). Abbreviations: *Sh*, sheath; *Se*, septum; *S*, sulfur inclusion; *PHB*, poly-β-hydroxybutyrate. Bars = 1.0 μm. (Reproduced with permission from T.M. Williams et al., Applied and Environmental Microbiology *53:* 1560–1570, 1987, ©American Society for Microbiology.)

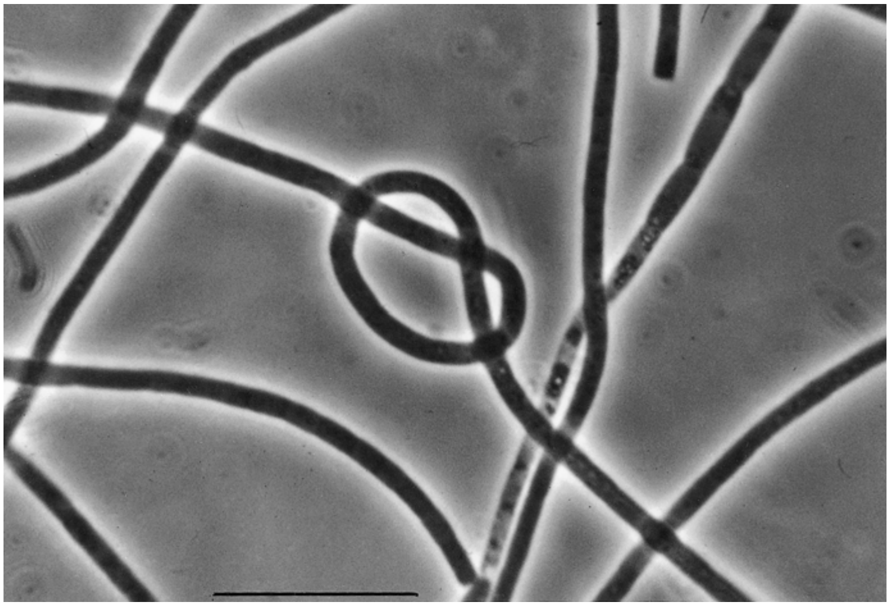

FIGURE BXII.γ.42. Knot produced in trichome by *Thiothrix eikelboomii*. Bar = 10 μm. (Reproduced with permission from T.M. Williams and R.F. Unz, Applied and Environmental Microbiology *49:* 887–898, 1985, ©American Society for Microbiology.)

face specimens are examined periodically by microscopy for evidence of the development of *Thiothrix* trichomes. Isolation of *Thiothrix* spp. is initiated by placing several loopfuls of enrichment culture films or dilute (10^{-1}) activated sludge in Petri dishes containing 7 ml of sterile MSV and, with the aid of a stereomicroscope (15–45× magnification), selecting 40–50 single filaments or rosettes to be washed by serial transfer six to seven times in fresh MSV. Washed trichomes are streaked on glucose–sulfide[3] or LT[4] medium.

Maintenance Procedures

The type species can be maintained in semisolid (0.15% agar) deeps of either MP or MY medium, with transfers at intervals of about 3–4 weeks. Other *Thiothrix* spp. survive monthly transfers in LTH[5] medium (sodium lactate supplied at 1.0 g/l) when stored at 10°C and cryopreservation at −83 to −90°C.

Procedures for Testing Special Characters

Larkin (1989) employed MP broth or appropriate modifications to test sole carbon (0.05%), nitrogen (0.02 or 0.05%), and sulfur (0.03%) sources in support of sustained growth of *T. nivea* strains through three successive transfers. Other *Thiothrix* species were nutritionally evaluated in MSV employing as a positive result the criterion of optical density equal to or greater than 4× that of controls (Williams and Unz, 1989).

3. Glucose–sulfide medium contains (per liter): glucose, 0.15 g; $(NH_4)_2SO_4$, 0.5 g; $Ca(NO_3)_2$, 0.01 g; $K_2HPO_4 \cdot 7H_2O$, 0.05 g; KCl, 0.05 g; $CaCO_3$, 0.1 g; $Na_2S \cdot 9H_2O$, 0.187 g; vitamin mix, 1.0 ml; and agar, 15.0 g, when needed. pH is about 7.5.

4. LT medium contains per liter of MSV: sodium lactate, 0.5 g; $Na_2S_2O_3 \cdot 5H_2O$, 0.5 g; and agar, 12.0 g. pH is about 7.5.

5. LTH medium contains per liter of MSV: sodium lactate, 0.5 g; $Na_2S_2O_3 \cdot 5H_2O$, 0.5 g; and HEPES buffer (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid), 0.01 M. pH is about 7.5.

Differentiation of the genus *Thiothrix* from other genera

Recent inclusion of new species within *Thiothrix* has exacerbated the problem of differentiation of the genus from other trichome-forming bacteria on morphological and physiological grounds. *Thiothrix* differs from *Beggiatoa* in that the latter is less nutritionally diverse, does not form gonidia, and trichomes are not ensheathed or in rosettes although they exhibit a gliding motility. *Thiothrix* is separated from *Thioploca* by the production of rosettes and the lack of gliding trichomes in the former and by the presence of multiple filaments within a single sheath and a multilayered cell wall in *Thioploca*. The unavailability of axenic cultures of *Thioploca* precludes further physiological comparison with *Thiothrix*. Analyses of 16S rDNA sequences recovered from purified *Thioploca* biomass collected from natural environments has shown that *Thioploca* spp. are distantly related to *Thiothrix* spp., although both genera belong to the *Gammaproteobacteria* (Teske et al., 1995; Ahmad et al., 1999). *Thioploca* spp. are more closely related to *Beggiatoa* spp. than to *Thiothrix* spp. (Teske et al., 1999; Ahmad et al., 1999). *Thiothrix* may be differentiated from *Leucothrix*, which it resembles morphologically, by the presence of a sheath in some species of the former and the unequivocal ability to deposit sulfur globules. It should be noted, however, that some *Leucothrix* strains may deposit intracellular sulfur (Brock, 1992; Dul' tseva et al., 1996; Grabovich et al., 1999); hence, this property alone may be insufficient to distinguish *Leucothrix* from *Thiothrix*. Although both genera exhibit gonidia formation, *Thiothrix* produces gonidia from only the end of a trichome, whereas the entire trichome of *Leucothrix* may fragment into gonidia.

Taxonomic Comments

The type species of *Thiothrix* is *Thiothrix nivea*. The original specimen for which the type species was named is nonexistent and *T. nivea* JP2 (DSM 5202) is the approved neotype strain. Sub-

sequent descriptions of *Thiothrix* spp. have largely been based on morphological criteria that have not progressed beyond descriptions at the genus level.

Morphology has been a primary criterion in the taxonomy of many filamentous bacteria and it has been suggested that this may be sufficient for the characterization of *Thiothrix* spp. (Polz et al., 1996). However, features considered diagnostic for *Thiothrix* spp. (holdfast and rosette formation and the production of gliding gonidia) are not exclusive as may be noted for *Leucothrix mucor* (Williams and Unz, 1985b; Brock, 1992) and the Eikelboom type 021N bacteria associated with bulking activated sludge. Woese (1987) has stressed that morphological characteristics are of little value as indicators of phylogenetic relationships among a majority of bacteria and axenic cultures of *Thiothrix* species have been observed to undergo change in morphology of trichomes (Shuttleworth and Unz, 1991, 1993; Brigmon et al., 1995). Despite extensive use of *in situ* morphology and staining reactions to identify filamentous bacteria associated with activated sludge bulking and foaming (Eikelboom, 1975; Jenkins et al., 1993), these characteristics can vary depending on environmental conditions and are singularly of limited diagnostic value. Furthermore, bacterial morphotypes termed *"Leucothrix cohaerens"* (Pringsheim, 1957; Cyrus and Sladka, 1970) and *Thiothrix* sp. forms I and II (Farquhar and Boyle, 1971) have been equated with Eikelboom type 021N bacteria (Eikelboom, 1975). The taxonomic position of the polymorphic Eikelboom type 021N bacteria and their relationship to the genus *Thiothrix* has been questioned (Williams and Unz, 1985a, 1989; Ziegler et al., 1990). In recognition of the limitations of morphological characterization in the taxonomy of many filamentous bacteria, molecular biological approaches based on comparative 16S rRNA analyses have been used in the attempt to clarify relationships among such bacterial morphotypes.

Analysis of 16S rRNA sequences derived from six *Thiothrix* spp. (including one *Thiothrix* sp. form I) and 8 Eikelboom type 021N bacteria revealed that they fell within a single monophyletic

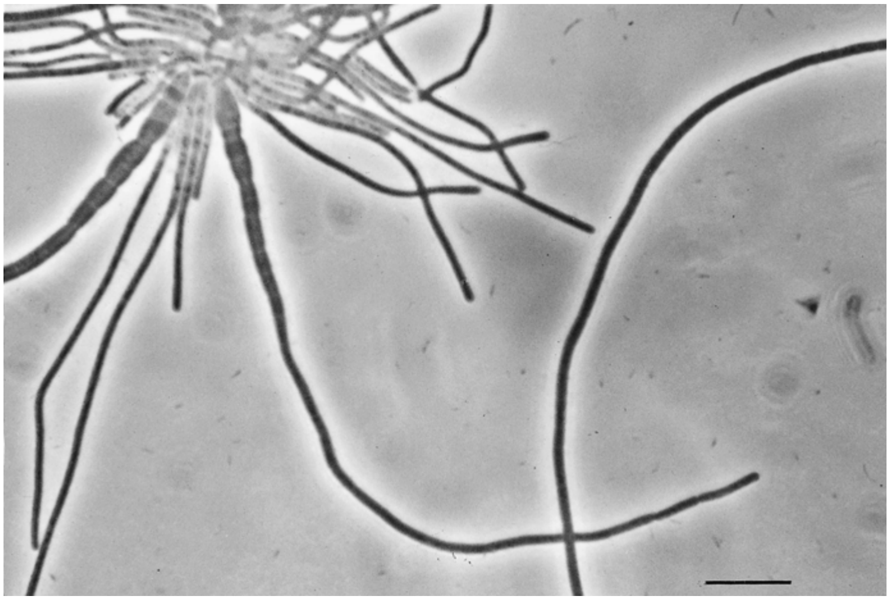

FIGURE BXII.γ.45. Base to tip differentiation in cell dimensions in a trichome of *Thiothrix fructosivorans*. Bar = 10 μm. (Reproduced with permission from T.M. Williams and R.F. Unz, Applied and Environmental Microbiology *49:* 887–898, 1985, ©American Society for Microbiology.)

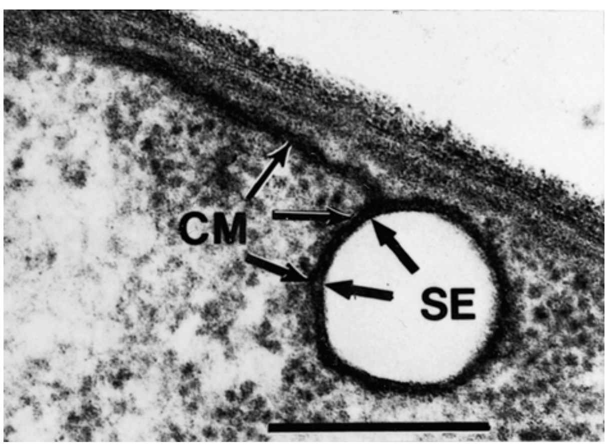

FIGURE BXII.γ.46. Sulfur inclusion in invaginated cytoplasmic membrane of a cell of *Thiothrix eikelboomii*. Abbreviations: *CM*, cytoplasmic membrane; *SE*, sulfur inclusion envelope. Bar = 250 nm. group suggesting a clear relationship between Eikelboom type 021N and *Thiothrix* spp. (Howarth et al., 1999). Consequently, four new *Thiothrix* species have been validly described with sequence identities below 97.5% (Howarth et al., 1999) and include strains categorized as *incertae sedis* in the previous edition of the *Manual*. Strains previously categorized as Eikelboom type 021N are now accommodated within the species, *T. eikelboomii*, of which strain AP3 (ATCC 49788) is the type strain and a single *Thiothrix* sp. form I is named *T. defluvii* (type strain Ben57). *T. unzii* is represented by type strain A1 (ATCC 49747) that, like *T. nivea*, requires a source of reduced sulfur and organic carbon for growth. *T. fructosivorans* is a chemoorganotrophic species represented by the type strain Q (ATCC 49748) and strain I (ATCC 49749), which is essentially identical to the type strain. Despite the close phylogenetic relationship between *T. fructosivorans*, *"T. ramosa"*, and *Thiothrix* sp. CT3 (>97% 16S rRNA sequence identity), *T. fructosivorans* is not known to be capable of autotrophic growth, notwithstanding evidence of RubisCo activity (Unz and Williams, 1989), whereas *"T. ramosa"* and *Thiothrix* sp. CT3 both grow autotrophically (Odintsova et al., 1993; Tandoi et al., 1994). Analysis of 16S rDNA sequences from a further 15 isolates, identified morphologically as Eikelboom type 021N, revealed the organisms to be most closely related to *Thiothrix* species (Fig. BXII.γ.51), although considerable additional phylogenetic diversity was discovered (Kanagawa et al., 2000). In addition to organisms related to *T. nivea* (group 0), several isolates related to *T. eikelboomii* (group II sensu Kanagawa et al., 2000), a completely distinct group (group I sensu Kanagawa et al., 2000), and a group related to, but significantly divergent from, *T. defluvii* (group III sensu Kanagawa et al., 2000) were resolved. Although these isolates showed a considerable degree of divergence in their 16S rRNA sequences, they had very homogeneous mol% G + C content (43.9–46.1) and all shared a characteristic deletion in helix 18 of their ribosomal RNA (positions 455–477 by *E. coli* numbering), which further supports their relationship to named *Thiothrix* spp. (Howarth et al., 1999; Kanagawa et al., 2000). Accordingly, groups I and III (Kanagawa et al., 2000) should be designated as new species.

During the preparation of this chapter the group of Takahiro Kanagawa described groups I and III as two new *Thiothrix* species: *Thiothrix disciformis* and *Thiothrix flexilis* (Aruga et al., 2002). *Thiothrix disciformis* corresponds to group I in Fig. BXII.γ.51. B3-1 is the type strain. *Thiothrix flexilis* corresponds to group III in Fig. BXII.γ.51 and EJ2M-B is the type strain. These organisms are morphologically recognizable as Eikelboom Type 021N and filaments exhibit considerable variability in cell morphology with discoid and ovoid cells often being present, as are elongate and

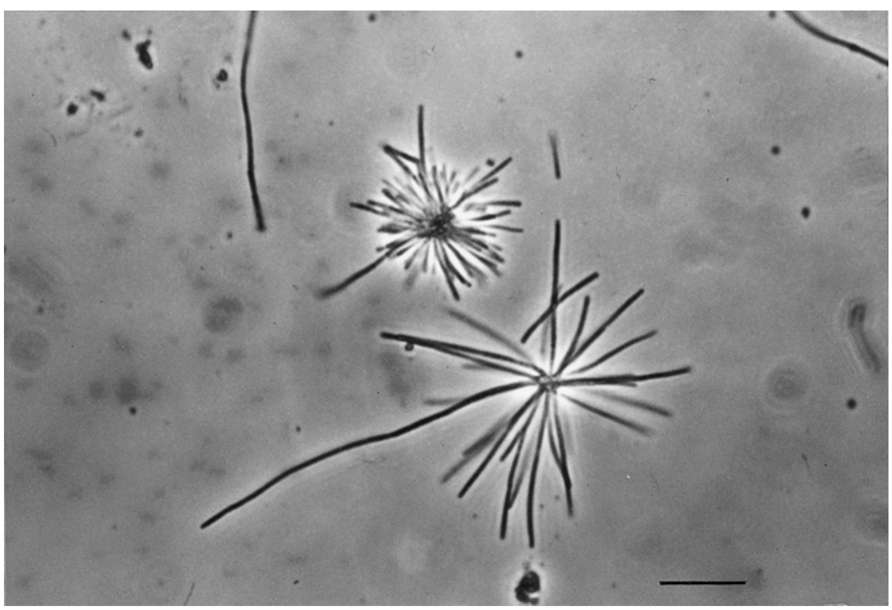

FIGURE BXII.γ.48. Rosettes of trichomes representative of *Thiothrix* spp. *Thiothrix eikelboomii*. Bar = 10 μm. (Reproduced with permission from T.M. Williams and R.F. Unz, Applied and Environmental Microbiology *49:* 887–898, 1985, ©American Society for Microbiology.)

swollen cells. Although elemental sulfur is deposited, reduced sulfur is not required for growth. Phenotypically the species are quite similar but show differences in carbon source utilization, the extent of sulfur deposition, nitrate reducing ability, and cell dimensions. They are, nevertheless, phylogenetically very distinct (Fig. BXII.γ.51). Readers are directed to the original publication for details of the phenotypic and genotypic analyses of these newly described species (Aruga et al., 2002).

The different phylogenetic groupings within the genus *Thiothrix* cannot be distinguished morphologically (Kanagawa et al., 2000). This further calls into question the validity of identification of trichome-forming microorganisms solely on morphological criteria. This is consistent with observations made using fluorescence *in situ* hybridization (FISH) where not all organisms morphologically identified as *Thiothrix* spp. hybridized with probes targeting *T. nivea* or Eikelboom type 021N bacteria (Per-

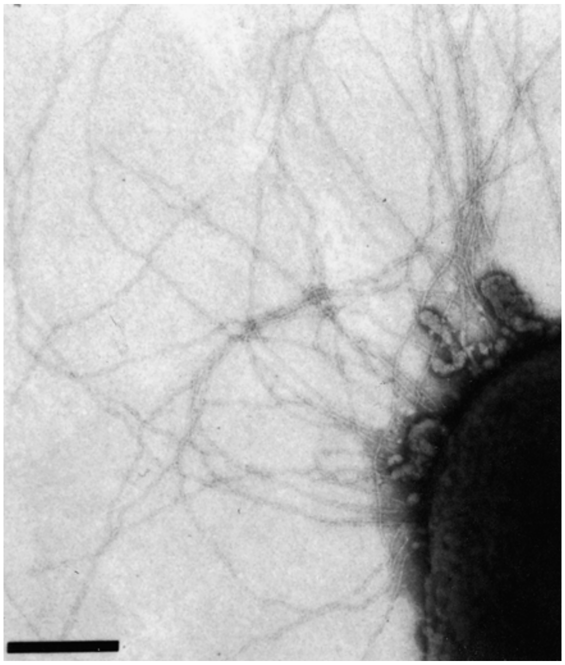

FIGURE BXII.γ.49. Fimbriae of a gonidium of *Thiothrix unzii*. Negative stained preparation. Bar = 0.5 μm. (Reproduced with permission from T.M. Williams et al., Applied and Environmental Microbiology *53:* 1560–1570, 1987, ©American Society for Microbiology.)

nelle et al., 1998). Also, trichomes morphologically identified as Eikelboom type 021N may bind with TNI probe specific for *T. nivea* but not an Eikelboom type 021N-specific probe (Nielsen et al., 1998), although results may, in part, be due to the poor specificity of the probes that were designed based on limited available sequence data. Nevertheless, some organisms with *Thiothrix*/Eikelboom type 021N-like morphology have proven to be phylogenetically very distantly related to *Thiothrix* spp., e.g., strain Ben47, which is most closely related to the *Alphaproteobacteria* (Howarth et al., 1999). A series of probes, designed for use in FISH or other rRNA hybridization assays to identify different groups of *Thiothrix* in environmental samples, are listed with their specificity indicated in Table BXII.γ.36. Readers are directed to the original publication for detailed information on the application of these diagnostic oligonucleotide probes (Kanagawa et al., 2000). Characteristics distinguishing *Thiothrix* from morphologically similar bacteria are listed in Table BXII.γ.37.

Acknowledgments

The authors acknowledge the original contributions of John Larkin contained in the contents of this writing and are most grateful to Takahiro Kanagawa for providing data on *Thiothrix disciformis* and *Thiothrix flexilis* prior to publication.

List of species of the genus Thiothrix

1. **Thiothrix nivea** (Rabenhorst 1865) Winogradsky 1888, 39[AL]
(*Beggiatoa nivea* Rabenhorst 1865, 94.)
ni′ve.a. L. adj. *nivea* snow-white.

Rods, about 1.0–1.5 μm in diameter, seriate in multicellular filaments (trichomes) of uniform diameter. Gram negative. Trichomes clearly ensheathed. Optimum temperature

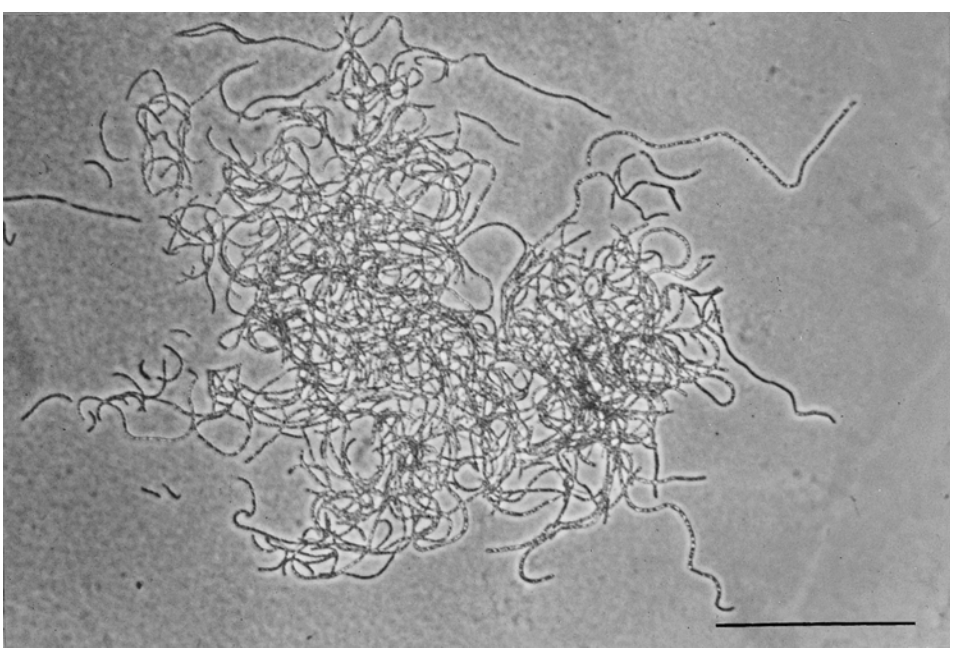

FIGURE BXII.γ.50. Colony morphology exemplified by *T. unzii*. LT medium. Bar = 60 μm. (Reproduced with permission from T.M. Williams and R.F. Unz, Applied and Environmental Microbiology *49:* 887–898, 1985, ©American Society for Microbiology.)

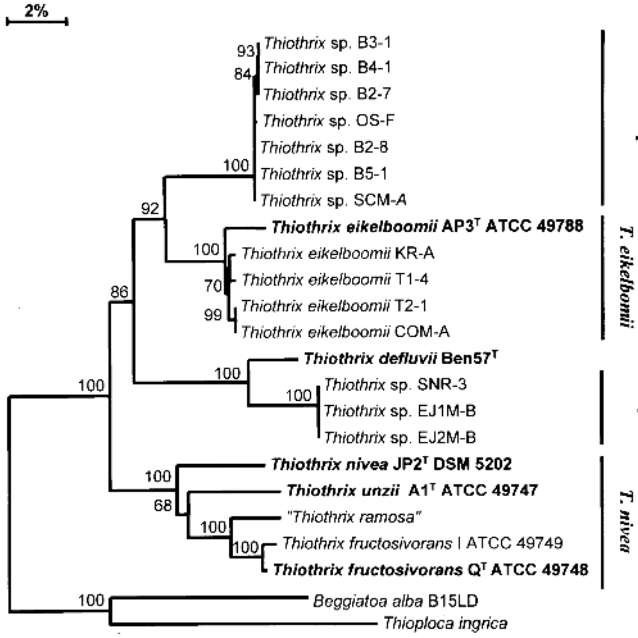

FIGURE BXII.γ.51. Phylogenetic distance tree derived from 16S rRNA sequences of *Thiothrix* spp. The tree was generated from an alignment comprising 1148 unambiguously aligned nucleotides. Figures at nodes represent percentage bootstrap values. Bootstrap values below 50% have been omitted. Sequences from *Beggiatoa alba* B15LD and *Thioploca ingrica* were used as an outgroup to root the tree. The type strains of all validly named species are shown in bold typeface. Bar = 2 nucleotide changes per 100 nucleotides in the 16S rRNA sequence.

is 25–30°C; maximum about 32–34°C; minimum about 6–8°C. Mixotrophic. Additional characteristics of the neotype strain, which are representative of the species, appear in the description of the genus and the data in Table BXII.γ.38.

The mol% G + C of the DNA is: 52 (T_m).

Type strain: JP2, DSM 5205.

GenBank accession number (16S rRNA): L40993.

2. **Thiothrix defluvii** Howarth, Unz, Seviour, Blackall, Pickup, Jones, Yaguchi and Head 1999, 1824[VP]

de.flu′vi.i. L. neut. n. *defluvium* sewage; L. gen. n. *defluvii* of sewage.

Rods, variable in shape (cylindrical, barrel-shaped, frequently elongate and swollen) in multicellular trichomes with base to tip differentiation; apical cells are 1.0–2.0 µm in diameter and 5.0–10.0 µm in length, whereas cells at the base of trichomes are 2.0–4.0 µm in diameter and 0.5–10 µm in length. Trichomes have no sheath but may form knots; rosettes, holdfasts, and gliding gonidia present in some strains. Gram negative or Gram variable. Growth occurs in the temperature range of 10–30°C but not at 4°C or 37°C. Isolates are extremely slow growing and biochemical properties of this organism have not been determined.

Isolated from activated sludge treatment plant located in Australia

The mol% G + C of the DNA is: unknown.

Type strain: Ben57.

GenBank accession number (16S rRNA): AF127020.

3. **Thiothrix disciformis** Aruga, Kamagata, Kohno, Hanada, Nakamura and Kanagawa 2002, 1315[VP]

dis.ci.for′mis. L. masc. n. *discus* a disc; L. n. *forma* shape; N.L. adj. *disciformis* disc-shaped, the main cell form.

Readers are referred to the original publication for a detailed description of this species (Aruga et al., 2002).

The mol% G + C of the DNA is: 43.9–44.7 (HPLC).

TABLE BXII.γ.36. Diagnostic oligonucleotide probes for characterization of *Thiothrix* spp.[a]

Probe	Target Group	Sequence (5′ → 3′)	Target site (16S rRNA, *E. coli* numbering)
G1B	Group I	TGTGTTCGAGTTCCTTGC	1029–1046
G2M	Group II	GCACCACCGACCCCTTAG	842–859
G3M	Group III[b]	CTCAGGGATTCCTGCCAT	996–1013
G123T	Group 0-III	CCTTCCGATCTCTATGCA	697–714

[a]Data from Kanagawa et al., 2000.

[b]In addition to group III organisms *T. eikelboomii* AP3 also contains the target site for this probe.

TABLE BXII.γ.37. Characteristics used to differentiate *Thiothrix* spp. from related, morphologically similar genera[a,b]

Characteristic	*Thiothrix*	*Beggiatoa*	*Leucothrix*	*Thioploca*
Colorless	+	+	+	+
Strains deposit elemental sulfur	+	+	–[c]	+
Sheath	+	–	–	+
Holdfast	+	–	+	–
Gliding gonidia	+	–	+	–
Filament formation	+	+	+	+
Rosette formation	+	–	+	–
Swollen cells produced in filaments	+	–	+	–
Knots produced	+	–	+	–
mol% G + C	43–53	35–39	46–51	nd
Deletion in helix 18 of 16S rRNA	+	–	–	–

[a]Note that these characteristics are illustrative only and many isolates may not exhibit all of these characteristics.

[b]For symbols see standard definitions; nd, not determined.

[c]Most reports suggest that *Leucothrix* spp. do not deposit intracellular sulfur; an organism described as *"Leucothrix thiophila"* has been shown to grow lithoheterotrophically and deposit elemental sulfur (Dul'tseva et al., 1996).

[b]Data obtained from Larkin (1989).

[c]Data obtained from Williams (1985).

[d]With sulfide or thiosulfate present in the case of *T. nivea* and *T. unzii*.

[e]Carbon sources not utilized by type strains in addition to those indicated in table: *T. nivea* (citrate, *cis*-aconitate, phosphoenolpyruvate, carbonate, glyoxylate, methylamine, D-ribose, D-arabinose, D-cellobiose, L-rhamnose, D-raffinose, D-sorbose, D-melebiose, D-xylose, ethanol, methanol, propanol, glycerol, i-erythritol); *T. unzii*, *T. fructosivorans*, and *T. eikelboomii* (citrate, L-rhamnose, D-xylose, L-fucose, D-ribose, mannoheptulose, L-sorbose, D-arabinose, glyceraldehyde phosphate, D-melibiose, D-gentiobiose, D-cellobiose, starch, inulin, esculin, glycerol, erythritol, galacturonic acid, glucuronic acid, gluconic acid, tributyrin, Tween 80, ethanol, *n*-propanol, *n*-butanol, *n*-amyl alcohol, methanol, isoamyl alcohol, phenol, *m*-toluate, glycolate, oleate, palmitate, myristate).

[f]Carbon and nitrogen sources not utilized by type strains in addition to those indicated in table: *T. unzii*, *T. fructosivorans*, and *T. eikelboomii* (DL-lysine, DL-cystine, DL-threonine, hydroxy-L-proline, glycine, L-arginine, DL-tryptophan, L-cysteine, L-proline, DL-phenylalanine, DL-serine, DL-methionine, DL-valine, DL-aspartate, DL-glutamine, L-asparagine, DL-isoleucine, L-leucine).

[g]Nitrogen sources not utilized by type strains in addition to those indicated in table: *T. nivea* (nitrite, dinitrogen); *T. unzii*, *T. fructosivorans*, and *T. eikelboomii* (nitrite, L-lysine, L-cystine, DL-threonine, glycine, DL-serine, DL-alanine).

Type strain: B3-1, DSM14473, JCM11364.

GenBank accession number (16S rRNA): AB042532.

4. **Thiothrix eikelboomii** Howarth, Unz, Seviour, Blackall, Pickup, Jones, Yaguchi and Head 1999, 1825[VP]

ei.kel.boom′ i.i. M.L. gen. n. *eikelboomii* of Eikelboom; named for D.H. Eikelboom, who pioneered morphological identification of filamentous bacteria in wastewater.

Rods may vary in shape (cuboidal, barrel-shaped, cylindrical, discoid, bead-like) and size depending on location in multicellular trichomes; apical cells are 0.6–0.8 × 1.0–1.5 µm and frequently bead-like, whereas cells at the base of trichomes are 1.0–3.0 µm in diameter and 0.4–0.7 µm in length and discoid. Trichomes have no sheath but may form knots; rosettes and a holdfast present in some strains.

The type strain does not form rosettes. Gliding gonidia occur only in rosette-forming strains and have a tuft of monopolar fimbriae but lack flagella. Gram negative or Gram variable. Growth occurs in the temperature range of 10–33°C but not at 37°C and in the pH range of 6.5–8.5. Chemoorganotrophic. Additional characteristics of the type strain, which are representative of the species, are given in Table BXII.γ.38.

Isolated from activated sludge treating domestic wastewater.

The mol% G + C of the DNA is: 44.1–46.1 (HPLC).

Type strain: AP3, ATCC 49788.

GenBank accession number (16S rRNA): AB042819.

5. **Thiothrix flexilis** Aruga, Kamagata, Kohno, Hanada, Nakamura and Kanagawa 2002, 1315[VP]

fle.xi'lis. L. adj. *flexilis* pliable.

Readers are referred to the original publication for a detailed description of this species (Aruga et al., 2002).

The mol% G + C of the DNA is: 44.0–44.4 (HPLC).

Type strain: EJ2M-B, DSM14609, JCM11135.

GenBank accession number (16S rRNA): AB042545.

6. **Thiothrix fructosivorans** Howarth, Unz, Seviour, Blackall, Pickup, Jones, Yaguchi and Head 1999, 1824[VP]

fruc.to.si.vo'rans. M.L. neut. n. *fructosum* fructose; L. part. pres. *vorans* eating; M.L. adj. *fructosivorans* fructose-eating.

Rods, 1.2–2.5 × 2.7–4.5 μm, in multicellular trichomes. Gram negative, trichomes ensheathed, rosettes formed, holdfast present, gliding gonidia with monopolar fimbriae but no flagella. Growth occurs in the temperature range of 4–28°C but not at 33°C and in the pH range of 6.5–8.5. Chemoorganotrophic. Additional characteristics of the type strain, which are representative of the species, appear in Table BXII.γ.38.

Isolated from activated sludge treating domestic wastewater.

The mol% G + C of the DNA is: unknown.

Type strain: Q, ATCC 49748.

GenBank accession number (16S rRNA): L79962.

7. **Thiothrix unzii** Howarth, Unz, Seviour, Blackall, Pickup, Jones, Yaguchi and Head 1999, 1824[VP]

un'zi.i. M.L. gen. n. *unzii* of Unz; named for R.F. Unz.

Rods, 0.7–1.5 × 1.5–3.0 μm, in multicellular trichomes. Gram negative, trichomes without sheaths, rosettes formed, holdfast present, gliding gonidia with monopolar fimbriae but no flagella. Growth occurs in the temperature range of 4–33°C but not at 37°C and in the pH range of 6.5–8.5. Mixotrophic. Additional characteristics of the type strain, which are representative of the species, appear in Table BXII.γ.38.

Isolated from activated sludge treating domestic wastewater.

The mol% G + C of the DNA is: unknown.

Type strain: A1, ATCC 49747.

GenBank accession number (16S rRNA): L79961.

Other Organisms

Two species of *Thiothrix*, *"T. ramosa"* (Odintsova and Dubinina, 1990) and *"T. arctophila"* (Dul'tseva and Dubinina, 1994) are proposed but invalidly published. The general morphology of the illegitimate species befits the traditional description of the genus *Thiothrix* with respect to presence of nonmotile, multicellular trichomes and the ability to form gonidia and rosettes. However, in addition to gonidia, both species form gliding hormogonia through fragmentation of trichomes, and the hormogonia of *"T. ramosa"* may develop into pseudobranching filaments. Further, *"T. ramosa"* exhibits chemolithoautotrophic growth with thiosulfate or carbon disulfide as sole electron donors, mixotrophic growth on lactate and any of several organic sulfur compounds, including carbon disulfide, and chemoorganotrophic growth on lactate alone (Odintsova et al., 1993). Additional information on these organisms and other *Thiothrix* isolates is given in the following paragraphs.

1. *"T. ramosa"*

ra.mo'sa. L. n. *ramosum* branch.

Three strains, namely TA, T1, and T2, are known. Cells 0.7–2.5 × 2.5–5.0 μm in ensheathed trichomes up to 100 μm in length. Gram negative. Intracellular sulfur inclusions formed in media containing thiosulfate or sulfide; however, reduced sulfur is not required for growth. Strictly aerobic. Optimum growth temperature is 28°C with sparse growth at 20°C and no growth at 4°C. Optimum growth pH is 7.2–7.3. All strains utilize acetate, malate, succinate, fumarate, and oxalacetate, whereas isocitrate, glycolate, lactate, α-ketoglutarate, and mannitol utilization varies among strains. Sugars, alcohols, and amino acids are not utilized with the exception of mannitol by strain T2. No growth on peptone, gelatin, casein, or yeast extract. Vitamins are required for growth. Nitrogen sources for all strains include ammonium salts, peptone, and glutamine; asparagine and aspartate are utilized by strain T1. Nitrates are not reduced to nitrite. Catalase and oxidase positive. Obtained from a hydrogen sulfide spring in Latvia.

The mol% G + C of the DNA is: 48–52.4.

2. *"Thiothrix arctophila"*

arcto'phi'la. L. adj. *arcto* cool; Gr. adj. *philus* loving; M.L. *arctophila* cool loving.

Only strain IN is known. Cells 0.7–2.6 × 3.0–5.0 μm in trichomes of variable length covered with a protein–polysaccharide sheath. Gram negative. Intracellular sulfur inclusions formed in media containing thiosulfate, sulfide, tetrathionate, or elemental sulfur. Strictly aerobic. Optimum growth temperature is 15°C with no growth at 3°C and 34°C. Optimum growth pH is 7.2. Carbon sources supporting growth are acetate, malate, pyruvate, succinate, fumarate, lactate, oxalacetate, propionate, maltose, melezitose, and butanol. Compounds not supporting growth are malonate, citrate, glyoxylate, formate, benzoate, caproate, glycolate, α-ketoglutarate, carbonate, glucose, lactose, fructose, sucrose, ribose, mannose, arabinose, cellobiose, rhamnose, raffinose, xylose, galactose, trehalose, gentiobiose, melibiose, sorbitol, methanol, ethanol, propanol, asparagine, methionine, serine, glutamate, alanine, aspartate, methylamine, glycerol, cysteine, mannitol, peptone, yeast extract, starch, Tween 80, urea, and phenol. Indole not produced from tryptophan. Nitrogen sources utilized are ammonia, nitrate, nitrite, glutamine, casein hydrolysate,

and peptone. Nitrogen sources not utilized are valine, glycine, phenylalanine, lysine, leucine, methionine, proline, cysteine, asparagine, aspartate, glutamate, urea, and dinitrogen. Nitrate is reduced to nitrite. Vitamins are required for growth. Nitrogen sources for all strains include ammonium salts, peptone, and glutamine; asparagine and aspartate are utilized by strain T1. Nitrates are not reduced to nitrite. Catalase negative and oxidase positive. Obtained from a combined wastewater treatment plant.

The mol% G + C of the DNA is: 55.0 (T_m).

3. *Thiothrix* CT3.

Thiothrix CT3 is a poorly characterized isolate recovered from an activated sludge in Italy and reported to be facultatively chemolithoautotrophic on thiosulfate, mixotrophic on acetate and thiosulfate, and chemoorganotrophic on acetate (Tandoi et al., 1994).

Several isolates of *Thiothrix* and Eikelboom type 021N, in addition to the type strains, were isolated and studied in the course of investigations leading to the naming of the species *T. unzii*, *T. fructosivorans*, and *T. eikelboomii*. Some of these may no longer be extant; however, certain ones are referred to in publications by other workers and are described in the last edition of the *Manual*. Strain A3 is essentially identical to the type strain of *T. unzii* and strain I (ATCC 49749) is essentially identical to the type strain of *T. fructosivorans*. Isolates TH1 and TH3 share many features of *T. fructosivorans* but are distinguished by the inability of the latter strain to utilize as many organic carbon compounds or any carbohydrates, ability to utilize several more amino acids and nitrate as nitrogen sources, display cell dimensions similar to *T. unzii*, require sodium ion for growth, and tolerate relatively high (3–4%) sodium chloride concentrations. A large number of Eikelboom type 021 N isolates were included in studies on the type strain of *T. eikelboomii* (Williams, 1985; Williams and Unz, 1985a, 1989), and notwithstanding minor morphological and nutritional differences, appear to befit the description of *T. eikelboomii*.

Genus II. **Achromatium** *Schewiakoff 1893, 1*[AL]

Hans-Dietrich Babenzien, Frank Oliver Glöckner and Ian M. Head

A.chro.ma′ti.um. Gr. pref. *a* not; Gr. n. *chromatium* color, paint; M.L. neut. n. *Achromatium* that which is not colored.

Spherical to ovoid or cylindrical unicells with hemispherical ends. In natural populations, cells of widely different sizes appear. Cells vary in size from spheres of about 10 μm in diameter to giant cylindrical forms up to 30 × 125 μm (extremes are dividing stages); **cells are on average 15 × 50 μm**. Many size classes may be present within a sample. However, genetically different subpopulations that overlap in their dimensions can occur in a single habitat. **Division of cells by binary constriction. Gram negative. Calcium carbonate (calcite) is deposited intracellularly.** Additionally, the **cells contain globules of S^0**.

Movement, if any, of a peculiar slow, rolling, jerky type or gliding on solid surfaces. Not motile by means of flagella. The **cell surface** is covered by a glycocalyx. **Catalase negative.** Pure cultures not available.

The **natural habitat is the oxic–anoxic boundary** in the top 0–5 cm of sediments, suggesting that the cells may use **oxygen as the electron acceptor**. The habitats for *Achromatium* include different aquatic ecosystems around the world, e.g., lakes, ponds, wetlands, bog lakes, rivers, saline environments, brackish waters, and marine environments. **Resting stages are not known.**

Phylogenetic analyses including sequences from different geographical locations confirm that ***Achromatium* (e.g., *A. oxaliferum* populations) forms a distinct, deeply branching monophyletic clade in the** *Gammaproteobacteria* (Fig. BXII.γ.52).

The topology of the clade indicates that beyond the two main clusters, A and B, at least three genetically distinct lineages exist (Fig. BXII.γ.52), and it is likely that several *Achromatium* spp. remain to be described. Several 16S rRNA-targeted oligonucleotide probes are available for *in situ* identification and differentiation of co-existing *Achromatium* spp. by techniques like fluorescence *in situ* hybridization (FISH).

The type species was originally found in the mud of the Neuhofer Altrhein, Germany.

The mol% G + C of the DNA is: not known.

Type species: **Achromatium oxaliferum** Schewiakoff 1893, 1.

Further descriptive information

From experiments with cell enrichments, it is now apparent that members of the genus encompass more than one physiological type. Some of them are capable of oxidizing reduced sulfur species to sulfate, suggesting that they obtain energy from this process, in which S^0 is deposited as an intracellular intermediate. The substrate spectrum appears to vary in different populations, and substrate utilization may involve a chemolithoautotrophic potential (assimilation of ^{14}C-labeled bicarbonate) or the uptake of organic C-compounds (e.g., acetate, protein hydrolysate) by a chemoorganoheterotrophic, chemolithoheterotrophic, or mixotrophic type of metabolism. Like the genus *Beggiatoa*, to which it is related, *Achromatium* appears to consist of a nutritionally heterogeneous group of bacteria. Without pure cultures, it is not possible to determine whether this physiological diversity exists within a single population, with induction or repression of different metabolic pathways under different environmental conditions, or if it instead corresponds with genetic heterogeneity. Twenty nearly full-length 16S rRNA sequences and three partial sequences, which were amplified from DNA extracted from highly purified cell enrichments from fresh water sediments of various habitats, have been deposited in public databases. The accession numbers are L42543 and L48222–L48227 (Head et al., 1996), AJ010593–AJ010596 (Glöckner et al., 1999) and AF129548–AF129559 (Gray et al., 1999).

The prevailing temperature at their natural habitats is around 10°C.

The use of comparative 16S rRNA analysis has clarified the position of *Achromatium* and has shown that natural communities of *Achromatium oxaliferum* comprise genetically distinct subpopulations. With this information, the physiological diversity of *Achromatium* spp. becomes understandable.

The *Achromatium oxaliferum*-derived sequences are consistently recovered with the *Chromatium* assemblage but are without strong

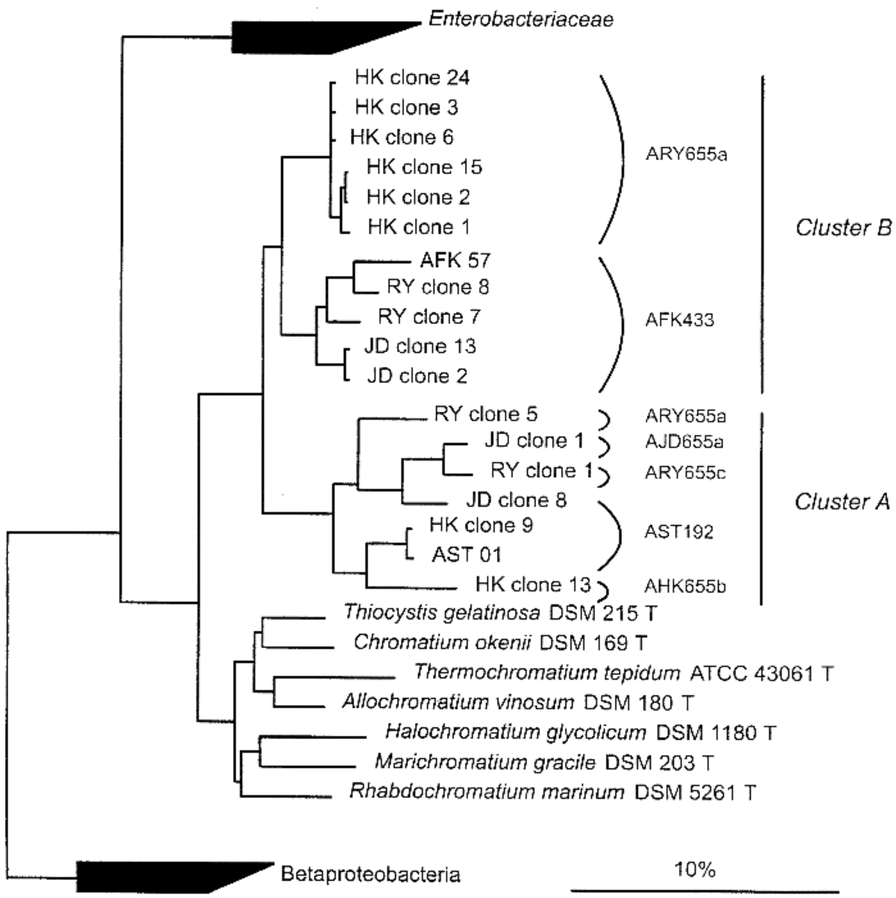

FIGURE BXII.γ.52. Phylogenetic tree based on comparative analysis of the 16S rRNA genes from all currently available full-length sequences from *Achromatium* and from selected sequences among the *Betaproteobacteria* and *Gammaproteobacteria*. The tree is a consensus tree based on maximum likelihood analysis, with highly variable positions excluded from the calculations. Sequences were obtained from *Achromatium* cells purified from different locations, including Hell Kettles (Co. Durham, UK), Rydal Water (Cumbria, UK), Jenny Dam (Cumbria, UK), Lake Fuchskuhle (Brandenburg, Germany), and Lake Stechlin (Brandenburg, Germany). These locations are designated with the suffixes HK, RY, JD, AFK, and AST, respectively. It has been proposed that the *Achromatium* spp. obtained from Lake Fuchskuhle (sequence AFK 57) is a new species *Candidatus* Achromatium minus. *T*, type strains. Bar = 10% estimated sequence divergence.

affiliation with any of the recognized lineages within this group. *A. oxaliferum* represents a novel clade within the *Gammaproteobacteria* and is therefore unrelated to the gliding bacteria of the *Cytophaga–Flavobacterium* group, as had been inferred prior to recent phylogenetic studies (La Riviere and Schmidt, 1989). 16S rRNA-sequences recovered from *Achromatium* cells from several locations have demonstrated that within the clade, two distinct phylogenetic clusters, termed cluster A and cluster B, are present. This bifurcation is strongly supported by distance analysis and maximum likelihood analysis ($P < 0.01$). Support for cluster A by parsimony analysis is also high, while support for cluster B is less pronounced. The two clusters can also be distinguished based on secondary structure elements (helical motifs) in the V6 region of the 16S rRNA molecule. Sequences from cluster A have a characteristic deletion and lack helix 38 (1024–1036, *E. coli* numbering), as do sequences from a number of *Archaea* and *Eucarya*. In contrast, sequences in cluster B have a V6 region that is in accordance with that of the majority of the domain *Bacteria* (Gray et al., 1999; Glöckner et al., 1999). Cluster B comprises two genetically different subgroups.

Whole-cell hybridization with fluorescently-labeled oligonucleotide probes specific for the different *Achromatium*-derived sequences has clearly demonstrated the co-existence of distinct subpopulations. In Lake Stechlin, Germany, a ratio of about 2:1:1 has been found for three different *Achromatium* populations identified by FISH, with the organism represented by 16S rDNA clone AST 01 accounting for nearly 50% of the total population.

In the habitats investigated using FISH, Lake Fuchskuhle (an acidic bog lake in Germany) was the only lake found to harbor a morphologically and genetically homogeneous population of *Achromatium*. Phylogenetic analysis of the 16S rDNA has assigned this population to cluster B of the *Achromatium* clade. Based on the unique features of the habitat, the homogeneous morphology and cell size, and the phylogenetic position of the population, a new species *Candidatus* Achromatium minus has been proposed (Figs. BXII.γ.52 and BXII.γ.54).

Unfortunately, until now there have been no probes available that cover the whole *Achromatium* clade or allow an exact separation of the two clusters by FISH. With the six probes shown in Fig. BXII.γ.52, it is possible to distinguish several subclusters and clones or, when probes are used in combination, to detect all currently available *Achromatium* sequences. Furthermore, with

probes ARY655a and AFK433, it should be possible to distinguish cluster B from cluster A, excluding clone 5 derived from Rydal Water, UK. In addition, the combination of probes AJD655a, ARY655c, AST192, and AHK655b is specific for cluster A, again with the exception of clone 5 from Rydal Water. All probes should work under the same conditions and must be applied with appropriate competitor probes as described in Glöckner et al. (1999) and Gray et al. (1999).

Morphological heterogeneity with extreme differences in cell size (Figs. BXII.γ.53 and BXII.γ.54) has been noted by all investigators, but evidence that differently sized cells represent genetically different populations has been obtained only recently. Different sub-populations coexist within the same habitat (Head et al., 2000b).

The cell volume can reach 50,000–80,000 μm^3, and the abundance of *Achromatium* cells in sediments is in the range of 10^3–10^5 cells/cm^3. Because of the large size of individual cells, *Achromatium* populations can be the major component of the bacterial community in some surficial sediments in terms of biomass. Cells divide by constriction in the middle, and before separation takes place, the daughter cells are connected by a hyaline "bridge" (Fig. BXII.γ.55). Often, *Achromatium* populations share the same habitat with other sulfide-oxidizing bacteria, like *Beggiatoa* spp. (Babenzien, 1991).

The most striking feature of the cells is the intracellular deposition of calcium carbonate crystals (calcite), a property unique in the *Bacteria*. These inclusions can reach 5 μm in size (Fig. BXII.γ.56) and the mean calcium content is approximately

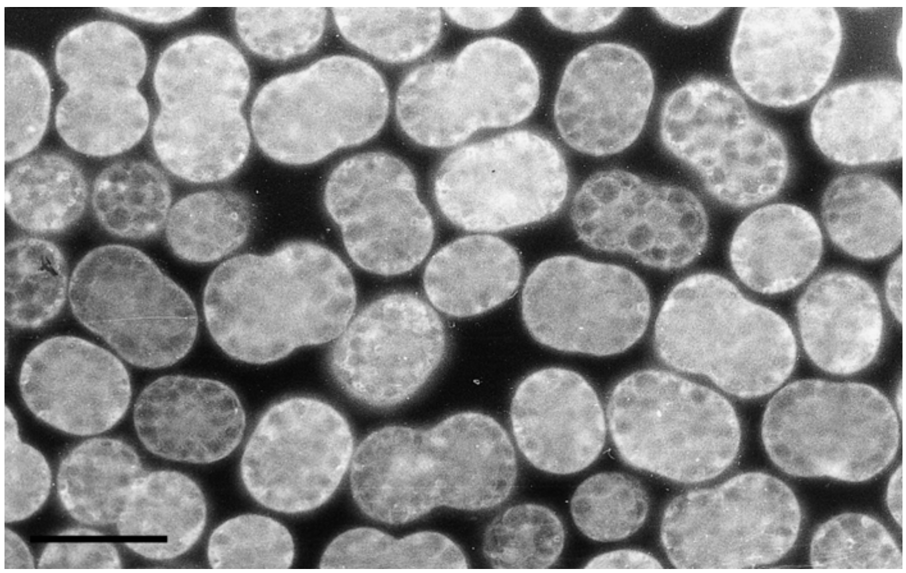

FIGURE BXII.γ.53. *Achromatium* cells collected from sediment of Lake Fuchskuhle (acidic bog lake, Brandenburg, Germany). In contrast to all other habitats this lake harbors a population that is homogeneous in morphology and size. Dark-field micrograph. Bar = 25 μm.

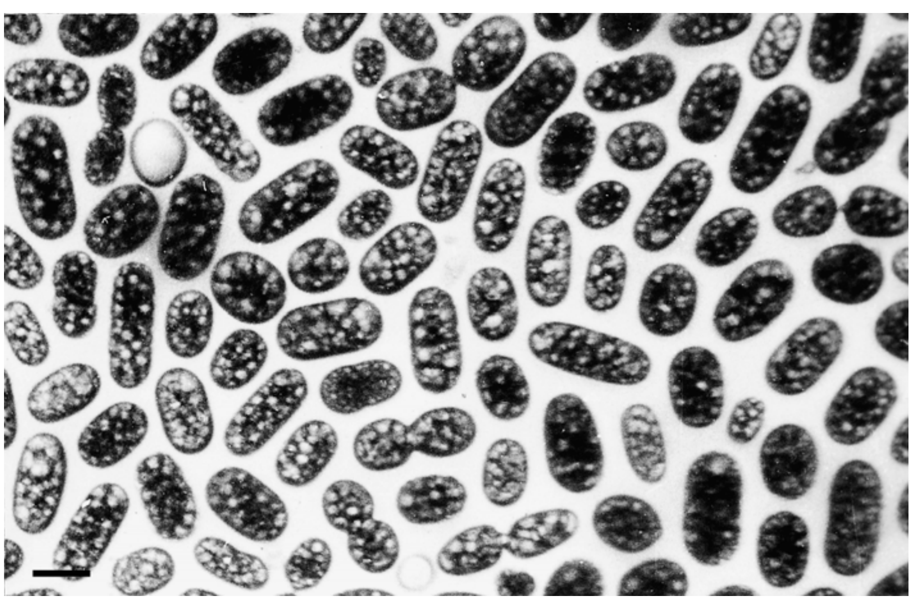

FIGURE BXII.γ.54. *Achromatium* cells collected from sediment of Lake Stechlin (Brandenburg, Germany). Considerable variation in size can be seen. Light micrograph. Bar = 50 μm.

2 ng/cell. In SEM preparations, the inclusions below the cell surface become visible due to shrinkage of the cell envelope (Fig. BXII.γ.57).

The function of the calcite inclusions is unknown, but it seems likely that the intracellular precipitation fulfils a metabolic role. The hypothesis that *Achromatium* possesses an active mechanism for concentrating calcium from the environment is consistent with the observation that cells in an acidic pond with very low levels of calcium in the water column contain calcite inclusions. In starvation experiments with physical cell enrichments, the inclusions tend to disappear. They can be easily removed by treating the cells with dilute acetic acid.

The presence of sulfur inclusions within the cells and the predominance of *Achromatium* in the micro-oxic zone of sediments suggest that *Achromatium* spp. may be sulfur-oxidizing chemolithoautotrophs. Microautoradiographic studies of the uptake of ^{14}C-labeled substrates have shown that *Achromatium* cells are able to assimilate ^{14}C from bicarbonate, acetate, and protein hydrolysate; however, glucose is not assimilated. The autotrophic potential for at least a proportion of cell enrichments is evident not only from inorganic carbon fixation, but also from the presence of genes similar to that encoding the large subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCo) (Head et al., 2000b).

From experiments incubating *Achromatium*-bearing sediment cores with ^{35}S-labeled sulfate in the presence or absence of sodium molybdate, it was deduced that the population was capable of oxidizing sulfide to intracellular S^0 and ultimately to sulfate. Moreover, sequences homologous to APS reductase genes (*aprBA*), were detected in purified DNA extracted from physically enriched cell preparations (Head et al., 2000b; Gray et al., 1997).

However, the pattern of organic substrate uptake within a single population suggests that physiological diversity occurs in natural *Achromatium* communities (Head et al., 2000a). In contrast to the response of some sulfide-oxidizing bacteria, e.g. *Beggiatoa* spp., sulfur droplets do not diminish in *Achromatium* enrichments under starvation conditions. It is possible that putatively heterotrophic members of the population can oxidize sulfide and deposit S^0 intracellularly as a mechanism for the detoxification of metabolically produced hydrogen peroxide in the manner previously suggested for heterotrophic *Beggiatoa* spp. (Burton and Morita, 1964).

The cells are surrounded by a specific glycocalyx. SEM-preparations of cells show a typical network that covers the whole cell surface (Fig. BXII.γ.58), which is consistent with results of TEM-preparations (Fig. BXII.γ.59). Presumably, these structures play an important role in the colonization of solid surfaces (adhesion) and possibly in the peculiar type of cell movement exhibited by *Achromatium* cells.

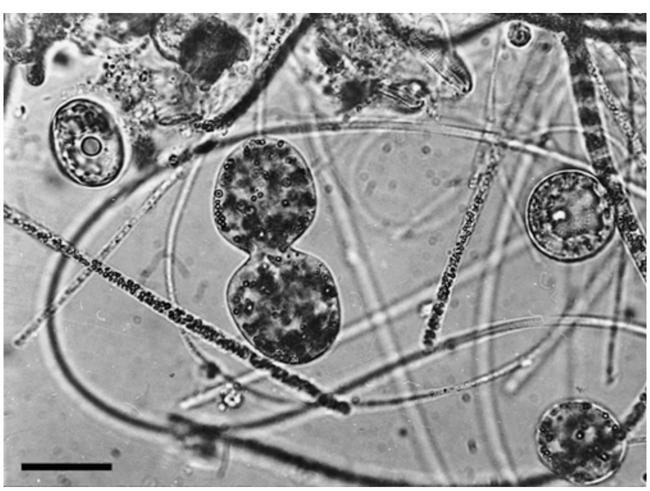

FIGURE BXII.γ.55. *Achromatium oxaliferum*, dividing stage of one cell. Sediment sample from Lake Dagow (Brandenburg, Germany). Filaments of *Beggiatoa* spp. and some diatoms are visible. Light micrograph. Bar = 25 µm.

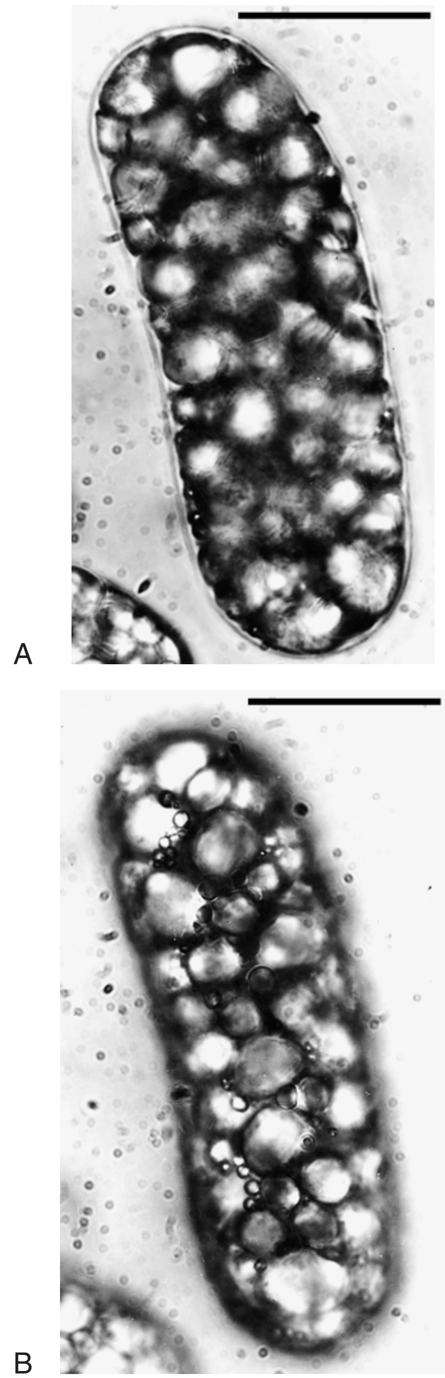

FIGURE BXII.γ.56. Light micrographs of an identical *Achromatium* cell, focused at various levels. The whole cell volume is filled with calcite crystals and small sulfur droplets. (*A*) surface of the cell, (*B*) center of the cell. Bars = 25 µm.

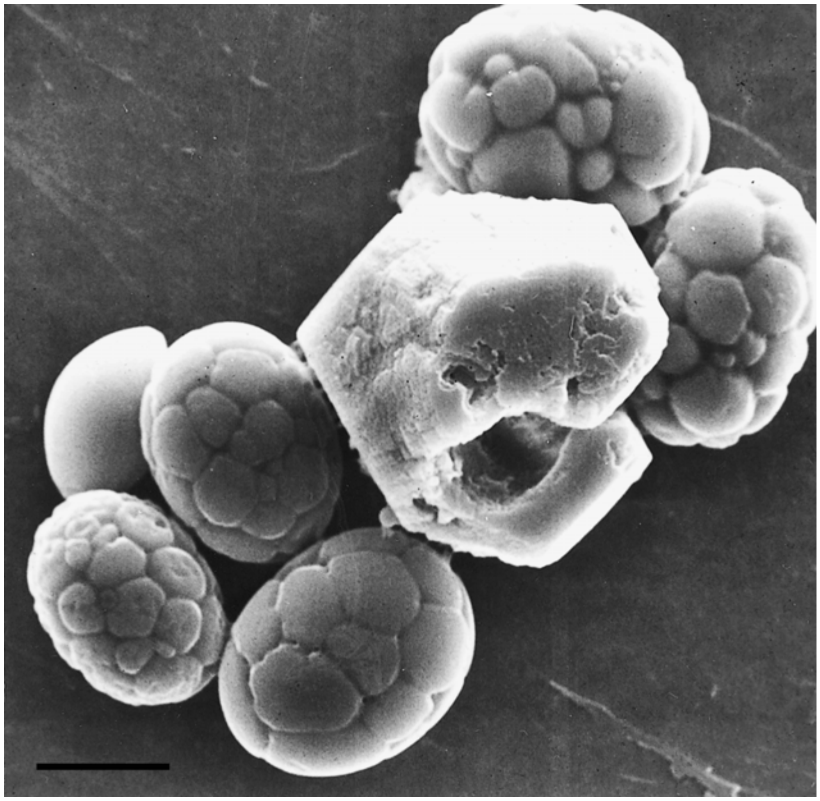

FIGURE BXII.γ.57. Scanning electron micrograph (SEM) showing some cells stuck to a calcite crystal from the sediment (Lake Stechlin, Brandenburg, Germany). The inclusions below the cell surface can be seen. Bar = 25 μm (Reproduced with permission from H.–D. Babenzien and H. Sass, Ergebnisse der Limnologie, *48:* 247–251, 1996, ©E. Schweizerbart'sche, Stuttgart.)

Enrichment and Isolation Procedures

No enrichment or isolation procedures are available. For experiments, cells must be collected physically from sediments by a swirling technique ("gold panning method"; De Boer et al., 1971). These cell enrichments may be washed carefully in sterile water and transferred with a Pasteur pipette several times to obtain highly purified preparations of cells.

Taxonomic Comments

There are two remarkable misinterpretations in the history of the genus *Achromatium.* The most striking inclusions present within cells were interpreted by Schewiakoff (1893) to be Ca-oxalate (hence the name of the species originally described); however, they consist of calcium carbonate. This was correctly described by Bersa (1920).

From the electron micrographs shown from De Boer et al. (1971), the glycocalyx was interpreted as peritrichously arranged appendages (flagella), and it was noted that "gliding motility should be caused by peritrichous flagella beating in a slime layer that surrounds the cell". The assumption of "gliding movement" was the main reason for inclusion of the organism in Section 23—Nonphotosynthetic, nonfruiting gliding bacteria—of the first edition of *Bergey's Manual of Systematic Bacteriology.* Today the means of movement of *Achromatium* remains unclear, but it has no flagella.

Although only one species (*A. oxaliferum*) is included in the Approved List of Bacterial Names, a second, *"A. volutans"*, was described earlier by Hinze (1903) under the proposed name *"Thiophysa volutans"*. The organism was found only in saline/marine waters, where it normally contains sulfur inclusions but lacks calcium carbonate crystals (La Riviere and Schmidt, 1992). More recently, Dando et al. (1998) described *"A. volutans"* at hydrothermal vents around the Greek island of Milos. The cells (diameter 5–90 μm) appeared with high density in the upper 1–15 mm of the sediment, forming "white sand" due to the reflective sulfur globules within the cells. Enzyme activity measurements of cell extracts (ribulosebisphosphate carboxylase, adenylphosphosulfate reductase, sulfate adenyltransferase) were indicative of autotrophic sulfur oxidizing activity.

The phylogenetic position of these populations is unclear and until further investigations are available, the position of *"Achromatium volutans"* as a genuine member of the genus *Achromatium* remains doubtful. Although only one species is validly published, the occurrence of genetically distinct subpopulations in *Achromatium* communities with greater than 2.5% divergence in their 16S rRNA sequences provides evidence to support the delineation of *Achromatium* into several different species.

Acknowledgments

The authors would like to thank Dr. Renate Hanschke (University of Greifswald) for kindly providing SEM and TEM micrographs, and Dr. W. Ludwig (Technical University of Munich) for the excellent program package ARB. Prof. Dr. N. Pfennig and Dr. R. Amann are gratefully acknowledged for helpful discussions. The studies have been funded by the Deutsche Forschungsgemeinschaft, FRG, and the Natural Environmental Research Council, UK.

List of species of the genus Achromatium

1. **Achromatium oxaliferum** Schewiakoff 1893, 1[AL]
ox.al.i′fe.rum. M.L. n. *oxalatum* oxalate; Gr. n. *oxalis* sorrel, a sour plant; L. v. *fero* to carry; M.L. adj. *oxaliferum* oxalate-containing.

The characteristics are as the same as those described for the genus.

The mol% G + C of the DNA is: not known.

Type strain: No culture isolated.

Genus III. **Beggiatoa** *Trevisan 1842, 56*[AL]

William R. Strohl

Beg.gi.a.to'a. M.L. fem. n. *Beggiatoa* a genus of bacteria; named in remembrance of F.S. Beggiato, a physician of Vicenza, (g.b. 1807), who authored the *Delle Terme Euganea*.

Colorless cells, ~1.0–200 × 2.0–10.0 µm, occurring in filaments 5.0–10 cm in length. Filaments usually have a consistent width over the entire length. Freshwater strains mostly, if not universally, possess filament diameters less than 5.0 µm, whereas marine beggiatoas with filament diameters ranging from 1.0 to 200 µm have been observed microscopically. No strain wider than 5 µm has been isolated in axenic culture from any source. The filaments may contain up to 100 or more cells, and in rare cases, up to several thousand. Cells in filaments are cylindrical and are longer than they are wide in the thinner strains (i.e., those less than ~5 µm in diameter). In wider strains (i.e., those greater than ~7 µm in diameter), cells are usually disk-shaped and typically are wider than they are long. Filaments occur singly, in sheets of cottony masses on sediment surfaces, or in mats in which each filament retains its individuality. Reproduction is by transverse binary fission of cells within filaments; division occurs by septation, in which the peptidoglycan and cytoplasmic membranes close like the iris of a diaphragm. Filament dispersion is via sacrificial cell death (necridial cells), filament breakage, or simple disintegration. In some strains, the disintegration of filaments occurs until mostly single or double cell units (hormogonia) exist; a hormogonium then can grow to become a filament. **Cells contain inclusions of sulfur when grown in the presence of H_2S and, for some strains, thiosulfate.** Intracellular inclusions of poly-β-hydroxybutyrate or polyphosphate may be present, particularly in freshwater strains. **Marine or brackish water strains having a filament diameter of >10 µm contain a large (~80% of the cell volume), central liquid vacuole that contains concentrated nitrate.** Resting stages are not known. **Attachment holdfasts or sheaths are not present.** Capsules are not formed, but filaments usually produce a slime matrix. Gram negative. **Filaments and hormogonia have gliding motility.** No motility organelles are known. **Aerobic or microaerophilic, having a strictly respiratory type of metabolism,** with oxygen and, in some instance, nitrate as the terminal electron acceptor. Anaerobic growth is not proven with pure cultures, but may occur with nitrate as the terminal electron acceptor for some strains studied in nature. Internally stored sulfur may also serve as an electron acceptor by freshwater strains for short-term maintenance in the absence of oxygen. Sulfate does not substitute as the terminal electron acceptor for anaerobic growth in strains thus far studied. **Chemoorganotrophic (freshwater strains), and either facultatively or constitutively chemolithoautotrophic (marine strains). H_2S or thiosulfate may be used as the electron donor for chemolithotrophic metabolism.** Acetate is oxidized to CO_2 by all freshwater strains tested thus far. **Several C_2, C_3, and C_4 organic acids and, sometimes, their amino acid equivalents are utilized as sole carbon and energy sources for heterotrophic growth.** Growth factors are not required by most strains, although some strains may require vitamin B_{12}. Gelatin and starch are not hydrolyzed. **N_2 is fixed by all freshwater and marine strains tested thus far.** Nitrate, nitrite, ammonium, N_2, or certain amino acids may be used as the sole nitrogen source. **Oxidase positive. Catalase negative.** Freshwater, estuarine, and marine strains are known. **Beggiatoas are inherently gradient organisms, growing in horizontal layers in sediments at the interface between the underlying anoxic sulfide-liberating zone and the overlying oxic zone.** Growth can occur in the range of 0–40°C. Obligately thermophilic strains have not been characterized, although some beggiatoas have been observed in high temperature runoffs associated with thermal springs, or in mats adjacent to thermal vents in the ocean floor.

The mol% G + C of the DNA is: 35–39.

Type species: **Beggiatoa alba** (Vaucher 1803) Trevisan 1842, 56.

Further descriptive information

Three subgroups of *Beggiatoa* can be discerned at present. The type and only named species is *Beggiatoa alba*, which is a member of the first subgroup. The three subgroups are: (i) thin, heterotrophic freshwater strains; (ii) thin, obligately or facultatively chemolithoautotrophic marine strains; and (iii) wide, autotrophic, vacuolated marine strains. Characteristics of the three subgroups *Beggiatoa* are listed in Table BXII.γ.39. Other features are described below.

Motility Gliding motility of beggiatoas is relatively rapid (1.0–8.0 µm/sec) and is often accompanied by flexing, bending, and/or rotation of the filaments. Gliding motility determines the nature of growth and colony formation; on agar media containing relatively few nutrients, spiral colonies are usually produced. The filaments are capable of gliding on agar surfaces to form various patterns of waves and concentric rings (Fig. BXII.γ.60).

Cell structure and life cycle of thin freshwater strains Cells within the filaments are separated by the membranes and the first cell wall layer (Fig. BXII.γ.61; Strohl and Larkin, 1978a). Cell division occurs by separation of those two inside layers (Fig. BXII.γ.61). Nearly one fourth of the cells in a trichome may be dividing simultaneously (Hinze, 1901). The outer cell wall layers do not take part in septation (Strohl et al., 1982) and are longitudinally continuous with the length of the filament. Beggiatoas do not contain a classical sheath but do exude large quantities of extracellular neutral polysaccharide slime (Strohl and Larkin, 1978b; Larkin and Strohl, 1983).

Filament dispersion in the thin freshwater strains occurs via sacrificial cell death (necridia formation) and filament breakage (Strohl and Larkin, 1978a) in a manner reminiscent to that observed in *Oscillatoria* spp. Filament dispersion may also occur via simple separation of an end cell to produce a hormogonium (Wiessner, 1981), or the filaments may divide by simple fragmentation (Pringsheim, 1949). Fragmentation, however, is often associated with filament death.

Although all beggiatoas stain Gram-negative (Strohl and Larkin, 1978b), they have a cell envelope which is much more complex than that of typical Gram-negative bacteria (Fig. BXII.γ.62; Maier and Murray, 1965; Strohl et al., 1982, 1986b). The A layer of the cell wall is probably a peptidoglycan layer, and the B layer is a unit membrane-like layer that is positionally similar to the lipopolysaccharide layer of Gram-negative bacteria (Fig. BXII.γ.62; Strohl et al., 1982). Depending on the strain and the method of fixation, two or three further external layers may be observed (Maier and Murray, 1965; Strohl et al., 1981a, 1982), the most external of which usually has a fibrillar pattern (Strohl et al., 1982).

TABLE BXII.γ.39. Characteristics of the three subgroups of the genus *Beggiatoa*[a,b]

Characteristic	Thin, heterotrophic freshwater strains (including *B. alba*)	Thin, obligately or facultatively autotrophic marine strains	Wide, autotrophic, vacuolated marine strains
Typical filament diameters, mm	~1–5	~1–7	~10–200
Sulfide oxidized to sulfur	+	+	+
Sulfur oxidized to sulfate	–	+	+
Sulfur reduced to sulfide	+	?	?

Representative strains	B18LD, OH-75-2a	MS-81-1c, MS-81-6	Monterey Canyon[d], Guaymas Basin [d], Warm Mineral Springs[d]

[a]Symbols: +, >90% positive; –, <90% negative; ?, not known; w, weak, insignificant levels; NA, not available; RubisCo, ribulose 1,5-bisphosphate carboxylase/oxygenase.

[b]The data presented in this table are not meant to be all-inclusive, but rather representative of the data, as they are known currently. There are likely to be exceptions to the given data based on individual strains or experimental conditions used.

[c]The mol% G + C content of the DNA of the freshwater *B. alba* strains B18LD (ATCC 33555), B15LD (ATCC 33556), and OH-75-2a are 37.1 mol%, 35.5 mol%, and 38.5 mol% (0.3 in duplicate and triplicate experiments), respectively, by T_m analysis (D.C. Nelson, personal communication).

[d]For the wide, marine example strains, there are no isolates. Thus, locations from which these organisms have been studied are given rather than strain names or numbers. It cannot be assumed, however, that the beggiatoas at these locations represent single species.

All *Beggiatoa* cells are known to contain at least three types of inclusions: poly-β-hydroxybutyrate (PHB; Pringsheim and Wiessner, 1963; Strohl and Larkin, 1978b; Strohl et al., 1982), polyphosphate (Maier and Murray, 1965; Strohl and Larkin, 1978b), and sulfur (Lawry et al., 1981; Strohl et al., 1981b). It is the latter inclusion that has traditionally separated organisms of the genus *Beggiatoa* from those in *Vitreoscilla* (Pringsheim, 1951; Leadbetter, 1974a; Strohl et al., 1986a). Several investigators have observed sulfur inclusions in thin sections of fixed and dehydrated *Beggiatoa* trichomes (Morita and Stave, 1963; Maier and Murray, 1965; Lawry et al., 1981; Strohl et al., 1981b; Larkin and Henk, 1996). The sulfur is dissolved away during dehydration with ethanol or acetone, leaving empty, electron-translucent spaces (Strohl et al., 1981b). Sulfur inclusions within these cytoplasmic membrane invaginations may be bound by envelopes typically composed of a single dense layer (Fig. BXII.γ.63; Strohl et al., 1981b). Unusual pentilaminar sulfur inclusion envelopes have been observed in cells of *B. alba* strain B15LD (Strohl et al., 1981b, 1982). Rudimentary pentilaminar envelopes have been observed in cells of strain B15LD grown in the total absence of reduced sulfur, indicating that a "primer" envelope was always present (Strohl et al., 1982). This may partially explain the rapidity with which sulfur inclusions appear after exposure of *Beggiatoa* cells to sulfide (Winogradsky, 1887; Burton and Morita, 1964; Schmidt et al., 1986). It may be physiologically significant that the sulfur inclusions of freshwater *Beggiatoa* strains are found within invaginations of the cytoplasmic membrane and are therefore periplasmic (i.e., external to the cytoplasmic membrane) in nature (Strohl et al., 1982).

Under certain growth conditions, PHB comprises over 50% of the cell dry weight of thin freshwater, heterotrophic *B. alba* strains (Güde et al., 1981; Strohl et al., 1981a). Furthermore, in one experiment, ~50% of the [^{14}C]acetate assimilated by heterotrophically grown cells was incorporated into PHB (Strohl et

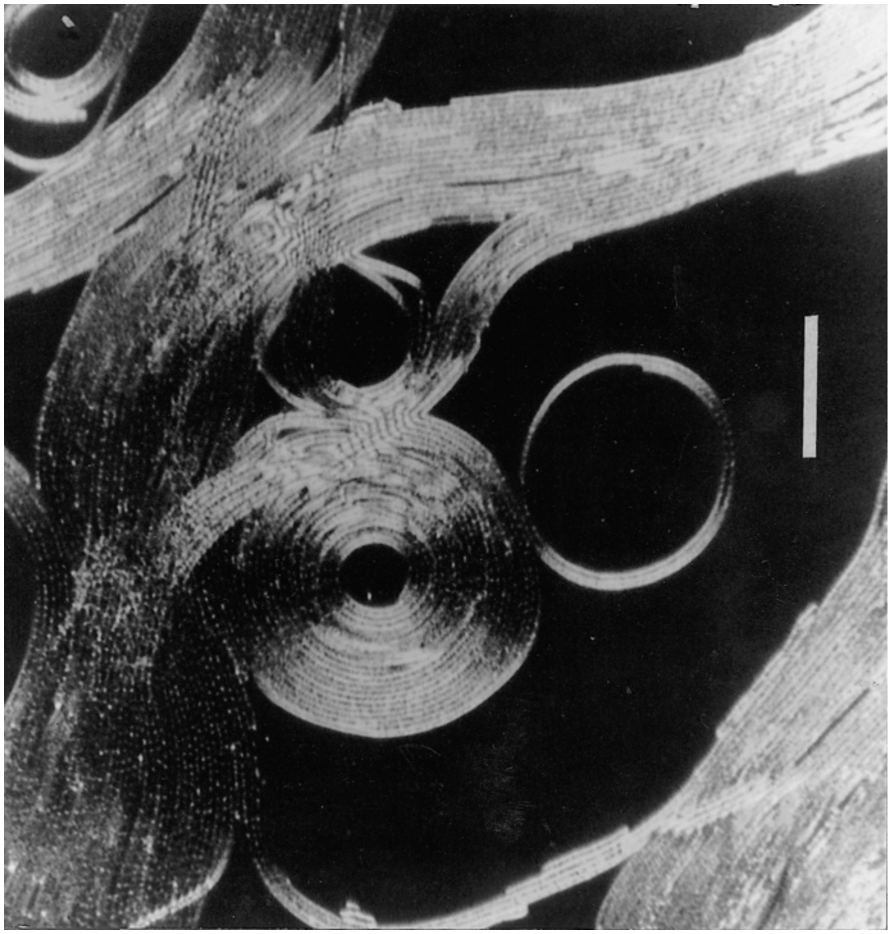

FIGURE BXII.γ.60. Light micrograph of a *Beggiatoa alba* colony on a 1.4% agar surface, taken through a dissecting microscope. Bar = 50 μm.

al., 1981a). The amount of PHB in the cells is usually proportional to the amount of acetate in the growth medium (Kowallik and Pringsheim, 1966). Cultures containing PHB have been shown to survive in media containing sulfide but lacking organic nutrients (Kowallik and Pringsheim, 1966), suggesting a survival role for the endogenous metabolism of PHB during carbon starvation. Furthermore, a freshwater *B. alba* strain containing massive PHB inclusions has been shown to be able to survive up to 7 days of starvation in a mineral salts medium lacking a carbon and an energy source (W.R. Strohl, unpublished observation).

Cell structure of wide, vacuolated, marine strains Larkin and Henk (1989) and Nelson et al. (1989b) simultaneously recognized that the large marine beggiatoas with diameters greater than 10 μm contain centrally located vacuoles (Figs. BXII.γ.64 and BXII.γ.65), similar to those previously observed in wide, marine *Thioploca* strains (Maier and Gallardo, 1984b). Larkin and Henk (1989) proposed that the vacuoles serve the purpose of generating a high surface to volume ratio, allowing for the large size of the trichomes. Later, Fossing et al. (1995) demonstrated that the vacuoles in *Thioploca* contain high concentrations (100–500 mM) of nitrate; similar analyses of the marine *Beggiatoa* central vacuoles also found high concentrations (130–150 mM) of nitrate (McHatton et al., 1996).

The cytoplasm, sulfur inclusions, and other cytoplasmic membrane intrusions are all found in a very narrow band at the outer edge of these large, vacuolated cells (Fig. BXII.γ.64 and BXII.γ.65). Although no high-magnification data are yet available, lower-magnification photographs of large, vacuolated beggiatoas (Nelson et al., 1989b; Larkin and Henk, 1989; Larkin et al., 1994) suggest a less complex cell wall with perhaps fewer layers than observed in the heterotrophic freshwater strains. Larkin and his colleagues also observed what appear to be symbiotic bacteria ultrastructurally similar to type II methanotrophic bacteria living within the cytoplasm of the wide, vacuolated marine beggiatoas (Larkin and Henk, 1996). Larkin and Henk (1996) proposed that the large, marine beggiatoas possessing internal symbionts might in fact be "dual" organisms much like the tubeworms and mussels found in the same habitat. This finding and its potential implications (e.g., potential symbiotic relationship) may have important implications for the potential ability to culture large beggiatoas axenically.

Sulfur metabolism of beggiatoas Oxidation of sulfide to sulfur by the heterotrophic freshwater strain *B. alba* is constitutive (Schmidt et al., 1986) and does not promote an increase in growth rate (Güde et al., 1981) or in the rate of protein synthesis (Schmidt et al., 1986). Sulfide oxidation by *B. alba* B18LD is oxygen-dependent (Vargas and Strohl, 1985b; Schmidt et al., 1987) and is inhibited by several specific electron transport inhibitors (Strohl and Schmidt, 1984; Schmidt et al., 1987), suggesting that sulfide oxidation is coupled with oxygen reduction

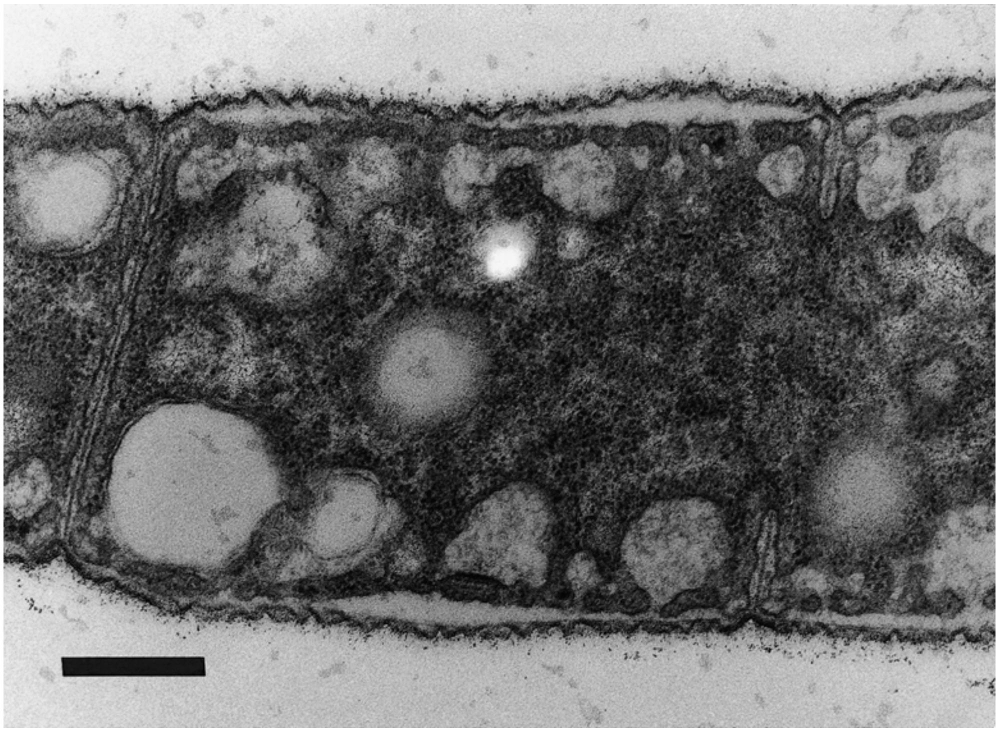

FIGURE BXII.γ.61. Thin section micrograph of *B. alba* B18LD showing the separation of cells in the filament by the cytoplasmic membranes and the peptidoglycan layer. A newly formed septation is also visible at the right. The outer walls, not well preserved by the modified Ryter–Kellenberger fixation technique (Strohl and Larkin, 1978b), are continuous with the length of the filament. Bar = 50 μm.

via the electron transport system. Nelson and Castenholz (1981b) have demonstrated that sulfur may comprise as much as 30% of the cell dry weight of the freshwater *Beggiatoa* strain OH-75-2a. Nelson et al. (1989b) have studied sulfide oxidation by the wide marine beggiatoas found near a hydrothermal vent at Guaymas Basin. They have shown that the sulfur, present mostly in the S_8 form, comprises ~14% of the cell dry weight (Nelson et al., 1989b). Although the form of sulfur in freshwater strains has not been determined, it is assumed to be in the S_8 form, as this is consistent with the sulfur found in other sulfur bacteria (Schmidt et al., 1971).

The significance of oxidation of the sulfur formed by freshwater strains such as *B. alba* to sulfate is not clear. Sulfur oxidation by strain OH-75-2a has been reported to be very slow (50 μmol sulfate produced/75 h/~30 mg cells; Nelson and Castenholz, 1981b); this rate—assuming 50% of cell dry weight is protein—calculates to a rate of ~0.4 nmol/min/mg protein. Hagen and Nelson (1997) have reported ATP sulfurylase activity in extracts of OH-75-2a to be about 1 nmol/min/mg of protein—slower than the rates of 23–30 nmol/min/mg protein and 1523–1710 nmol/min/mg protein for the facultatively autotrophic marine strain, MS-81-6, and the chemolithoautotrophic strain, MS-81-1c, respectively. In other experiments, Schmidt et al. (1987) did not observe significant *in vivo* oxidation of sulfur to sulfate (~5–10% maximum conversion) over periods of 22–72 hours, as evidenced by isotopic and chemical studies; a control strain, *Thiothrix nivea* strain JP3, produced considerable sulfate from sulfur inclusions in similar experiments (Schmidt et al., 1987). Similarly, another freshwater strain showed no (sulfuric) acid production from sulfur inclusions, whereas *Thiothrix* strains isolated from similar sources did so (Williams and Unz, 1985a). On the other hand, Hagen and Nelson (1997) have recently demonstrated the presence, albeit low, in a heterotrophic, freshwater strain (OH-75-2a) of an enzyme activity (sulfite-dependent, AMP-independent ferricyanide reduction) that is normally considered to be involved in oxidation of sulfur to sulfate. This observation supports the contention that sulfur can be oxidized to sulfate by freshwater strains of *Beggiatoa*, albeit rather slowly as compared to the same process by marine strains (Hagen and Nelson, 1997).

Although sulfate appears to be a slowly produced product of sulfide oxidation by the heterotrophic, freshwater strains, the sulfur accumulated by these strains can be reduced back to sulfide under anaerobic conditions (Nelson and Castenholz, 1981b; Schmidt et al., 1987). For *B. alba* B18LD, this process occurs at a rate of ~6–7 nmol/min/mg protein (Schmidt et al., 1987), a 5–10-fold greater rate than the sulfur oxidation rates observed by Nelson and colleagues (Nelson and Castenholz, 1981a; Hagen and Nelson (1997)), and to be coupled with the oxidation of H_2 (Schmidt et al., 1987). Whether this process is ecologically relevant for these strains is as yet unknown, but it is possible that the heterotrophic beggiatoas utilize sulfur reduction as a temporary form of anaerobic respiration under anaerobic conditions, allowing them a form of energy to fuel the movement back to favorable conditions. Thus, sulfur reduction by the freshwater strains may provide an ecological role analogous to that proposed for anaerobic nitrate respiration in the wide, marine beggiatoas and thioplocas (Jørgensen and Gallardo, 1999).

Using cultures with vertical, convergent oxygen and sulfide gradients, Nelson et al. (1986a) have demonstrated in the thin, marine strain MS-81-6 a molar growth yield (Y_{H_2S}) on sulfide of

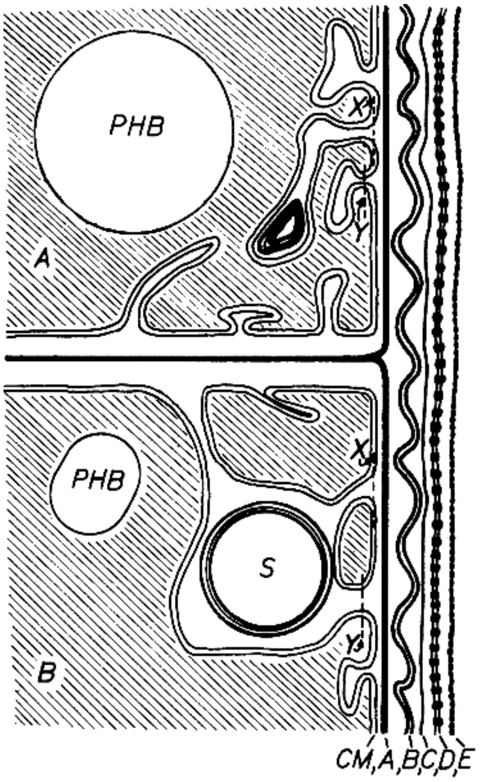

FIGURE BXII.γ.62. Model of a freshwater *Beggiatoa* cell wall (strain B15LD; Strohl et al., 1982). Note the pentilaminar sulfur (*S*) inclusion (which is single-layered in other *Beggiatoa alba* strains; Strohl et al., 1981b) external to the cytoplasmic membrane (*CM*); poly-beta-hydroxybutyrate, (*PHB*); cell wall layers from inside to outside (*A–E*); plane through which freeze-fracture shows invaginations (*X*); and plane through which thin sections have been made that give a different view of the invagination of membranes around sulfur inclusions (*Y*).

~8.4 g/mol. The marine strain grew linearly in a horizontal plate with a doubling time of ~11 h at the position at which the oxygen and sulfide gradients converged. Hagen and Nelson (1997) have compared the sulfide oxidation of two marine strains, the obligately chemolithoautotrophic marine *Beggiatoa* strain MS-81-1c and the facultatively autotrophic strain MS-81-6. They demonstrated that MS-81-1c stores more elemental sulfur and has a higher yield for sulfide oxidation than does strain MS-81-6 (Y_{H_2S} for MS-81-1c on sulfide was 15.9 g/mol, compared with 8.3–8.4 g/mol for MS-81-6). Similarly, O_2 consumption rates by strain MS-81-1c were observed to be consistently 2–3-fold greater than those of the facultatively autotrophic strain, MS-81-6. Moreover, strain MS-81-1c oxidizes sulfur to sulfate by either the adenosine phosphosulfate pathway or a highly regulated sulfite: acceptor oxidoreductase, whereas strain MS-81-6 uses only the sulfite: acceptor oxidoreductase (Hagen and Nelson, 1997).

Electron transport in beggiatoas Although Burton and Morita (1964) stated that *Beggiatoa* strains lacked cytochrome systems, all beggiatoas thus far analyzed have been found to contain cytochromes (Cannon et al., 1979; Strohl et al., 1986b; Prince et al., 1988). Room temperature spectra have indicated that *B. alba* and other strains might contain several *b* type, *c* type, *a* type, and CO-binding cytochromes, as well as ubiquinone 8 and NAD(P)H dehydrogenases; however, the spectra obtained in those studies were not of high quality (Strohl et al., 1986b). Schmidt and Dispirito (1990) have reinvestigated the cytochromes of *B. alba* B18LD and found four *c*-type cytochromes, three of which bind CO. One of the cytochromes was found to be a flavocytochrome *c*, somewhat analogous to cytochromes present in photosynthetic sulfide oxidizing bacteria (Schmidt and Dispirito, 1990).

Prince et al. (1988) determined that a sample of marine *Beggiatoa* filaments obtained from a marine sediment (suspension 1615B, which contained organisms of ~30 μm diameter; Nelson et al., 1989b) contained only *c*-type cytochromes. These *c*-type cytochromes from marine *Beggiatoa* filaments did not bind CO, nor were flavocytochromes detected (Prince et al., 1988), thus making them substantially different from the *c*-type cytochromes isolated from the freshwater strain, *B. alba* B18LD (Schmidt and Dispirito, 1990).

Carbon metabolism of beggiatoas Freshwater strains of *Beggiatoa* grow heterotrophically (Pringsheim, 1964; Strohl and Larkin, 1978b; Nelson and Castenholz, 1981a; Strohl et al., 1981a; Larkin and Strohl, 1983). They can utilize acetate as the sole carbon and energy source (Larkin and Strohl, 1983; Strohl et al., 1986b). Moreover, several *Beggiatoa* strains have been shown to grow on C_2, C_3, and C_4 organic acids, although none of the beggiatoas described thus far has grown on C_5 or C_6 organic acids or on hexoses (Burton and Morita, 1964; Burton et al., 1966; Nelson and Castenholz, 1981a; Mezzino et al., 1984; Williams and Unz, 1985a). Although Burton et al. (1966) have suggested a type of reverse tricarboxylic acid cycle for CO_2 fixation and acetate utilization by a freshwater *Beggiatoa* strain, the accumulated data indicate that freshwater, heterotrophic *Beggiatoa* strains likely utilize the glyoxylate and tricarboxylic acid cycles during growth on acetate (Nelson and Castenholz, 1981a; Larkin and Strohl, 1983).

A small amount of CO_2 is fixed by freshwater strains of *Beggiatoa*, but most of it is assimilated primarily via heterotrophic metabolism mechanisms, rather than by the Calvin–Benson cycle (Nelson and Castenholz, 1981a; Strohl et al., 1981a). Low levels of ribulose 1,5 bisphosphate carboxylase/oxygenase (RubisCo) activity have been observed in extracts of the freshwater strains OH-75-2a and *B. alba* B18LD (Nelson et al., 1989a). In addition, a probe derived from the gene encoding the large subunit of *Anacystis nidulans* RubisCo has been found to hybridize strongly to DNA isolated from strain OH-75-2a but not to that from strain B18LD (Nelson et al., 1989a). Thus, although the data strongly suggest that the freshwater beggiatoas possess RubisCo, the levels of activity demonstrated so far are not of physiological significance (Nelson et al., 1989a).

Thin, marine strains of *Beggiatoa* can grow autotrophically. During such growth, CO_2 is fixed by RubisCo at levels consistent with the support of autotrophic growth (Nelson and Jannasch, 1983; Hagen and Nelson, 1996). Strain MS-81-1c, an obligately chemolithoautotrophic strain, has been shown to lack 2-ketoglutarate dehydrogenase activity and does not regulate its RubisCo activity greatly. This strain accumulates acetate into biomass but does not oxidize acetate to CO_2—similar to what has been observed with the chemolithoautotrophic thiobacilli (Hagen and Nelson, 1996). Strain MS-81-6, on the other hand, regulates both 2-ketoglutarate dehydrogenase and RubisCo activities and appears to possess facultative chemolithoautotrophic metabolism (Hagen and Nelson, 1996).

Suspensions of wide, marine beggiatoas have been shown by Nelson et al. (1989b) to fix CO_2 by RubisCo at levels consistent with chemolithoautotrophic growth, and the CO_2 fixation can

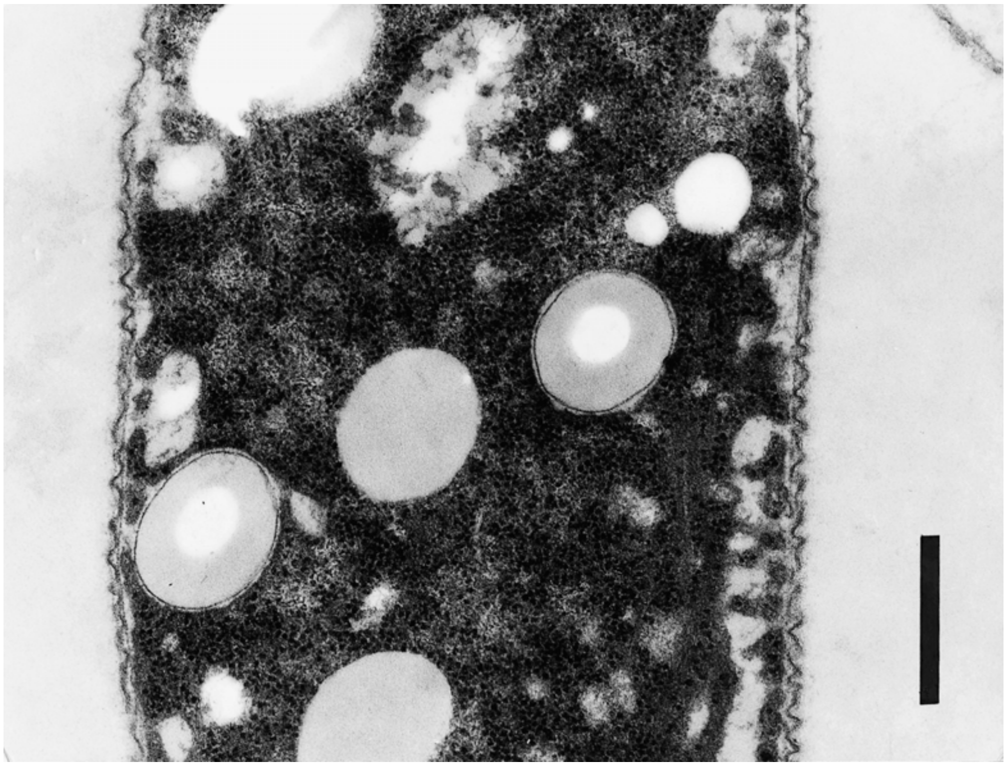

FIGURE BXII.γ.63. Thin section micrograph of *B. alba* B18LD showing the monolayered (4 nm thick envelope) sulfur inclusions external to the cytoplasmic membrane. Bar = 0.5 μm.

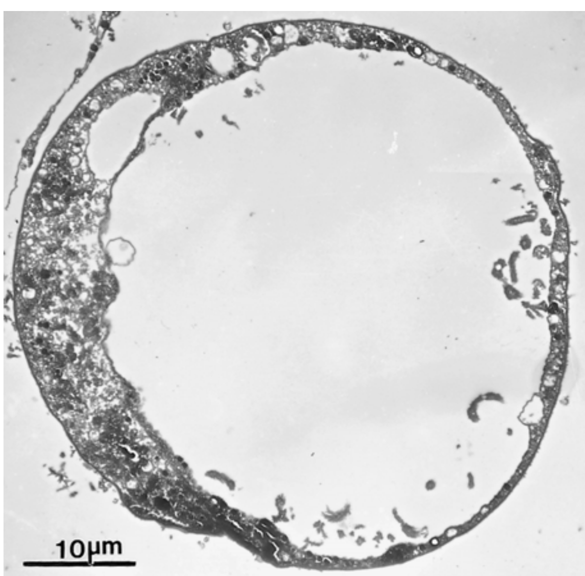

FIGURE BXII.γ.64. Thin section, cross-section of a wide, vacuolated, marine *Beggiatoa* strain showing an enormous central vacuole, with the cytoplasm and sulfur inclusions all squeezed into the thin outer "shell" surrounding the vacuole (Reproduced with permission from J.M. Larkin and M.C. Henk, Microscopy Research Technique *33:* 23–31, 1996, ©John Wiley & Sons, Inc.).

be stimulated approximately 7-fold by the addition of sulfide. Both RubisCo and phosphoribulokinase activities have been observed at significant levels in the suspensions of these marine beggiatoas (Nelson et al., 1989b), whereas 2-ketoglutarate dehydrogenase activities are below the limit of detection (McHatton et al., 1996). These data are supported by autoradiography, which has demonstrated extensive $^{14}CO_2$ fixation by intact strains (Nelson et al., 1989b). Interestingly, the vent beggiatoas from the Guaymas Basin exhibit 1.6–4.8-fold greater RubisCo activity at 50°C than at 30°C (whereas the thin, marine strain has approximately 4-fold more RubisCo activity at 30°C), suggesting a relatively high optimal temperature for their enzyme activity. Whole cell autoradiography of these organisms, however, demonstrates that CO_2 is not fixed above 40°C (Nelson et al., 1989b).

Steele et al. (1995) have reported that suspensions of the wide beggiatoas found in Warm Mineral Springs, FL, assimilate CO_2 at a level that would predict a 27-hr doubling time, suggesting that this organism also grows chemolithoautotrophically. This organism grows in an environment that is at approximately half the salinity of seawater (Lackey et al., 1965); thus, it is expected that it is more similar to the wide marine beggiatoas than to the freshwater strains.

Nitrogen metabolism Ammonia is a nitrogen source used by every *Beggiatoa* tested thus far (Larkin and Strohl, 1983). In studies by Vargas and Strohl (1985a), the glutamine synthetase (GS)–glutamate synthase (GOGAT) pathway was found to be the primary route for ammonia assimilation by *B. alba* B18LD. Glutamate dehydrogenase activity has not been observed and only low alanine dehydrogenase activity is observed under "high" ammonia conditions (Vargas and Strohl, 1985a). Other nitrogen sources that support growth of *B. alba* B18LD are nitrate, nitrite, urea, aspartate, and, to a lesser degree, asparagine, alanine, and thiourea (Vargas and Strohl, 1985a). Glutamate, aspartate, or

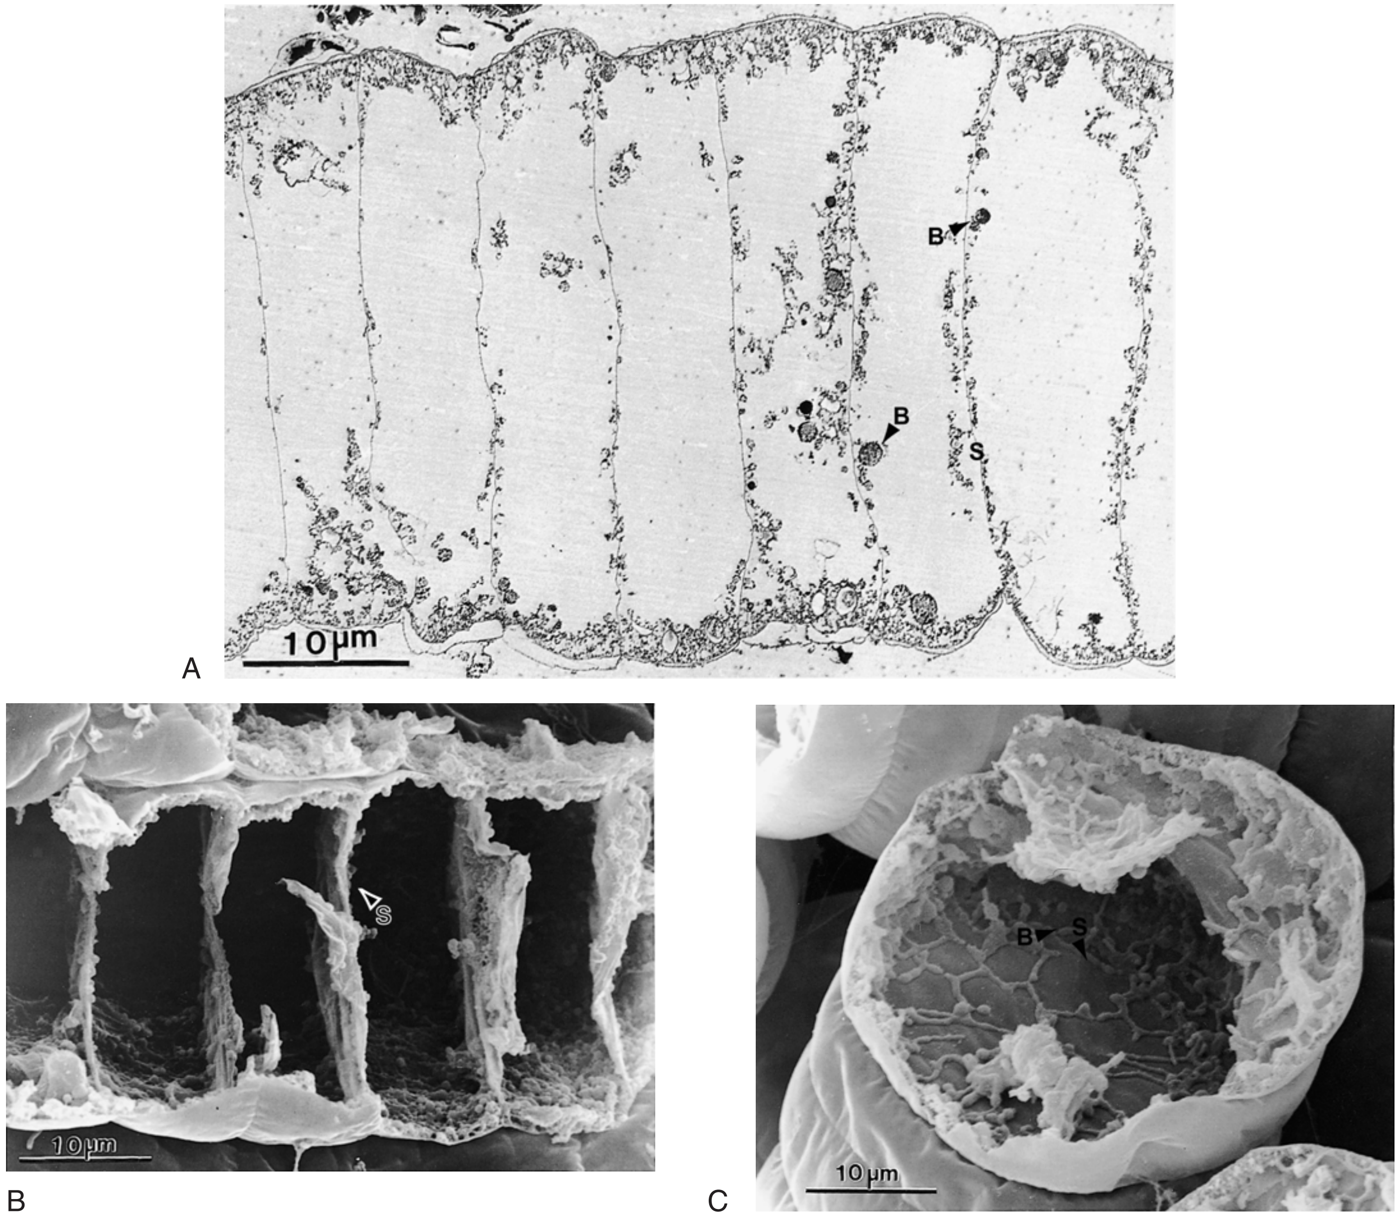

FIGURE BXII.γ.65. A typical thin section (*A*) of a *Beggiatoa* filament with a diameter of greater than 10 µm. Small blebs (*B*) of cytoplasm can be seen on the septa (*S*) and the remainder of the cytoplasm is restricted to a thin layer beneath the cell membrane. Scanning electron micrographs (*B, C*) of wide, marine, vacuolated *Beggiatoa* spp. The hollowed-out spaces where the nitrate vacuoles are located are easily observed. (Reproduced with permission from J.M. Larkin and M.C. Henk, Microscopy Research and Technique *33:* 23–31, 1996, ©John Wiley & Sons, Inc.)

asparagine support the growth of certain other beggiatoas, indicating that they can be used as sole nitrogen, carbon, and energy sources for those strains (Pringsheim, 1964).

Beggiatoas can utilize nitrate (Nelson et al., 1982; Vargas and Strohl, 1985b; Williams and Unz, 1985a) or nitrite (Vargas and Strohl, 1985b) as a sole nitrogen source. The product of nitrate reduction by *B. alba* is not N_2 or N_2O but ammonia, indicating that it has an assimilatory type nitrate reduction mechanism (Vargas and Strohl, 1985b). *B. alba* B18LD is unable to grow anaerobically by using nitrate as an electron acceptor, and nitrate reduction is not coupled with sulfide oxidation (Vargas and Strohl, 1985b). The nitrate reductase of *B. alba* B18LD has also been shown to be primarily in the soluble fraction (Vargas and Strohl, 1985b). Later experiments by Sweerts et al. (1990) showed that a freshwater mat of *Beggiatoa* spp. denitrified nitrate to N_2 *in situ*. They also suggested, based on minimal experimental results, that under certain conditions *B. alba* B18LD may be able to denitrify nitrate to N_2 (Sweerts et al., 1990).

Perhaps the most significant recent discovery is that the wide, vacuolated marine strains of *Beggiatoa* (i.e., those strains greater than 10 µm in diameter) have the ability to assimilate and accumulate nitrate in their large, central liquid vacuoles (McHatton et al., 1996), in a manner similar to that of large, marine *Thioploca* strains (Fossing et al., 1995). These large, marine organisms concentrate nitrate to 130–160 mM, or ~3000–4000-fold greater than the concentration of ~40 µM measured in the sea water in which they are found (Fossing et al., 1995; McHatton et al., 1996; Otte et al., 1999). On the other hand, the nonvacuolated thin,

marine strains MS-81-1c and MS-81-6 do not accumulate nitrate, indicating that the ability to accumulate and concentrate nitrate is correlated with the presence of the large central vacuoles (McHatton et al., 1996). Because the nitrate reductase activities of vacuolated, wide, marine beggiatoas are largely membrane bound—thus differing from the soluble nitrate reductase found in *B. alba* B18LD (Vargas and Strohl, 1985b) and the two thin, marine strains (McHatton et al., 1996)—the nitrate stored in these large vacuoles was originally thought to be denitrified to N_2 (McHatton et al., 1996). More recent evidence, however, suggests that ammonia is the major end product of nitrate reduction (D.C. Nelson, personal communication). Based on the thickness of the mats found at Guaymas Basin, the low level of oxygen present in the sea water, and the inadequacy of oxygen diffusion to support the sulfide oxidation present in such biomass, McHatton et al. (1996) made a strong case for the coupling of sulfide oxidation to nitrate reduction in those marine *Beggiatoa* mats. They calculated that enough nitrate was stored to support the organism for approximately 4.8 h of anaerobic growth without input of fresh nitrate (McHatton et al., 1996). Otte et al. (1999) have recently demonstrated that wide, marine *Thioploca* enrichments reduce most of their stored nitrate to NH_4^+, with a minor fraction (~15% of the NH_4^+ produced) going to N_2. Based on the rate of nitrate reduction to ammonia and the rate of sulfide oxidation, Otte et al. (1999) have suggested that the nitrate present in the vacuoles of marine *Thioploca* spp. might be sufficient for 200 hours of maintenance without additional input of nitrate. It has been calculated that the nitrate accumulation and reduction by these large marine beggiatoas and thioplocas should have a major impact on the nitrogen cycling in the oceanic sediments in which these organisms are found (Fossing et al., 1995; McHatton et al., 1996; Otte et al., 1999). Clearly, the fate of the nitrate reduction products (N_2 versus NH_4^+) by these organisms ought to be significant in the balance of nitrogen in the marine niches they occupy.

Nine strains of *Beggiatoa*—freshwater and marine, all with diameters less than 5 µm—have been shown to fix N_2 at rates of 3–12 nmol/min/mg protein when grown in tubes of semisolid agar in which the redox, sulfide, and oxygen gradients had been established (Nelson et al., 1982). The gradient cultures are required to provide proper redox conditions for N_2 fixation by both the freshwater and marine strains (Nelson et al., 1982). Nitrate or ammonia inhibits the fixation of nitrogen, and sulfide is required by some of the beggiatoas to fix nitrogen (Nelson et al., 1982). Polman and Larkin (1988) later found that ammonia and urea inhibit the activity of *B. alba* B18LD nitrogenase *in vitro*, whereas nitrate, nitrite, glutamine, and asparagine do not. Nitrite and nitrate, however, were found to inhibit *in vivo* nitrogenase induction. On the other hand, glutamine stimulates nitrogenase activity of *B. alba* B18LD (Polman and Larkin, 1988).

Autotrophy and sulfide oxidation Winogradsky (1887) developed his theory of chemoautotrophy based on his observations of sulfide oxidation by beggiatoas in slide cultures. The beggiatoas were considered autotrophs until the mid-1900s when Cataldi (1940), Faust and Wolfe (1961), Scotten and Stokes (1962), Burton and Morita (1964), Pringsheim (1964), and Burton et al. (1966) described heterotrophic growth for various freshwater strains of *Beggiatoa*. At that point, controversy began between various investigators about the role of sulfide oxidation in *Beggiatoa* metabolism. Pringsheim and his colleagues claimed that *Beggiatoa* was a facultative autotroph with the ability to grow autotrophically with sulfide used as the sole energy source or heterotrophically with acetate used as the sole carbon and energy source (Kowallik and Pringsheim, 1966). Burton and Morita (1964) claimed that sulfide oxidation was responsible for the detoxification of peroxides produced during *Beggiatoa* growth. Because sulfide was oxidized in the presence of organic carbon, Pringsheim (1967, 1970) later rescinded his claim of autotrophy and suggested that the beggiatoas were capable of "mixotrophic" growth, obtaining their carbon from acetate and CO_2 and their energy from sulfide oxidation (and perhaps from acetate oxidation). *B. alba* B18LD was postulated to grow mixotrophically, with sulfide or thiosulfate serving as a supplemental energy source (Güde et al., 1981; Strohl and Schmidt, 1984).

On the other hand, very careful experiments carried out by Nelson and Castenholz (1981b) demonstrated that the increased increments in dry weights (~30% increases) brought about by the oxidation of sulfide could be entirely accounted for by the weight of the sulfur itself, indicating that no yield could be accounted for by energy conserved by the sulfide oxidation. Moreover, the continuous culture experiments carried out by Güde et al. (1981) have been brought into question by others (c.f., Kuenen and Beudeker, 1982; Nelson, 1989, 1992), leading most investigators in the field to conclude that mixotrophic growth could not be inferred by the outcome of those experiments. Finally, the oxidation of sulfur to sulfate by freshwater strains is, at best, very inefficient (at least under the laboratory conditions used in the various experiments; Nelson and Castenholz, 1981b; Schmidt et al., 1987; Hagen and Nelson, 1997), indicating that the most favorable energy conservation steps, i.e., oxidation of sulfur to sulfate, were not being utilized efficiently by these freshwater *Beggiatoa* strains. Thus, the overwhelming bulk of data available currently suggest that the thin, freshwater beggiatoas are solely heterotrophic and that the oxidation of sulfide must serve a physiological purpose other than energy conservation.

What purpose does sulfide oxidation serve for these strains, if not for the conservation of energy? As stated above, Burton and Morita (1964) suggested that this process might be coupled to the detoxification of peroxides. Experiments by Nelson and Castenholz (1981b) support that contention. On the other hand, both Nelson and Castenholz (1981b) and Schmidt et al. (1987) have demonstrated that sulfur can be reduced back to sulfide anaerobically. Schmidt et al. (1987) showed that this reduction can be coupled with the oxidation of H_2, an energetically favorable reaction; thus, perhaps sulfur is utilized as a short-term electron acceptor for maintenance metabolism under anaerobic growth conditions; this is somewhat analogous to the role suggested for nitrate metabolism by the wide, vacuolated marine beggiatoas (McHatton et al., 1996).

Although all of the experiments to date have fallen short in proving mixotrophic growth for freshwater beggiatoas, there are three bodies of evidence that are intriguingly suggestive as to its occurrence. First, experiments by Strohl and Schmidt (1984) and Schmidt et al. (1987) have demonstrated clearly that specific electron transport inhibitors inhibit not only the oxidation of acetate to CO_2, but also the oxidation of H_2S to internally stored sulfur, suggesting a linkage of sulfide oxidation with electron transport. *B. alba* B18LD has also been shown to possess a flavocytochrome *c*, not unlike those linking sulfide oxidation and electron transport in photosynthetic sulfur bacteria (Schmidt and Dispirito, 1990). Second, both strains OH-75-2a and B18LD were shown by Nelson et al. (1989a) to possess RubisCo activity, albeit at insignificant levels with respect to growth. Nevertheless, it is possible that conditions have not yet been found in the labo-

ratory to optimize this activity. Finally, Hagen and Nelson (1997) have recently shown that the freshwater *B. alba* strain OH-75-2a possesses a regulated, sulfide-inducible sulfite:acceptor oxidoreductase, suggesting that perhaps under certain conditions, these strains might be capable of oxidizing sulfur to sulfate, a distinctly "lithotrophic-like" metabolism. While the rate of sulfur oxidation is very slow under the conditions tested thus far, oxidation does appear to occur. These three lines of data are still the most critical evidence to date for the potential conservation of energy from H_2S oxidation by heterotrophic freshwater strains. Nevertheless, without convincing orthogonal data to substantiate the mixotrophy claims, the freshwater strains should still be considered to be (only) heterotrophic. Perhaps the evolutionary progenitors of these freshwater strains possessed the ability to couple sulfide and sulfur oxidation with energy conservation mechanisms, but lost it, retaining the vestigial biochemical remains that we see today.

There is no controversy about the autotrophic nature of the marine strains. Careful experiments carried out by Nelson and colleagues (Nelson and Jannasch, 1983; Nelson et al., 1986b; Hagen and Nelson, 1996, 1997) have shown definitively that two thin, marine *Beggiatoa* strains, MS-81-1c and MS-81-6, can grow autotrophically in gradient cultures. Further experiments have in fact shown that strain MS-81-1c is an obligately chemolithoautotrophic marine *Beggiatoa* strain and that MS-81-6 is a facultatively autotrophic strain, capable of increasing growth yields by the assimilation of organic carbon. The data accumulated on the wide, marine beggiatoas all support chemolithoautotrophic growth with either oxygen or nitrate as the terminal electron acceptor (Nelson et al., 1989b; McHatton et al., 1996).

Ecological characteristics Beggiatoas exhibit four physiological characteristics that describe their ecological niche. First, they appear to be oligotrophic organisms that generally do not tolerate or utilize high concentrations of organic (W.R. Strohl, unpublished observations) or nitrogenous (Vargas and Strohl, 1985b) nutrients. Low concentrations (e.g., $\leq$20 mM) of organic acids and, in some cases, amino acids are apparently optimal for the growth and metabolism of freshwater, heterotrophic beggiatoas. Autotrophic, marine beggiatoas are even more fastidious and may or may not utilize organic nutrients.

Second, beggiatoas are respiratory organisms that couple the oxidation of organic acids (heterotrophic strains; Scotten and Stokes, 1962; Nelson and Castenholz, 1981a; Strohl et al., 1986b) and/or sulfide (autotrophic strains; Hagen and Nelson, 1997), with the reduction of oxygen (Schmidt et al., 1987; Hagen and Nelson, 1996, 1997) or nitrate (McHatton et al., 1996) as the terminal electron-accepting step. It appears that stored S^0 can be utilized, at least by the heterotrophic freshwater strains, as an alternative electron acceptor under strictly anaerobic conditions (Nelson and Castenholz, 1981b; Schmidt et al., 1987). Because the pool of internally stored sulfur would be limiting, however, the sulfur is probably used only as an electron acceptor *in situ* for maintenance purposes while the filaments glide to a new sulfide–oxygen interface. It is not yet known whether autotrophic strains can also utilize sulfur as an electron acceptor.

Third, beggiatoas are microaerophilic bacteria (Larkin and Strohl, 1983) that exhibit a phobic response to oxygen (Møller et al., 1985). Microaerophilic bacteria have been described as "aerobic or facultatively anaerobic bacteria, which under aerobic conditions use O_2 as hydrogen acceptor in a respiratory way of energy production and show optimal growth at low oxygen tensions" (Stouthamer et al., 1979). Heterotrophic beggiatoas apparently produce hydrogen peroxide in potentially autolytic quantities (Burton and Morita, 1964); however, peroxide accumulation has not been quantified. High levels of nutrients usually induce post-growth autolysis of *Beggiatoa* (Faust and Wolfe, 1961; Scotten and Stokes, 1962; Strohl and Larkin, 1978b), which may be directly related to the amount of peroxide produced. Catalase is not produced to degrade the potentially toxic peroxides (Burton and Morita, 1964; Joshi and Hollis, 1976; Strohl and Larkin, 1978b; Nelson and Castenholz, 1981b). Addition of catalase to growth medium may enhance growth yields (Burton and Morita, 1964) or survival of certain *Beggiatoa* strains (Strohl and Larkin, 1978b). In a carefully performed set of experiments, however, Nelson and Castenholz (1981a) showed that catalase does not increase growth rates or yields significantly over cultures lacking catalase. Moreover, their experiments indicated that peroxides are not formed during exponential growth phase (Nelson and Castenholz, 1981b).

Finally, and most importantly, beggiatoas are gradient organisms that live in sediments, in which they occupy the horizontal interface between sulfide emanating upward from below and O_2 diffusing downward from above (Jørgensen and Revsbech, 1983; Nelson et al. 1986b). Jørgensen and his colleagues (Jørgensen and Revsbech, 1983; Møller et al., 1985; Nelson et al., 1986b) have described the sulfide/oxygen interface location of *Beggiatoa* mats and plates both *in situ* and *in vivo*. In marine *Beggiatoa* mats, gradients of O_2 and sulfide are created by the beggiatoas above and below the horizontal mats, respectively (Jørgensen and Revsbech, 1983). In creating such concentration gradients, the beggiatoas apparently do not produce high concentrations of most nutrients at their surface, a phenomenon probably preferential to their oligotrophic nature. O_2 in high concentrations, especially if coinciding with concentrations of carbon nutrients, is apparently toxic to the beggiatoas, probably due to formation of peroxide or other toxic product. Thus, the vertical gradient effect, which permits only minute amounts of oxygen to the organisms, is seemingly ideal for them (Nelson et al., 1986b). Stimulation of certain enzymes, such as nitrogenase (Nelson et al., 1982) and RubisCo (Nelson and Jannasch, 1983), and even the ability to grow (Nelson and Jannasch, 1983) may depend on the attributes of the gradient effect (i.e., gradients of oxygen and sulfide in which the organism selects its best position).

Beggiatoas possess unique physiological mechanisms to maintain their proper position in nutrient gradients. Nelson and his colleagues have elaborated a series of phobic responses by beggiatoas that guide their mat-forming behavior. First, the beggiatoas were found to possess a photophobic response that results in a daily migration of beggiatoas to the surface at night and down into the sediments during the sunlight hours (Nelson and Castenholz, 1982). It was later discovered that beggiatoas also possess phobic responses to both O_2 (Möller et al., 1985) and sulfide (Jørgensen and Postgate, 1982), resulting in the movement to the proper position in sediments at which the two substrates overlap (Jørgensen and Revsbech, 1983; Nelson et al., 1986b). A significant difference is observed between the freshwater, heterotrophic strains and the marine, chemolithoautotrophic strains in gradient cultures. The marine strains utilize sulfide much more efficiently, with the sulfide and oxygen gradients overlapping by only ~50–100 μm (D. Nelson, personal communication), whereas sulfide and oxygen overlap significantly in gradients of the less efficiently sulfide-oxidizing freshwater strains (Nelson et al., 1986b). The rapid gliding motility exhibited by

beggiatoas allows them to position themselves at the optimal nutrient concentrations and to move quickly as environmental conditions change.

The interwoven, horizontal mats formed by wide, marine beggiatoas found near the hydrothermal vents in the Guaymas Basin can be up to 30 cm in thickness and are virtual monocultures of *Beggiatoa* filaments (Nelson et al., 1989b; McHatton et al., 1996). This is in striking contrast to mats formed by freshwater filaments, which typically reach only 1–2 mm in thickness at most, as well as to mats of ~1–2 cm formed by marine beggiatoas in other locations (Larkin et al., 1994). Marine *Thioploca* spp., on the other hand, form vertical columns of filaments reaching up out of the sediments, indicating that they possess an ecology that is somewhat unique when compared to the beggiatoas found in similar environments (McHatton et al., 1996; Jørgensen and Gallardo, 1999).

Beggiatoas of various morphological and physiological types have been found in environments as diverse as hydrothermal vents at 2000 m of depth (McHatton et al., 1996), desert hypersaline pools (Lackey et al., 1965), freshwater and marine marsh sediments, mineral and sulfur springs (Lackey et al., 1965), runoffs from thermal springs and geysers, activated sludge in sewage treatment plants (particularly those utilizing rotating biological contractors; Chung and Strom, 1997), microbial mats, and sediments ranging from sandy and pristine to polluted and silty. In marine microbial mats, a succession of colorless sulfur bacteria occur, starting with *Thiospira* and *Macromonas*, followed by *Thiovulum*, and then finally *Beggiatoa* spp. (Bernard and Fenchel, 1995).

An environment in which *Beggiatoa* strains appear to play a significant "economic" role is the rice rhizosphere, another gradient environment, set up by oxygen transport by the rice plants to their roots and the surrounding submerged, anoxic sediments (Pitts et al., 1972; Joshi and Hollis, 1977). A symbiotic relationship between the rice plants and *Beggiatoa* has been postulated in which the rice plants provide not only the gradient environment, but also catalase to the beggiatoas to protect them from toxic oxygen, while the beggiatoas protect the plants from sulfide by oxidizing it to harmless elemental sulfur (Joshi and Hollis, 1977).

Finally, a marine *Beggiatoa* spp., along with the cyanobacterium, *Phormidium corallyticum*, and sulfate-reducing bacteria, has been observed to be associated with black band disease of coral (Carlton and Richardson, 1995; Richardson, 1996). While not directly implicated in causation of the disease itself, the *Beggiatoa* is hypothesized to be a stable and contributing member to the consortium of bacteria associated with the presence of the disease (which is most likely caused by sulfide generated by the sulfate reducers) (Carlton and Richardson, 1995; Richardson, 1996).

Genetic characteristics Little has been done to characterize the beggiatoas genetically. The molecular mass of the *B. alba* genome, as characterized by C_0t analysis, is 2.02×10^9 (3.03×10^3 kilobase pairs; Genthner et al., 1985). Thus, the *B. alba* genome is approximately the same size as that of *Escherichia coli* (Genthner et al., 1985). Three *B. alba* strains contain plasmids with molecular masses of $12.3–12.8 \times 10^6$ (18.9–19.7 kb; Minges et al., 1983); however, no function has been ascribed to these plasmids. No phages specific for infection of *Beggiatoa* species have been found, either in sediment samples or endogenously in the genome of four strains tested (W.R. Strohl, unpublished data). No mutants or strains containing auxotrophic markers have yet been described for any *Beggiatoa* species.

Enrichment and Isolation Procedures

Freshwater strains Keil (1912) isolated *Beggiatoa* by washing the filaments repeatedly with sterile stream water. The washed filaments were placed in Petri dishes containing stream water and were incubated under a bell jar containing the gases H_2S (7.8 Pa), O_2 (147 Pa), CO_2 (245 Pa), and H_2. It has been suggested that Keil's methods have been the only isolation procedures to be specifically designed to enrich for and isolate autotrophic strains.

Cataldi first observed *Beggiatoa* during her studies with iron bacteria (Cataldi, 1940), and she used the extracted hay technique that Winogradsky had developed for enrichment of iron bacteria. Recent investigators (Joshi and Hollis, 1976; Strohl and Larkin, 1978b) have successfully used various modifications of Cataldi's boiled hay procedure. Burton and Lee (1978) used an alternative procedure in which gallon jars were filled with raw sewage and aerated for 3 days, after which bundles of *Beggiatoa* filaments were observed on the surface.

For enrichment of salt marsh or estuarine beggiatoas, a marine salt mix can be added to a typical hay enrichment to approximate 50% seawater (Strohl and Larkin, 1978b). An excellent enrichment procedure for marine beggiatoas uses the sulfuretum concept of Baas-Becking (1925). A 1–2-inch layer of sea sand is covered by a 1-inch layer of sulfide-emanating mud and a few inches of 50–80% seawater. Decaying leaves (or boiled hay) and $CaSO_4$ (~1 g/l) are then added. Two thirds of the tank is darkened by wrapping in aluminum foil, and a light is shined on the remaining third so that a natural sulfur cycling takes place between the photosynthetic and the dark zones, as well as between the aerobic and reduced zones. Combined cyanobacterial, photosynthetic bacterial, and *Beggiatoa* mats develop in about 2 weeks and remain stable for months.

Depending on the nutritive conditions of the hay enrichments and the agar plates upon which the beggiatoas are isolated, it is likely that a wide variety of different nutritional types of beggiatoas can be obtained (Strohl and Larkin, 1978b). Cataldi (1940) used the gliding motility of *Beggiatoa* strains to isolate them. She placed washed filaments from enrichments into the center of a Petri dish containing 0.1% yeast extract, 0.6% ethanol, and 1.2% agar. After 48 h, the contaminant-free trichomes at the edge of the plates were picked up by a Pasteur pipette and were placed into the liquid medium (Cataldi, 1940). Most investigators have used various modifications of Cataldi's isolation procedures (Faust and Wolfe, 1961; Scotten and Stokes, 1962; Pringsheim, 1964; Burton and Lee, 1978; Strohl and Larkin, 1978b). The following is a general isolation procedure for *Beggiatoa* strains. Filaments from enrichments are washed 5 times with sterile basal salts containing 5 mM neutralized Na_2S. Tufts of filaments are transferred from one wash bath to the next using microforceps. The tufts of filaments are teased and prodded to remove as much macroscopic contaminating material as possible. The washed tufts are placed onto a dry 1.6% agar plate for about 1 min to absorb away as much of the excess fluid as possible. They can be touched with a corner of filter paper to further remove excess fluid (Burton and Lee, 1978). The tufts of filaments are then removed from the "drying plate" and placed onto pre-scored (Burton and Lee, 1978), freshly prepared 1.4% agar plates containing 2 mM Na_2S, 0.01% each of yeast extract and sodium acetate, and basal salts (Vargas and Strohl, 1985a). After 5–48 h, the plates may be observed with a dissecting microscope to detect any contaminant-free filaments, which, along with a small

amount of the agar beneath them, are removed using flame-sterilized 23–26-gauge needles. It is usually best to wait for at least 24 h, so that the contaminated filaments are overgrown, and to make sure that the pure filaments are far away from the contaminants, making them easy to isolate.

For growth of most freshwater beggiatoas, a defined medium can be constructed that contains the following nutrients: 0.2–10.0 mM sodium acetate, succinate, or malate as carbon source, ~2.0 mM ammonium or nitrate as nitrogen source (Vargas and Strohl, 1985b), and standard basal salts (Vargas and Strohl, 1985a). An apparent requirement for a high concentration of calcium and a low concentration of phosphate is notable. A reduced sulfur source, such as sulfide or thiosulfate, can be added at concentrations of 1–2 mM to the heterotrophic medium above. Increasing carbon nutrients shortens the survival time of the organism, perhaps due to higher levels of the peroxides produced. A good general purpose medium for growth, isolation, and maintenance of most freshwater beggiatoas is one modified from the MY medium described by Larkin (1980). It contains 0.01% each of sodium acetate, yeast extract, and nutrient broth (Difco, Detroit, Michigan), 2 mM neutralized $Na_2S \cdot 9H_2O$, and basal salts (Vargas and Strohl, 1985a). For routine maintenance, Na_2S can be added prior to autoclaving, after which the medium should appear gray due to production of FeS. About 90% of the sulfide is lost upon autoclaving (Vargas and Strohl, 1985a). The medium should be inoculated immediately after cooling so that some of the sulfide can be used before it is chemically oxidized or volatilized. For critical experiments, the sulfide should be neutralized and then autoclaved separately under a nitrogen atmosphere in sealed Wheaton serum bottles. It may then be added to the medium just prior to inoculation.

Marine strains To date, the only marine strains that have been successfully cultured in the laboratory are two relatively thin, marine, chemolithoautotrophic strains—one obligately autotrophic and the other facultatively autotrophic (Nelson and Jannasch, 1983; Hagen and Nelson, 1996, 1997). One of the keys to the study of these thin, marine beggiatoas was the development and use of gradient cultures using gel-stabilized sulfide/oxygen gradients (Nelson et al., 1982, 1986a; Nelson and Jannasch, 1983). Wide, marine strains have been studied, however, by carefully washing the trichomes from thick marine mats in order to reduce the contamination to virtually background noise levels. These types of studies have generated significant physiological information about these strains, allowing investigators to determine their overall physiological and phylogenetic parameters. Additionally, Lackey et al. (1965) reported that they were able to culture wide, brackish water beggiatoas in mixed-culture environmental chambers, such as the sulfuretum described above, for several months, although those of intermediate size ranges (described as *"Beggiatoa arachnoidea"* [5–14 µm diameter] and *"Beggiatoa mirabilis"* [15–21 µm diameter]) did not survive under those conditions.

Maintenance Procedures

The best media for general maintenance of freshwater beggiatoas are usually low nutrient media with adequate sulfide or thiosulfate concentrations and relatively low oxygen concentrations. The modified MY medium described above is a good general medium for the maintenance of freshwater beggiatoas. Biphasic cultures can be constructed by overlaying a 1.6% agar plug of MY medium, modified by increasing the sulfide concentration to 4 mM, with either MY liquid medium or MY and 0.2% semisolid agar medium. Normally, cultures will survive about 1 month under any of these conditions. For growth and maintenance of marine cultures, refer to methods described by Nelson et al. (1982) and Nelson and Jannasch (1983).

Beggiatoa strains have been preserved for long term viability by freezing them in the presence of 20–30% glycerol at −70°C or −196°C. Survival at −196°C is at least several months for the strains tested.

Differentiation of the genus *Beggiatoa* from other genera

Although the beggiatoas make up a relatively heterogeneous group, considering the major differences observed between the thin, freshwater strains and the wide, vacuolated, marine strains, they can still be differentiated as a group from members of other genera (Table BXII.γ.40). The primary distinguishing characteristics include their abilities to glide and deposit sulfur when grown on sulfide, their inability to produce sheaths or holdfasts, and their absence of pigmentation.

Taxonomic Comments

Much has been learned about the physiology, ecology, and phylogeny of beggiatoas since the last edition of *Bergey's Manual of Determinative Bacteriology* (Strohl, 1989)—particularly in reference to the large, marine strains—that bear on *Beggiatoa* taxonomy. The three general groupings listed in Table BXII.γ.39 are heterogeneous and should not be construed as "taxonomic" designations; nevertheless, they do represent the three major physiological, morphological, ecological, and phylogenetic groups of

TABLE BXII.γ.40. Characteristics differentiating the genus *Beggiatoa* from other phylogenetically or phenotypically similar genera[a]

Characteristic	*Beggiatoa*	*Thioploca*	*Thiothrix*	*Vitreoscilla*

[b]Different strains of this species give different results, and some individual strains do not give consistent results.

beggiatoas studied to date. As exemplified by the notable exceptions below, discovery and characterization of additional strains in various niches may significantly alter this profile in the future.

Currently, there are three possible exceptions to the generalized groupings given above. Both the marine strain L1401-14 ("strain 14") and a Pringsheim marine strain isolated from a marine estuary near Plymouth exhibit a requirement for saltwater and grow heterotrophically (Pringsheim, 1964). Also, Uphof (1927) reported the presence of wide (i.e., >10–20 μm diameter) beggiatoas in Florida freshwater sulfur springs; Lackey and Lackey (1961) later showed that many of the Florida sulfur springs are brackish, and suggested that Uphof may have observed large beggiatoas similar to those seen at Warm Mineral Springs, Florida, which apparently require salt for growth (Lackey et al., 1965; Larkin et al., 1994). The third possible exception is the most intriguing—the finding of a natural population of freshwater *Beggiatoa* filaments from Hunters Hot Springs that shows activities of RubisCo comparable to those of autotrophic marine strains (D.C. Nelson, personal communication). Further physiological and phylogenetic investigations of this group of organisms could clarify the taxonomy of the members of the genus *Beggiatoa*.

Phylogenetic analyses have greatly clarified the taxonomy of these organisms, but they have also opened new questions about taxonomic relationships, particularly between the wide, marine beggiatoas and the thioplocas (see the chapter on *Beggiatoa* and the chapter on *Thioploca* in this volume). All of the beggiaoas thus far analyzed fall into the *Gammaproteobacteria*, which is most closely aligned with the thioplocas (see the chapter on *Thioploca* in this volume and Teske et al., 1995, 1999; Ahmad et al., 1999; Jørgensen and Gallardo, 1999). Teske et al. (1995) have pointed out that positioning of the beggiatoas and thioplocas in the *Gammaproteobacteria* places them as developing in the Proterozoic Period, suggesting that they are relatively "young" organisms phylogenetically.

While the resemblance of *Beggiatoa* filaments to those of cyanobacteria caused Pringsheim to label them as colorless forms of cyanobacteria (Pringsheim, 1949), none of the *Beggiatoa* species is phylogenetically related to any cyanobacterium (Reichenbach et al., 1986; Stahl et al., 1987). In addition, as pointed out by Stahl et al. (1987), phylogenetic analysis of beggiatoas and similar organisms has demonstrated that gliding motility is not a particularly useful taxonomic or phylogenetic marker. Additionally, the separation of *Beggiatoa* spp. from *Thioploca* spp. has traditionally been dependent on the formation of sheaths by the thioplocas. Several phylogenetic studies have now shown that wide, marine, autotrophic beggiatoas are more closely related to both the wide, marine and narrow, freshwater thioplocas than they are to the narrow, freshwater heterotrophic *Beggiatoa* strains. Although *Thiothrix* spp. are members of the *Gammaproteobacteria* (Polz et al., 1996), they are not closely related to either *Beggiatoa* or *Thioploca* spp. (Stahl et al., 1987; Lane et al., 1992; Polz et al., 1996; Teske et al., 1999; see chapter on *Thioploca* in this volume).

Recent 16S rRNA sequence analyses have shown that the freshwater *Beggiatoa* strains (OH-75-2a, B15LD, B18LD) cluster very tightly (see again chapter on *Thioploca*), making up the type species (which now can be more narrowly defined as freshwater only). Two other freshwater strains, L1401-13 (Pringsheim, 1964) and AA5A (unpublished strain from Azeem Ahmad; D.C. Nelson, personal communication; (also see *Beggiatoa* and *Thioploca* in this volume) which cluster near the three *B. alba* strains but are clearly different from them.

Sequence analysis of the 5S rRNA placed *Beggiatoa alba* B18LD (neotype strain) and *Vitreoscilla beggiatoides* strain B23SS (neotype strain) in the *Gammaproteobacteria* (Stahl et al., 1987; Woese, 1987; also see chapter on *Beggiatoa* in this volume). Stahl et al. (1987) stated, however, that *V. beggiatoides* was "specifically, but distantly, related to *B. alba*" strain B18LD. Based on the 5S rRNA similarity, it is likely that *Vitreoscilla beggiatoides*—a nonsulfur-depositing species that is similar in other features to the *B. alba* species—would fit within this cluster. However, the 16S rRNA of *V. beggiatoides* has not yet been sequenced. Subsequent analyses may show that deposition of sulfur—the key physiological criterion separating *V. beggiatoides* from freshwater, heterotrophic *Beggiatoa* spp.—may not be a valid criterion for separation of the two genera (just as gliding motility [see again chapter on *Beggiatoa* in this volume] and sheath formation by wide, marine thioplocas [see chapter on *Thioploca* in this volume] have proven to be invalid as taxonomic separators).

The two thin, chemolithoautotrophic marine strains of *Beggiatoa* (i.e., MS-81-1c and MS-81-6) cluster with the *Beggiatoa*–*Thioploca* group, but clearly are more closely related to the wide, marine beggiatoas than to the thin, freshwater, heterotrophic *B. alba* types. These two strains, however, are clearly separated from each other, both physiologically (Hagen and Nelson, 1996, 1997) and phylogenetically (Jørgensen and Gallardo, 1999(also see again chapter on *Thioploca* in this volume).

Finally, based on 16S rRNA sequence analyses, the wide marine "strains" of *Beggiatoa* from Bay of Concepción and Monterey Canyon form a discrete cluster with the wide, marine, autotrophic thioplocas (*Thioploca araucae* and *T. chileae*), and the freshwater, thin *Thioploca* strain, *T. ingrica* (Teske et al., 1995, 1999; Ahmad et al., 1999; Jørgensen and Gallardo, 1999; see chapter on *Thioploca* in this volume), as well as the newly described marine sulfur microorganism, *Thiomargarita namibiensis* (Schulz et al., 1999a). These phylogenetic data suggest that taxonomic changes are due for the genera *Beggiatoa* and *Thioploca*. While no specific changes can be made at this time, it is clear that rearrangements within at least these two genera, as well as within *Vitreoscilla* (see chapter on *Vitreoscilla* in this this volume), will need to be made based on the phylogenetic data. Additional 16S rRNA sequence analyses and strain–strain nucleic acid hybridizations with a greater variety of beggiatoas, thioplocas, and similar non-sulfur-depositing strains are clearly needed to place these organisms into their proper taxonomic locations with respect to related organisms.

Historical information *Beggiatoa alba* was the only species of *Beggiatoa* recognized in the ninth edition of *Bergey's Manual of Determinative Bacteriology* (Strohl, 1989). This remains true for the present edition, although evidence is accumulating that should allow additional species descriptions by the next version. In the seventh (Buchanan, 1957) and eighth (Leadbetter, 1974a) editions of *Bergey's Manual of Determinative Bacteriology*, six species were recognized, each differentiated on the basis of filament diameter alone: *B. alba* (type species; 2.5–5 μm diameter), *"Beggiatoa arachnoidea"* (5–14 μm diameter), *"Beggiatoa gigantea"* (26–55 μm diameter), *"Beggiatoa leptomitiformis"* (1–2.5 μm diameter), *"Beggiatoa minima"* (<1 μm diameter), and *"Beggiatoa mirabilis"* (15–21 μm diameter). In the eighth version, an additional 18 species names were listed as *species incertae sedis*, differentiated based on filament diameter, habitats and other general characteristics. Until strain B18LD was proposed as the neotype strain of the *B. alba* (Mezzino et al., 1984), species designations in *Beggiatoa* had been made solely based on filament diameter, general morphology, or habitat.

B. alba was originally described in 1803 as *"Oscillatoria alba"*, an organism characterized by "white filaments, of diameter of 1/800th of the length, distance between septa equal to diameter, extremities rounded and not pointed" (Vaucher, 1803). The length of *Beggiatoa* filaments is variable (Strohl and Larkin, 1978a, b), however; thus, the diameter of the first observed *"O. alba"* cannot be calculated. Trevisan (1842) described the genus *Beggiatoa*, in which *"O. alba"* (Vaucher) was included as a species. The two original species of *Beggiatoa*, *B. alba* and *"Beggiatoa leptomitiformis"*, were differentiated by their filament tips being rounded and pointed, respectively (Trevisan, 1842, 1845), not by filament diameter as in more recent years. Strohl (1989) has described in detail how the use of filament diameters has been both arbitrary and inconsistent (i.e., different authors using different filament diameters for the same species) over the years, especially for the thinner strains, making that criterion virtually useless in defining species. For example, historically, *"B. mirabilis"* has been described by different investigators as having a filament diameter (in µm) of 16 (original description), 20–40, 20–38, 20–45, 30–42, 16–45, and 15–45 (Klas, 1936). This interesting, but confusing, state of affairs in *Beggiatoa* taxonomy prompted the deletion of all but *B. alba*, the type species, from acceptance (Skerman et al., 1980), with the hope that the move would induce future descriptions of new *Beggiatoa* species to include physiological and phylogenetic data as well as morphological data. In subsequent descriptions, filament width should be considered as a single characteristic among several that differentiate the various species.

On the other hand, good historical logic and experimental evidence exist that support using filament diameter as a differentiation tool for certain beggiatoas. In various field investigations, beggiatoas have been observed ranging from <1 to >50 µm in diameter. Klas (1936) found that two size ranges of marine beggiatoas, 14.8–21.4 µm (18.4 µm average) and 26.4–49.2 µm (34.4 µm average), existed among trichomes from environmental samples. Likewise, Jørgensen (1978) found clusters in the size classes of 3–5 µm, 8–17 µm, and >23 µm among the marine beggiatoas he observed. McHatton et al. (1996) reported size clusters of 65–85 µm diameter from Clam Field Seep and 24–32 µm, 40–42 µm, and 116–122 µm diameter from Guaymas Basin. Some of these filaments were reported to reach 10 cm in length. Based on the maximum cell length of 36 µm reported in that study (McHatton et al., 1996), this would suggest that some filaments may contain as many as 270,000 cells, which would clearly qualify them as the most "multicellular" procaryotic organisms ever observed. Larkin and Henk (1996) similarly observed clusters of marine beggiatoas with diameters of 20–30 µm, 40–50 µm, and ~110–130 µm. They also observed marine *Beggiatoa* filaments with diameters of nearly 200 µm (Fig. BXII.γ.66) and lengths of over 2 cm (Larkin and Henk, 1996), making these among the largest procaryotes in existence, along with the recently discovered *Thiomargarita namibiensis* (Schulz et al., 1999a). Whereas a continuum of sizes is not observed from individual sites in nature, a compilation of all wide beggiatoas observed by nine different groups of investigators results in a broad continuum of reported sizes of ~7–50 µm, with much larger filament diameters also observed (Fig. BXII.γ.67). Clearly, more phylogenetic data on filaments of different sizes will be required to determine how to differentiate species among the larger marine beggiatoas.

Acknowledgments

I sincerely thank Bo B. Jørgensen for sharing a preliminary version of the *Thioploca* chapter, which helped to stimulate thoughts about the taxonomy of these organisms, and Douglas C. Nelson for sharing his thoughts and expertise on *Beggiatoa* taxonomy and physiology, as well as for unpublished data and updates on his current research efforts in the area.

List of species of the genus Beggiatoa

1. **Beggiatoa alba** (Vaucher 1803) Trevisan 1842, 56.[AL]
al′ba. L. adj. *albus* white.

The characteristics are as described for the genus, with the following additional features. The filaments measure about 1.5–4.0 μm in diameter and are of uniform width; the filament diameter may vary with growth conditions. The cells are usually 3.0–9.0 μm long, with filament lengths averaging 60–120 μm. Ends of the filaments are rounded. Necridia and hormogonia may be produced. Circuitans type colonies are usually formed. Sulfur is deposited as inclusions external to the cytoplasmic membrane, but within the cell wall, when the organism is grown in the presence of sulfide or thiosulfate. PHB and polyphosphate deposits are often present.

Chemoorganotrophic growth is obtained by using acetate, fumarate, lactate, malate, pyruvate, succinate, or ethanol as sole carbon and energy sources. The oxidation of sulfide, thiosulfate, or H_2 has been proposed to be coupled with energy conservation for chemolithotrophic metabolism, although this has yet to be proven. Ammonia, nitrate, nitrite, or urea is used as the sole source of nitrogen.

Organisms grow by a respiratory metabolism, with molecular oxygen used as the terminal electron acceptor. Microaerophilic to aerobic. Maintenance under anaerobic conditions, with sulfur used as the terminal electron acceptor, may occur.

Gelatin, starch, and casein are not hydrolyzed. Filaments are catalase-negative, and *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) cytochrome oxidase-positive. No growth is observed in the presence of 0.05% sodium dodecyl sulfate or 1.5% NaCl. Strains thus far have been isolated only from freshwater sediments.

The neotype strain, B18LD, was isolated from an enrichment obtained from a rice paddy in Lacassine, Louisiana, U.S.A. This strain, along with other *B. alba* strains, was described in detail by Mezzino et al. (1984).

The mol% G + C of the DNA is: 35–39 (T_m).

Type strain: LSU B18LD, ATCC 33555.

Additional Remarks: Based on phylogenetic and physiological data, other well-characterized strains that now should be considered as *B. alba* strains are OH-75-2a (Nelson and Castenholz, 1981a, b) and B15LD (ATCC 35556; Strohl et al., 1982; Ahmad et al., 1999).

Other Organisms

Among the thin, heterotrophic, freshwater strains, a strain not presently assigned to the species *Beggiatoa alba* is L1401-13 ("strain 13" as described by Pringsheim, 1964; Kowallik and Pringsheim, 1966). The thin, marine strains include the obligately chemolithoautotrophic strain MS-81-1c and the facultatively chemolithoautotrophic strain MS-81-6 (Nelson and Jannasch, 1983; Nelson et al., 1986a; Hagen and Nelson, 1996, 1997)

The wide, autotrophic, vacuolated, marine beggiatoas include, e.g., Monterey Canyon, Guaymas Basin, and Bay of Concepcion suspensions, which are phylogenetically related to marine thioplocas (Table BXII.γ.39) (Jannasch et al., 1989; Nelson et al., 1989b; Ahmad et al., 1999; Jørgensen and Gallardo, 1999; Teske et al., 1999).

Genus IV. **Leucothrix** *Oersted 1844, 44*[AL]

JUDITH A. BLAND AND THOMAS D. BROCK

Leu' co.thrix. Gr. adj. *leucus* clear, light; Gr. n. *thrix, trichis* hair; M.L. fem. n. *Leucothrix* colorless hair.

Long filaments composed of short, cylindrical or ovoid cells (**gonidia**), cross-walls clearly visible, **colorless**, **unbranched**; typically uniform filaments may taper from base to apex, showing under some conditions an apical beady chain of gonidia connected from end to end. Filaments may attain a length of over 100 μm, and lengths of several hundred micrometers are not unusual (Harold and Stanier, 1955; Pringsheim, 1957). The filaments, particularly when attached to a substrate, may be somewhat tapered, with the apex being 2–3 μm and the base 5–6 μm in diameter (Harold and Stanier, 1955; Pringsheim, 1957; Brock, 1969). In nature, **filaments are usually attached to solid substrates by means of inconspicuous holdfasts; stalks** and **sheaths absent**. **Filaments do not glide**, but may wave sporadically from side to side. **Dispersal by means of gonidia** (single cells arising from cells of the filaments by rounding up, often released primarily from apices, but they may also be formed in an intercalary fashion); **gonidia often**, but not **always, show jerky gliding motion** on solid substrates. **Rosette formation** is a key diagnostic characteristic of the genus that is seen frequently in laboratory culture but less commonly in nature. The rosettes may be formed of gonidia or, after gonidial growth, of several or more filaments attached at their bases. Filaments in a laboratory culture often form true knots. These structures also occur in nature, but rarely. The organism morphologically resembles some filamentous cyanobacteria but does not form photosynthetic pigments. **Gram negative**. **Strictly aerobic**, **heterotrophic**. **Aquatic; typically marine**, although one freshwater strain has been reported. Strains require NaCl for growth; optimum concentration: about 1.5% NaCl; grows at concentrations of 0.3–6.0% NaCl. Most strains do not require growth factors. Optimum temperature: 25°C; maximum: 30–35°C; minimum: 0°C, forming visible colonies within 1–2 weeks. Strains from tropical waters are more stenothermal, not growing below 15°C. Catalase positive. Oxidase positive.

According to Woese et al. (1985), the "definition" of the *Leucothrix* group (two strains tested—*L. mucor* ATCC 25707 and a "*Thiomicrospira*-like isolate") is the set of 16S rRNA signature sequences consisting of AACCUUAUCCAUCCCUUG, CACUUUCAAUUG, UUAACUUUAG, and AUCUAUAG. The most specific 16S rRNA probe sequence published is CCCCTCTCCCAAACTCTA, positions 652–669 (a non-ATCC culture; Wagner et al., 1994a). Sequences of 16S rRNA sequences are also available for two other isolates (Reichenbach et al., 1986; Nielsen et al., 1998). Also defined is a 23S rRNA sequence (Ludwig et al., 1995).

The mol% G + C of the DNA is: 46.9–51 (Brock and Mandel, 1966; Kelly and Brock, 1969a, b).

Type species: **Leucothrix mucor** Oersted 1844, 44.

FURTHER DESCRIPTIVE INFORMATION

Phylogenetic treatment *Leucothrix* was first isolated in pure culture from a marine source by Harold and Stanier (1955), who characterized the organism "as a chemoheterotrophic counterpart of the colorless sulfur-oxidizing organism *Thiothrix*." The two organisms have many features in common, and the life cycles of both organisms can be superimposed. Both genera were placed in the family *Leucotrichaceae* (Buchanan and Gibbons, 1974). *Leucothrix* and *Thiothrix* were further described as colorless evolutionary descendants of cyanobacteria (Harold and Stanier, 1955; Pringsheim, 1957; Raj, 1977), since each have a gliding form, the gonidium, and are loosely associated with other gliding, heterotrophic bacteria. Focus on the presence of a sheath in *Thiothrix*, its chemoautotrophy, and its sulfur metabolism eventually distanced this species from *Leucothrix*. Currently, as a result of 16S rRNA studies, *Leucothrix* is classified as a eubacterium belonging to the *Gammaproteobacteria* (Woese et al., 1985). Studies of the 23S rRNA support this classification (Ludwig et al. 1995). The findings of both Woese et al. (1985) and Ludwig et al. (1995) place *Leucothrix* by itself with its relationship to the other *Gammaproteobacteria*.

Cell morphology *Leucothrix* is a complex marine bacterium with diverse morphologies. A commonly seen form, especially in nature, is the filament (Bland and Brock, 1973; Harper and Talbot, 1984; Hansen and Olafsen, 1989), which is composed of individual cells that appear slightly beaded under the light microscope (Fig. BXII.γ.68). Filaments in nature extend perpendicularly outward from the surface to which they are attached via holdfast (Fig. BXII.γ.68). Cell division occurs throughout the filament (Brock, 1967). Filaments are of variable length, often much greater than 100 μm, with a diameter of 2–3 μm or more. They are colorless, unbranched, nonmotile (although they occasionally wave back and forth), and lack a sheath. Storage granules are often visible (Fig. BXII.γ.69). Filaments frequently grow intertwined or in dense tangles. One of the intriguing characteristics of *Leucothrix* is the ability of most strains to form true knots (Brock, 1964). The function of knot formation is unknown, and it may actually be an accidental process, but it seems to be characteristic of most *Leucothrix* strains as part of the growth process. Swollen cells often form apparently at random along filaments. Larger structures (bulbs) usually form in knotty cultures, possibly as the result of fusion of cells in the region of knots.

Gonidia (Figs. BXII.γ.69 and BXII.γ.70) are formed by rounding of cells in the filaments. At a low concentration of an organic energy source, filaments do not grow very long, and gonidia are formed more readily. Gonidial formation is also increased if growth rate is slowed by anaerobiosis, starvation, or reduction of the temperature of incubation (Pringsheim, 1957; Bland and Brock, 1973). Gonidia move by a jerky sort of gliding motility, which can only be seen well when observations are made in slide cultures. Single gonidia may move for extended periods before attaching and dividing to form filaments. If the gonidial density is high enough, gonidia appear to be attracted to each other by homotaxis, and they form aggregates, a process that ultimately results in rosette formation (Fig. BXII.γ.69). Rosettes are also seen in nature (Fig. BXII.γ.70; Solangi et al., 1979; Hansen and Olafsen, 1989). Free gonidia appear to lack holdfast material; however, once a gonidium has attached to a surface or to another gonidium (after elaborating holdfast), it remains attached indefinitely. Gonidia grow into filaments if conditions are favorable. Holdfasts can also be visualized by fluorescence microscopy. The fluorochrome dye primulin, when viewed in blue light, causes holdfast material to fluoresce red and the cell wall to fluoresce yellow.

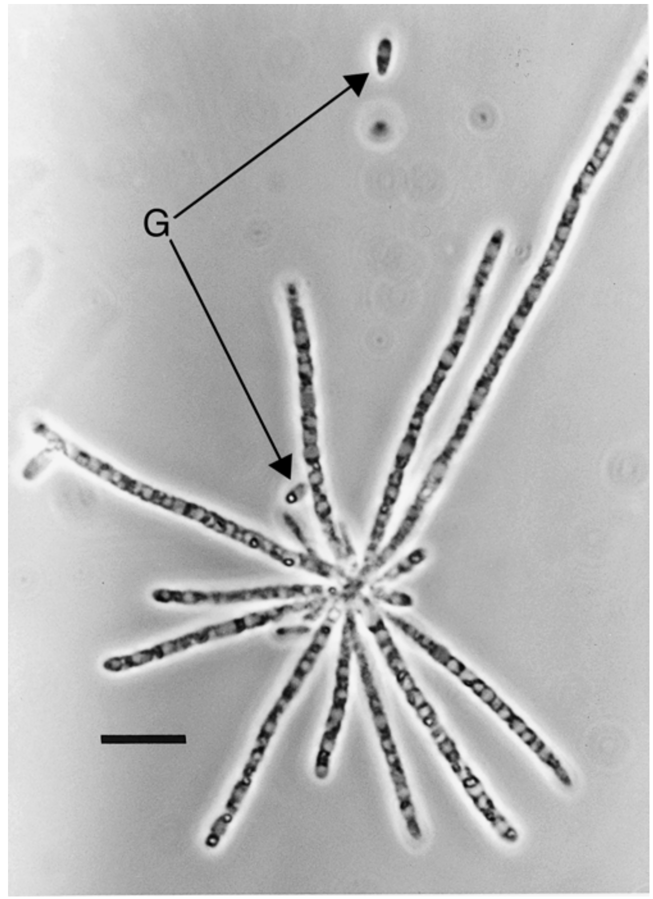

FIGURE BXII.γ.69. Rosette of *L. mucor* in laboratory culture, with storage granules visible in the filaments. Free gonidia (*G*) are visible. Bar = 15 μm (Phase microscopy).

Cell wall composition To date, no chemistry for the cell walls of *Leucothrix* has been published.

Fine structure Electron microscopic studies of *Leucothrix* have been presented by Brock and Conti (1969), Snellen and Raj (1970), Raj (1977), Couch (1978), Solangi et al. (1979), and Hansen and Olafsen (1989). The filaments of *Leucothrix* are multicellular, with the individual, somewhat square cells being separated by well-defined cross-walls (Fig. BXII.γ.71). Membranous and storage vesicles are obvious in both filament cells and gonidia (Figs. BXII.γ.71 and BXII.γ.72). The cell wall shows structural features characteristic of the Gram-negative bacterial envelope. No sheath is apparent (Figs. BXII.γ.71 and BXII.γ.72). In gonidia formation, the vegetative cells in the filament become rounded with no apparent internal fine-structural changes (Brock and Conti, 1969) and disassociate from each other (Harold and Stanier, 1955). Released gonidia may either attach singly to a surface via holdfast or aggregate into rosettes and elaborate holdfast at the aggregated cell ends. Figure BXII.γ.72 depicts aggregated gonidia with the associated holdfast material easily seen in the electron microscope as an electron-dense material, possibly a polysaccharide, peripheral to the outer wall layer. A micrograph by Solangi et al. (1979) shows holdfast material external to a brine shrimp structure. A similar finding is demonstrated by Couch (1978). His pictures reveal *Leucothrix* attached via holdfast to the gill cuticle of pink shrimp. The holdfast adheres to the cuticle (e.g., Fig. BXII.γ.73) and does not penetrate into the organism. Snellen and Raj (1970) have demonstrated that many bizarre forms of *Leucothrix*, including knots and bulbs, can be induced by calcium deficiency, and they have shown the resultant fine structure.

Life cycle The life cycle of *Leucothrix* is shown in Fig. BXII.γ.74. Rosette and gonidia formation are not obligatory; the organism can grow indefinitely in the filamentous form. Gonidia formation occurs in nature, ensuring the dispersal of the organism.

Nutrition and growth conditions *Leucothrix* is a versatile heterotroph that is able to grow on a variety of organic energy sources, including sugars, amino acids, sugar alcohols, alcohols, lipids, and organic acids (Raj, 1977; Williams and Unz, 1985a, 1989; Brock, 1992). Walker et al. (1975) reported utilization of a mixed hydrocarbon substrate by the type strain, ATCC 25107. Strains exhibit variable use of both inorganic and organic nitrogen sources (Williams and Unz, 1989), but *Leucothrix* is unable to fix N_2 (Mague and Lewin, 1974). Many strains do not need growth factors; however, a stenothermal strain required vitamin B_{12} for growth (Kelly and Brock, 1969b).

Metabolism and metabolic pathways The physiology and the metabolism of *Leucothrix* have been extensively reviewed by Raj (1977). *Leucothrix* is a strict aerobe, with an optimum temperature

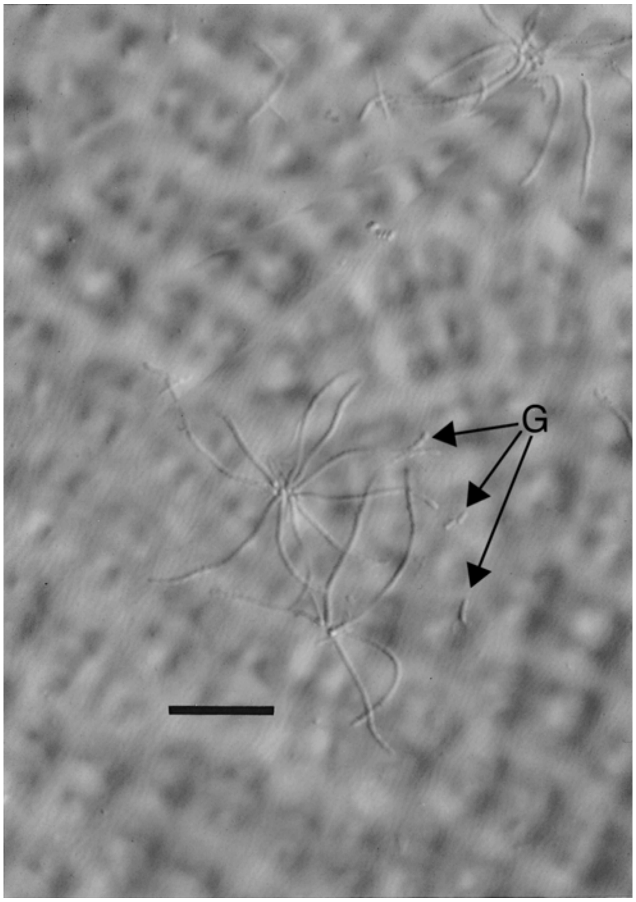

FIGURE BXII.γ.70. Rosette of *Leucothrix* on the surface of the red alga *Porphrya*. Gonidia (*G*) are visible. Bar = 20 μm (Nomarsky interference optics).

for growth of 25–30°C, an optimum pH for growth of 7.6, and an optimum salinity of 1.5%. Bland and Brock (1973) have shown that *Leucothrix* is able to withstand several hours of drying without any apparent reduction in viability, which is consistent with the fact that the organism extensively colonizes *Bangia fuscopurpurea*, a red algal species found high in the intertidal zone and frequently subject to drying during low tides. Radiorespirometric studies have shown that *Leucothrix* oxidizes carbohydrate substrates primarily via the Entner–Doudoroff pathway, with contributions from the pentose phosphate and the Embden–Meyerhoff pathways and the TCA cycle (Raj, 1977). Operation of the TCA cycle is consistent with the presence of isocitrate and malate dehydrogenases (Kelly and Brock, 1969a). The organism is catalase and oxidase positive (Poffe et al., 1979; Williams and Unz, 1985a). The electron transport pathway has been studied by Biggins and Dietrich (1968) using spectrophotometric methods. The terminal electron transport system is a particulate cytochrome chain containing cytochrome b_{562}, cytochrome c_{552}, and cytochrome b_{558}. Cytochrome b_{558} has been proposed to be functionally equivalent to cytochrome *o*, and it operates as the terminal oxidase. Cytochrome b_{558} has high CO-binding properties. The activity of the oxidase system is markedly affected by the degree of aeration during growth. Although several strains of *Leucothrix* have been tested for ability to oxidize hydrogen sulfide, these tests have all been negative (Harold and Stanier, 1955; Williams and Unz, 1985a). However, K. Eimhjellen of the Technical University in Trondheim has found sulfide-oxidizing ability and deposition of elemental sulfur in a pure marine culture of *Leucothrix* isolated from Pacific Grove, California (Brock, 1992). He has also been able to demonstrate oxidation of thiosulfate to either tetrathionate or sulfate and followed this latter oxidation manometrically. Eimhjellen's strain is obviously different from those studied by Harold and Stanier (1955). In light of the uncertainty surrounding the ability of *Leucothrix* to oxidize sulfur compounds, more work on this aspect of *Leucothrix* metabolism is in order.

Genetics Very limited genetic information is available for *Leucothrix*. Buoyant density determinations of DNA base composition have been determined by Brock and Mandel (1966) and by Kelly and Brock (1969a) for 46 strains isolated from various locations around the world. The mol% G + C content for all strains is in the range of 46.9–51.0, indicating great homogeneity at the DNA level. However, enzyme mobility data for 35 of the strains tested by Kelly and Brock (1969a) has revealed more diversity. Electrophoresis of malate dehydrogenase (MDH) and isocitrate dehydrogenase results in 17 different banding patterns, with MDH showing the most variability. Strains from the same geographical area vary as much as those from different geographical locations.

Antibiotic sensitivity Limited antibiotic sensitivity data exist for *Leucothrix*. According to Raj (1977), growth of *Leucothrix* can be inhibited by penicillin (0.1 mg/l), streptomycin (5.0 mg/l), or chloromycetin (0.7–0.9 mg/l). An isolate tested by Williams and Unz (1985a), *Leucothrix* sp. N11, was found to be completely inhibited by <0.125 mg/l of streptomycin, gentamicin, tetracycline, ampicillin, and penicillin G. The same strain is resistant to sulfanilamide and lincomycin, at >64 mg/l for both antibiotics, and is somewhat sensitive to chloramphenicol (0.5 mg/l) and bacitracin (4.0 mg/l).

Pathogenicity *Leucothrix* is an opportunistic pathogen of marine organisms reared in aquaculture or aquaria. Johnson et al. (1971) showed that *Leucothrix* was able to grow extensively on benthic crustacea, invertebrates, and fish eggs (cod and winter flounder) in laboratory spawning tanks and aquaria where they were infected with *Leucothrix* introduced by the seawater system. Since that report, *Leucothrix* has been found to cause infestations of crustaceans and fish eggs under cultivation in high-density aquaculture situations (Shelton et al., 1975; Couch, 1978; Fisher, 1978; Solangi et al., 1979; Harper and Talbot, 1984; Dale and Blom, 1987; Hansen and Olafsen, 1989; Carr, 1996). Harper and Talbot (1984) were unable to show differences in mortalities of wild and laboratory spawned lobster eggs (*Homarus gammarus* and *H. americanus*) in cases where *Leucothrix* was one of the epiphytes observed. In contrast, Lightner et al. (1975) theorized that penaeid shrimp heavily infested with *Leucothrix* died as a result of oxygen depravation. In a similar vein, Couch (1978) reported that mortality of penaeid shrimp was proportionate to the extent of growth of *Leucothrix* on their gills. He suggested that the mortality may have been due to the massive growth of the bacterium over the gill cuticle, blocking normal gas diffusion across the gill surfaces. Solangi et al. (1979) noted that *Leucothrix* attached to all available surfaces on cultured brine shrimp, *Artemia salina*, and caused mortality. They found that exposure of shrimp to terramycin (100 ppm) for two days eliminated *Leucothrix*, while treatment with various chemicals proved toxic to

Membranous (*M*) and storage (*S*) vesicles are obvious in both filament cells and gonidia. Bar = 1 μm. (Reproduced with permission from T.D. Brock and S.F. Conti, Archives of Microbiology *66:* 76–90, 1969, ©Springer-Verlag.)

FIGURE BXII.γ.73. *Leucothrix* filaments attached to the cuticle of *B. fuscopurpurea*. Bar = 10 μm (Nomarsky interference optics).

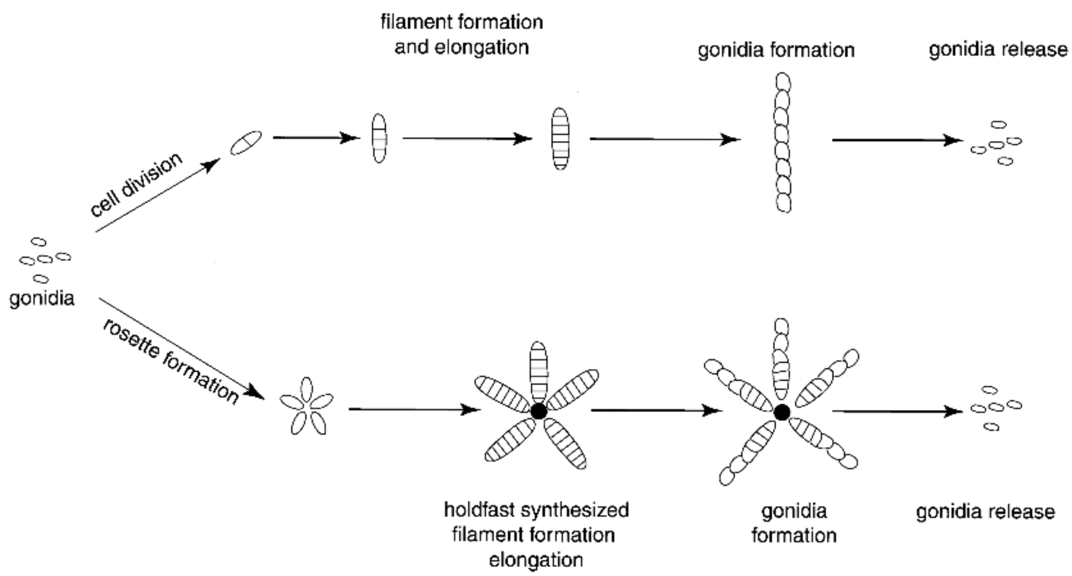

FIGURE BXII.γ.74. Life cycle of *Leucothrix*. Gonidia may attach to a substrate or to each other (rosette formation) with subsequent cell division. Ultimately, filament cells become gonidia that are released to repeat the cycle.

the shrimp. Colonization of uninfected organisms or eggs is apparently rapid. Cod and halibut eggs in aquaculture were colonized within 2 h of fertilization by a variety of bacteria including *Leucothrix* according to Hansen and Olafsen (1989). The authors further report heavier *Leucothrix* growth on cod eggs, giving them a "hairy" appearance that could be mistaken for fungal growth. Antibiotic treatment may be used to prevent such overgrowth. In addition to the antibiotics mentioned above, *Leucothrix* infections have been treated with penicillin, streptomycin, and neomycin (Johnson et al., 1971; Raj, 1977; Fisher, 1978). Also, Sadusky and Bullis (1994) report that dilute bleach solutions are effective in controlling *Leucothrix* infections in the lobster.

Ecology *Leucothrix* is found widely in the littoral zone in marine environments worldwide, growing primarily as an epiphyte of micro- and macroscopic algae or animals. The dominant

form of *Leucothrix* in the marine environment is the filament, suggesting an advantage to this morphology that might involve entrapment of available nutrients from seawater, better exposure to available oxygen, and access to any materials released by the host. The dispersive, or colonizing, form of *Leucothrix* is the gonidium. *Leucothrix* has been reported to colonize almost every type of marine algae, including species of diatoms and red, green, and brown algae (Brock, 1966; Kelly and Brock, 1969a; Johnson et al., 1971; Bland and Brock, 1973). Some algae are routinely more heavily colonized than others. Bland and Brock (1973) have reported that the red alga *Bangia fuscopurpurea*, a filamentous species living in the high intertidal region, has *Leucothrix* populations 10–30 times larger than those on other algal species. The cuticle of this alga contains mannose (Frei and Preston, 1964), a sugar readily utilized by *Leucothrix* (Bland and Brock, 1973). Johnson et al. (1971) have also reported a preference for red algal species. Brock (1966) has shown that *Leucothrix* can grow on nutrients produced or liberated from algae. However, algae also produce inhibitory chemicals, e.g., sulfuric acid, acrylic acid, and tannins (Bland and Brock, 1973). Furthermore, extracts of 5 of 39 species of corals tested were shown to inhibit a *Leucothrix* culture (Jensen et al., 1996). Although *Leucothrix* is also able to colonize artificial substrates (plastic strips) in the marine environment, Bland and Brock (1973) have shown that growth is much poorer on these strips than on seaweeds, a result that further supports the notion a living host provides a nutritional advantage for *Leucothrix*.

Johnson et al. (1971) have observed *Leucothrix* on many kinds of free-living benthic and pelagic crustaceans, including crabs, lobster, prawns, shrimp, and copepods. Filaments of the organism attach to antennae, pleopods, uropods, and egg masses. *Leucothrix* grows on cultured fish eggs (see section on Pathogenicity), but no data about its occurrence on wild fish has been found. *Leucothrix* may serve as a source of food for some crustaceans. The grass shrimp *Palaemonetes pugio* has been observed to graze on heavy growths of *Leucothrix* on its pleopods while grooming (Johnson et al., 1971). Bauer (1987) has experimentally determined that the growth of *Leucothrix* on the antennae and gills of the stomatopod *Gonodactylus oerstedii* is far heavier on organisms unable to groom than those that were. He has also observed that *Leucothrix* does not colonize the eyes of the organism or most other parts of the body, indicating that some mechanism restricts attachment or growth. McAllen and Hannah (1999) have observed that *Leucothrix* is a major biofoulant of the marine copepod *Tigriopus brevicornus*, a species that has no grooming structure. McAllen and Scott (2000) have additionally reported that the biofouling interferes with swimming behavior.

There are controversial reports about the presence of *Leucothrix* in sewage treatment processes. *Leucothrix*-like organisms have reportedly been associated with activated sludge systems, where they have been implicated in the phenomenon of bulking, and they have been observed in self-purification and other biological waste treatment processes (Eikelboom, 1975, 1977; Cyrus and Sladka, 1970). In most such cases, brackish water was involved (Eikelboom and van Buijsen, 1981), although one strictly freshwater strain, said to be *Leucothrix*, has been isolated from petrochemical wastewater undergoing activated sludge treatment (Poffe et al., 1979). Even this strain grows well at seawater salinity and thus may be considered simply more euryhaline than are other isolates. However, more recent data (Wagner et al., 1994a; Nielsen et al., 1998) from a *Leucothrix mucor* rRNA-targeted oligonucleotide probe did not identify *Leucothrix* in activated sludge samples where organisms morphologically similar to *Leucothrix* were seen. All in all, investigators claiming to have isolated *Leucothrix* from freshwater environments should be encouraged to confirm the culture identity with molecular genetic tools, such as probes.

Enrichment and Isolation Procedures

Although any marine-type seawater salts base may be used in the formation of a culture medium, pH control and the avoidance of metal precipitation are easier in a Provasoli-type culture medium (Provasoli, 1964). The salts formulation (Brock, 1966) in *Leucothrix* medium[1] has proven to be quite effective. The low phosphate concentration in this salts base is critical, as media of more typical phosphate concentrations are frequently inhibitory. Most strains have no vitamin requirements and are able to use glutamate as their sole source of carbon, nitrogen, and energy. If a richer culture medium is desired, 0.1% tryptone plus 0.1% yeast extract can be used. Other media have been described by Raj (1977) and Williams and Unz (1985a, 1989).

In the initial isolation step, it is best to keep the concentration of organic materials low to avoid problems with overgrowth by unicellular bacteria. Although Harold and Stanier (1955) describe a procedure for enrichment of *Leucothrix* from rotting seaweeds, direct isolation from fresh seaweeds is preferable. Rapidly growing, highly motile, unicellular bacteria frequently present problems when isolation of *Leucothrix* from rotted materials is attempted. An effective way of obtaining cultures of *Leucothrix* is to place relatively clean seaweeds taken directly from the sea onto an agar medium that will support the growth of *Leucothrix*. The plates are incubated overnight at 20–25°C and examined within 12–18 h for the presence of *Leucothrix* colonies. This examination is best done by using $\times 125$ magnification ($\times 12.5$ eyepiece and $\times 10$ objective) with a long working-distance condenser. It is important to use short incubation periods in order to find *Leucothrix* colonies before they become overgrown by motile contaminants. A *Leucothrix* colony may be recognized by its coiled rope or thumbprint morphology. Colonies are immediately picked by touching them with a sterile insect pin and transferring them in patches to fresh agar plates of the same composition. One advantage of isolating *Leucothrix* in this manner is that the precise habitat of the organism can be recognized; such information is of considerable value in studies on the molecular evolution of the organism (Kelly and Brock, 1969a). Transfer of agar cultures to liquid medium frequently presents problems. It has been observed that if a small inoculum is used in a large volume of liquid medium, growth often does not occur, whereas if the inoculum is placed in a small volume of medium, i.e., 1–2 ml, heavy growth occurs overnight. Once satisfactory growth has been obtained in an initial small-volume liquid culture, it is possible to make transfers to large volumes of liquid medium. In liquid medium, growth is best when flasks are shaken gently, as on a wrist-action shaker or slowly on a rotary shaker. When a rotary shaker is used, growth rate is increased if the flasks contain small internal baffles, made by pushing in the sides of the flasks while heating with an oxygen flame.

---

1. *Leucothrix* medium consists of (g/l deionized water, pH 7.6): Basal salts: NaCl, 11.75; $MgCl_2 \cdot 6H_2O$, 5.35; Na_2SO_4, 2.0; $CaCl_2 \cdot 2H_2O$, 0.75, KCl. 0.35; Tris(hydroxymethyl)aminomethane, 0.5; Na_2HPO_4, 0.05; Organic ingredients: monosodium glutamate, 1.0 or tryptone + yeast extract, 1.0 + 1.0.

Identification While an experienced researcher can identify *Leucothrix* simply based on morphological examination with the light microscope, a novice might initially want to work with a known isolate. Other than its distinct morphology and usual occurrence in the marine habitat, there are no conventional diagnostic tests specific for *Leucothrix*. In the extensive isolations of Kelly and Brock (1969a), all of the isolates recognized morphologically had virtually the same physiological properties. The morphological properties described at the beginning of this article are generally found in any *Leucothrix* strain that is isolated. The availability of 16S and 23S rRNA (or other molecular) probes make confirmation possible when identification is critical, and these should especially be used for putative freshwater isolates.

Maintenance Procedures

Once rapidly growing liquid cultures have been obtained (see above), there are no special maintenance problems. Cultures in the early stages of growth can be stored in the refrigerator for several months, after which they may consist mostly of gonidia. Cultures can also be lyophilized, with the best suspension medium being skim milk. When a lyophilized culture is rehydrated, it is best if the dry plug is placed in 1–2 ml of liquid medium and 0.1 ml of this suspension placed in another tube of 1–2 ml of liquid medium. Both tubes are then incubated for 1 or 2 days. If there is no visible growth in the dilution, 0.1–0.2 ml of the tube containing the original rehydrated culture should be transferred to another tube containing 1–2 ml of medium, followed by another incubation period. Only after good growth has been obtained in a small volume of medium should large-volume cultures be prepared. Contamination is easy to recognize, since *Leucothrix* cultures never show uniform turbidity. Microscopic examination of a culture should permit contamination to be readily determined. Streaking onto a seawater agar medium containing tryptone and yeast extract is also a satisfactory way of recognizing many contaminants. If contaminants do become established, they will generally grow better than the *Leucothrix* and as a result will quickly take over the culture.

Differentiation of the genus *Leucothrix* from other genera

Molecular techniques using both 16S rRNA (Woese et al., 1985) and 23S rRNA (Ludwig et al., 1995) place *Leucothrix* in a group by itself in the *Gammaproteobacteria*. Woese et al. (1985) consider *Leucothrix* to be a peripheral member of the *Gammaproteobacteria* core and specifically related to the enterics, vibrios, and oceanospirilla. Ludwig et al. (1995) define the position of *Leucothrix* as "somewhat unstable . . . This organism may represent the currently deepest branch of the gamma-subclass of the proteobacteria or a branch at or even below the level of gamma- and beta-subclass relatedness." In short, it is clear what *Leucothrix* is not, but not what it is. *Thiothrix*, the genus with which *Leucothrix* was once paired, is also classed within the *Gammaproteobacteria* along with other sulfur-oxidizing, gliding bacteria (*Thioploca*, *Beggiatoa*, and *Achromatium*). A head-to-head use of 16S rRNA probes for *Leucothrix* and *Thiothrix* in activated sludge has shown no relatedness, as judged by the lack of cross-reaction (Nielsen et al., 1998). The gliding characteristic is now recognized as not being unique to any group of bacteria; gliders are located widely across the spectrum of the proteobacteria. Relatedness of *Leucothrix* to the cyanobacteria has also been ruled out; Reichenbach et al. (1986), using 16S rRNA techniques, have demonstrated that *Leucothrix* is not a colorless cyanobacterium.

Taxonomic Comments

To date, the only recognized species of *Leucothrix* is *Leucothrix mucor*, with nine marine isolates available in the American Type Culture Collection. While the genus has many phenotypic features in common with other organisms, its 16S and 23S rRNA profiles put it in a class by itself. The only characteristic in dispute is the ability of *Leucothrix* strains to oxidize sulfide. Brock (1992) cites work by Eimhjellen that demonstrated the ability of an isolate to oxidize sulfide, sulfur, and thiosulfate. The sulfide oxidation resulted in the internal deposition of sulfur granules, causing *Leucothrix* to resemble *Thiothrix*. Unfortunately, this culture is not available. One of the two organisms used by Woese et al. (1985) for the *Leucothrix* group in his classic 16S rRNA study is identified as a "*Thiomicrospira*-like isolate, " a label that suggests sulfide-oxidizing ability. Overall, the *Leucothrix* genus would benefit from new experimental attention to better characterize this possible ability.

List of species of the genus Leucothrix

1. **Leucothrix mucor** Oersted 1844, 44[AL]

mu'cor. L. n. *mucor* mold; M.L. n. *mucor* a genus of molds.

The characteristics are the same as those described for the genus.

Occurs in marine habitats.

The mol% G + C of the DNA is: 46.9–51 (T_m).

Type strain: ATCC 25107, DSM 2157.

GenBank accession number (16S rRNA): X87277.

Genus V. **Thiobacterium** *(ex Janke 1924) la Rivière and Kuenen 1989b, 496^{VP} (Effective publication: la Rivière and Kuenen 1989a, 1838)*

J. Gijs Kuenen

Thi' o.bac.te' ri.um. Gr. n. *thios* sulfur; Gr. dim. n. *bakterion* a small rod; M.L. neut. n. *Thiobacterium* small sulfur rod.

Rod-shaped cells, each containing one or more sulfur globules. Cells embedded in **gelatinous masses**, which are spherical when free-floating or are dendroid when attached to a solid substrate. **Nonmotile.** No resting stages known. Has not been grown in pure culture.

Type species: **Thiobacterium bovista** (ex Janke 1924) la Rivière and Kuenen 1989b, 496 (Effective publication: la Rivière and Kuenen 1989a, 1838.)

Further descriptive information

Rod-shaped cells 0.4–1.5 × 2.5–9 μm with up to nine sulfur inclusions. When these are present, cell masses are white in reflected light and black or bluish in transmitted light. Gram negative (Scheminzky et al., 1972). In the spherical colonies, the cells are embedded in the gelatinous walls of a bladder-like structure filled with water and up to 4 mm in diameter. Such colonies occur near the water surface and have the appearance of groups of puff balls of different sizes. Dendroid colonies show extensive branching and may reach 2–3 mm.

The only species in this genus, *T. bovista*, has been found in marine, brackish, and freshwater environments containing hydrogen sulfide and at temperatures of up to 45°C in thermal springs.

Enrichment and Isolation Procedures

Molisch (1912) reported enrichment of the spherical colony type at the surface of Winogradsky columns prepared with decaying algae, mud, and seawater from the Gulf of Trieste. The dendroid form could not be enriched for but could, after being taken from nature, be kept alive for 3 months in the laboratory at 20°C in jars with water from the original habitat (Lackey and Lackey, 1961). Further details are given by la Rivière and Schmidt (1981). For micrographs, see articles by Lackey and Lackey (1961) and Scheminzky et al. (1972). No pure cultures are known.

Taxonomic Comments

Although this genus and its type species do not appear in the Approved Lists of Bacterial Names, maintaining their descriptions in the present edition of the *Manual* and reviving the name appears justified because reports of *Thiobacterium* have occasionally been published (Scheminzky et al., 1972; Caldwell and Caldwell, 1974; Naganuma and Seki, 1991; Hedoin et al., 1996).

List of species of the genus Thiobacterium

Genus VI. **Thiomargarita** *Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999b, 1325^{VP} (Effective publication: Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999a, 493)*

Heide N. Schulz and Bo Barker Jørgensen

Thi'o.mar.ga.ri' ta. Gr. n. *thion (theion)* sulfur; L. n. *margarita* pearl; M.L. fem. n. *Thiomargarita* sulfur pearl.

Very large **spherical cells held together** like a string of pearls **by a common gelatinous mucus**. The cells are not joined to each other, which is the main difference to the closely related filamentous genera, *Thioploca* and *Beggiatoa*. **Numerous sulfur inclusions** occur in a thin outer layer of cytoplasm. The cells appear hollow due to a **large central vacuole in which nitrate is stored**. Most strings of cells are linear and typically contain 20–60 cells, but some are branched or coiled. Both single cells and strings of more than 100 cells occur. **Nonmotile.** Gram negative. **Oxygen tolerant.** *Thiomargarita* appear to have an autotrophic or mixotrophic, sulfide-oxidizing, nitrate-reducing metabolism, comparable to the large marine forms of *Thioploca* and *Beggiatoa*, which are its closest relatives according to partial 16S rDNA sequence analysis.

Type species: **Thiomargarita namibiensis** Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999b, 1325 (Effective publication: Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999a, 493.)

Further descriptive information

The cell diameters of the only described species, *Thiomargarita namibiensis*, vary between 50 and 750 μm, with the majority of

cells being between 100 and 300 μm in diameter. Although most cells are spherical, the shape of the cell is variable. Occasionally, more irregular or barrel-shaped cells (Fig. BXII.γ.75C) occur. The mucus sheath surrounds the single cells completely, which is apparent when cells disintegrate and leave empty mucus pockets (Fig. BXII.γ.75B, left side). The strings of cells seem to grow by lateral division (Fig. BXII.γ.75B, cells in division). Bacteria, including filamentous forms resembling *Thiothrix* and *Desulfonema* (Fig. BXII.γ.75A), are frequently found living attached to the outside of the mucus.

16S rRNA phylogeny and systematics Partial 16S rDNA sequence analysis shows that *Thiomargarita* belongs to the *Gammaproteobacteria* and is the closest relative to the vacuolated marine *Thioploca* and *Beggiatoa* species. Details of the phylogeny are discussed in the chapter on the genus *Thioploca*.

Morphology and cell structure Electron micrographs have shown that, similar to the nitrate-storing *Thioploca* and *Beggiatoa* species, the cytoplasm of *Thiomargarita* is restricted to a thin outer layer of 1–2 μm thickness. About 98% of the cell is comprised of a large liquid vacuole. Apart from the sulfur inclusions along the periphery of the cells (Fig. BXII.γ.75A, black arrow), numerous smaller inclusions which have not been identified can be observed (Fig. BXII.γ.75A, white arrow).

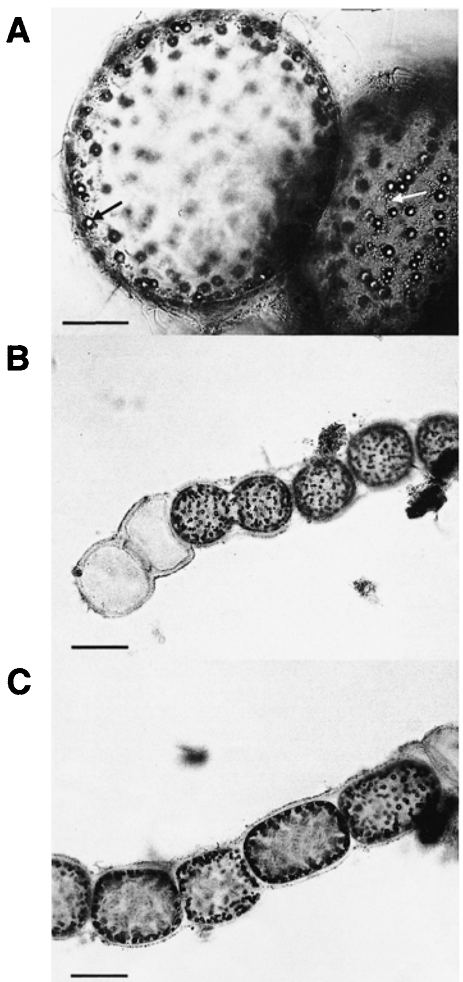

FIGURE BXII.γ.75. *Thiomargarita namibiensis* as it appears under light microscopy. (*A*) The terminal cell of a string. The black arrow points to a sulfur inclusion, the white arrow to a smaller unidentified type of inclusion. The inclusions are restricted to the periphery of the cell. Outside the cell there are various filamentous bacteria, resembling *Desulfonema*, attached to the mucus sheath. Bar = 50 μm. (*B*) To the left, two empty sheaths; in the middle, a dividing cell. Bar = 100 μm. (*C*) A chain of barrel-shaped *Thiomargarita* cells. Bar = 50 μm.

Metabolism *Thiomargarita* stores nitrate at 0.1–0.8 M concentration and elemental sulfur at a concentration equivalent to 0.4–1.7 M. Growth of *Thiomargarita* can be induced by adding nitrate and sulfide to the natural sediment. Therefore, an autotrophic or mixotrophic metabolism is assumed, by which sulfide is oxidized with nitrate, comparable to the metabolism of the large marine *Thioploca* and *Beggiatoa* species. In contrast to these, however, *Thiomargarita* tolerates prolonged exposure to oxygen up to air saturation, as well as to high sulfide concentrations (~0.8 mM) (Schulz and de Beer, 2002). *Thiomargarita* has a remarkable capability to survive starvation. Sediment samples maintained at 5°C without addition of sulfide or nitrate contained intact cells after more than two years. Without addition of nitrate or sulfide, no dividing cells were observed and cell numbers decreased.

Ecology The only known species, *Thiomargarita namibiensis*, was found in shelf sediments off the Namibian coast. The upwelling area off Namibia is characterized by high plankton productivity, which leads to sediments rich in organic material and with high sulfate reduction rates. In contrast to the upwelling area off the Pacific coast of South America, where the related *Thioploca* species thrive, the upwelling intensity off Namibia fluctuates more. *Thiomargarita* occurs in high density (about 50 g/m^2) in the area of Walvis Bay. The population seems to be associated with an unusual type of sediment, a fluid, sulfidic diatom ooze. The highest density of *Thiomargarita* was observed directly at the sediment surface, declining exponentially with depth. As *Thiomargarita* cells are not motile, but are highly resistant towards nitrate starvation and high oxygen concentrations, it is assumed that they take up nitrate only occasionally, when nitrate-rich bottom water is introduced into the sediment, possibly co-occurring with elevated oxygen concentrations. Between such events, *Thiomargarita* is able to survive high concentrations of sulfide accumulating in the sediment. Due to its large volume (50–750 μm in diameter), which is mainly due to a central vacuole with nitrate concentrations up to 800 mM, *Thiomargarita* has a large storage capacity for its electron acceptor, nitrate. Sulfide, produced by sulfate-reducing bacteria, is permanently available as electron donor in the organic-rich sediment. Thus, *Thiomargarita* can continuously oxidize sulfide, although the electron acceptor, nitrate, is only intermittently available.

Maintenance Procedures

Thiomargarita may be grown in a 2–3 cm thick layer of natural sediment on agar containing 0.5 mM sulfide and covered by oxic or anoxic seawater containing 1 mM nitrate. A frequent resuspension of the sediment enhances growth, whereas addition of organic substrates such as acetate or glucose has no clear effect.

Differentiation of the genus *Thiomargarita* from other genera

In contrast to the closely related genera *Thioploca* and *Beggiatoa*, *Thiomargarita* forms filaments, but does not form trichomes. The extremely large, nonmotile cells are surrounded by a mucus that keeps them attached to each other in a string. The ability to survive under atmospheric oxygen concentration is unique among the vacuolated, nitrate-storing sulfur *Bacteria*.

List of species of the genus Thiomargarita

1. **Thiomargarita namibiensis** Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999b, 1325[VP] (Effective publication: Schulz, Brinkhoff, Ferdelman, Hernández Mariné, Teske and Jørgensen 1999a, 493.)
na.mi.bi.en' sis. M.L. gen. n. *namibiensis* of Namibia.

Genus VII. Thioploca *Lauterborn 1907, 242*[AL]

Bo Barker Jørgensen, Andreas Teske and Azeem Ahmad

Thi.o.plo' ca. Gr. neut. n. *thion, theion* sulfur; Gr. fem. n. *ploke* a braid, a twist; M.L. fem. n. *Thioploca* sulfur braid.

Flexible, uniseriate, colorless filaments made up of numerous cells and enclosed by a **common gelatinous sheath**. Gram negative. Cells are disk-shaped or cylindrical, generally harbor **sulfur inclusions** in their cytoplasm, and are separated by distinct cross-walls. Cells of large marine *Thioploca* species **appear hollow due to central vacuoles in which nitrate is stored**. Individual filaments are of uniform diameter, often with **tapered terminal cells**. Filaments fall into distinct classes of **different diameters, which represent different species**. Filaments show **independent gliding movement** within a sheath. They can emerge from the end or from breaks in the sheath and may be found outside sheaths. **Chemotactic.** May be attracted by nitrate but avoid high oxygen and sulfide concentrations. *Thioploca* sheaths are mostly vertically orientated to allow the filaments to move between spatially separated pools of electron donor (sulfide) and acceptor (nitrate, possibly oxygen). The sheath surrounding several filaments is the main feature distinguishing the genus *Thioploca* from the similar, closely related genus *Beggiatoa.* Not in pure culture. Large, marine *Thioploca* species have an autotrophic or mixotrophic, sulfide-oxidizing, nitrate-reducing metabolism. By 16S rRNA, *Thioploca* is a member of the *Gammaproteobacteria* **and is the closest relative of the genera *Beggiatoa* and *Thiomargarita*.**

Type species: **Thioploca schmidlei** Lauterborn 1907, 242.

Further descriptive information

Thioploca filaments fall into distinct diameter classes, which are the traditional basis for species designation (Table BXII.γ.41, Fig. BXII.γ.76). At least two different groups of *Thioploca* species are apparent, the smaller freshwater and brackish water species, of which *T. ingrica* is the best-known representative, and the large marine species, which include *T. araucae* and *T. chileae.* Diameters of accepted species range from 0.8–43 µm, but occasionally marine sheathed *Thioploca* of up to 125 µm diameter have been observed (H.N. Schulz and B.B. Jørgensen, unpublished observations). The large, marine filaments are easily visible with the unaided eye.

Thioploca typically grow in bundles surrounded by a common sheath (Figs. BXII.γ.77 and BXII.γ.78A). The number of filaments in a sheath ranges from a few to tens but may also reach a hundred. When bundles are observed (and slightly squeezed) in a microscope preparation, intertwining filaments may have the appearance of a braid, giving rise to the name *Thioploca* (Fig. BXII.γ.78C). Each bundle presumably represents a clone, and neighboring bundles may, accordingly, show small but significant differences in mean filament diameter (Schulz et al., 1996). Inspection of many sheaths of the marine *Thioploca* has revealed that ~20% of the sheaths have mixed bundles of two or three of the species *T. araucae*, *T. chileae*, and *"T. marina"*. *Thioploca* filaments may leave their own sheath under environmental stress, such as sulfide accumulation in the sediment. They can also survive as free-living filaments and may perhaps subsequently enter another sheath or form a common sheath with another species. Such mixed bundles also occur in the freshwater species; these gave rise to the name *"T. mixta"* (Koppe, 1924), which is no longer in use. The transparent sheath of young and growing bundles is thin and tough but it may become very wide and loose around older and senescent bundles.

16S rRNA phylogeny and systematics Based on near-complete 16S rRNA sequences, filamentous sulfur-oxidizing bacteria of the genera *Thioploca* and *Beggiatoa* form a monophyletic, highly diversified cluster within the *Gammaproteobacteria* that currently consists of three distinct groups (Teske et al., 1995, 1999; Ahmad et al., 1999): *Thioploca* and large, marine *Beggiatoa*; heterotrophic, freshwater *Beggiatoa*; and autotropic, marine *Beggiatoa* (Tree 1 of Fig. BXII.γ.79). The clade of marine, vacuolated, nitrate-accumulating *Thioploca* spp. (*T. araucae* and *T. chileae*), large, marine *Beggiatoa* spp., and *Thioploca ingrica* has 82–100% bootstrap support for near-complete sequences. For partial sequences (Tree 2 of Fig. BXII.γ.79), this clade includes the species *T. araucae* and *T. chileae* as well as the unicellular *Thiomargarita namibiensis* (Schulz et al., 1999a; Schulz and Jørgensen (2001)). The heterotrophic, freshwater *Beggiatoa* and the autotrophic, marine *Beggiatoa* clades do not contain *Thioploca* species (Tree 1 of Fig. BXII.γ.79). The heterotrophic, freshwater *Beggiatoa* clade contains a tight cluster of the *Beggiatoa alba* type strain B18LD (Mezzino et al., 1984) and closely related strains, always supported by

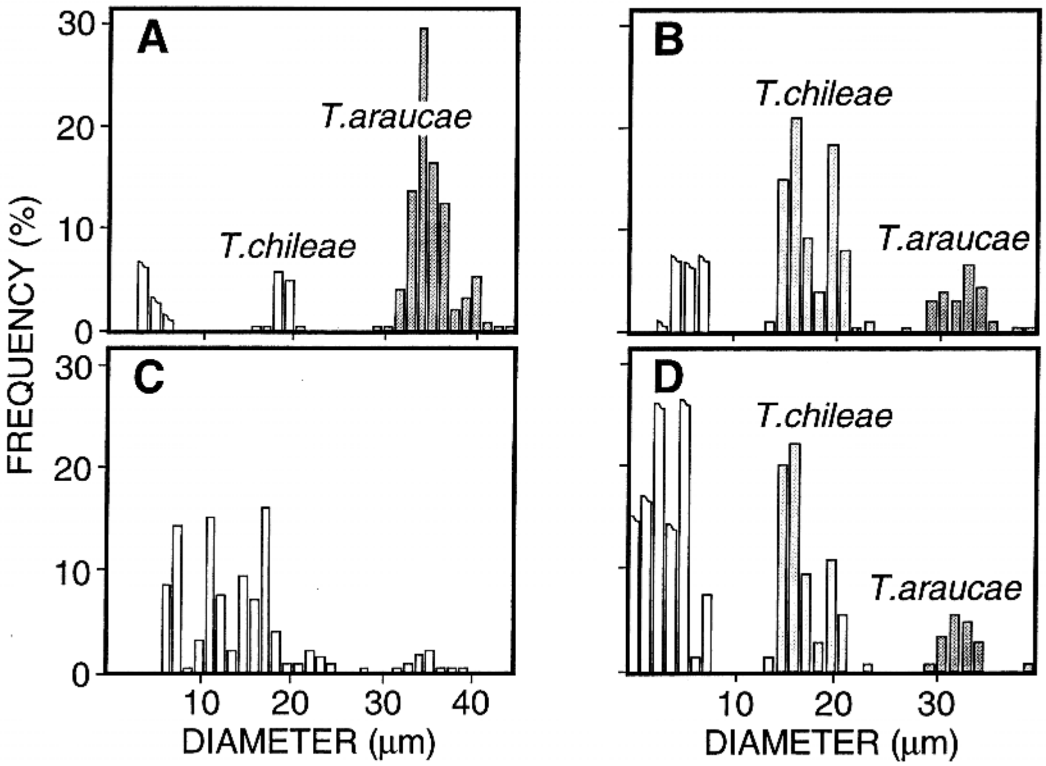

FIGURE BXII.γ.76. The presence of a common sheath and the diameters of trichomes are used to define the genus and species of *Thioploca*. The graphs illustrate the problems of this classification with regard to two marine populations from the surface layer of shelf sediments off the coast of Chile. Several hundred trichomes were randomly picked for each diagram, and the relative frequency distribution of their diameters is shown at ~1 µm resolution. Frames (*A*) and (*C*) are from a station at 40 m water depth and frames (*B*) and (*D*) from a station at 80 m water depth. Frames (*A*) and (*B*) represent trichomes picked from bundles surrounded by a common sheath. Frames (*C*) and (*D*) represent trichomes picked from the abundant free trichomes without visible sheaths. The two species, *T. chileae* and *T. araucae*, are clearly distinguished, as are the filaments of a narrower species which partially corresponds to *T. marina* (the narrow species occurred in larger numbers than indicated). At the shallow station (*A* + *C*), many free trichomes were of diameters not represented by the neighboring thioplocas in sheaths (they should consequently be called *Beggiatoa* spp.). At the deep station (*B* + *D*), there was a good correspondence between diameter distributions of sheathed and free trichomes, thus indicating that the latter were thioplocas outside sheaths. As indicated by the available 16S rRNA sequence database (see Fig. BXII.γ.79) the vacuolated marine thioplocas and beggiatoas are phylogenetically intertwined and, therefore, a distinction based on morphological characteristics (sheath, diameter) is probably not possible or meaningful. (Data from Schulz et al., 1996).

100% bootstrap. The sequence data demonstrate that the physiological and morphological similarities within and among these groups result from evolutionary relatedness.

Within the *Thioploca/Beggiatoa* clade, representatives of both genera are phylogenetically intertwined. The current distinction between the genera *Thioploca* and *Beggiatoa* does not follow phylogenetic lines but is instead determined by a morphological characteristic, the formation of a sheath around a filament bundle. This point is illustrated by a large, marine *Beggiatoa* from the Bay of Concepcion on the Chilean shelf that resembles *T. araucae* in filament diameter, 16S rRNA sequence, nitrate content, and habitat, but that occurs in individual filaments instead of sheathed filament bundles (Teske et al., 1999). The large *Beggiatoa* spp. from Monterey Canyon with 60–80 µm filament diameter (Ahmad et al., 1999) could represent a similar case, since ensheathed *Thioploca* with the same filament diameters are also known from this habitat (K. Buck, personal communication). Representing a possible challenge to the generality of this interpretation are massive assemblages of vacuolated *Beggiatoa* collected from the Guaymas Basin vents (Nelson et al., 1989b) that show no indication of forming sheathed filament bundles (A. Teske, unpublished data; D. C. Nelson, unpublished data). Parallel observations come from extensive *Beggiatoa* mats in the Gulf of Mexico (D.C. Nelson, unpublished data).

The 16S rRNA data support the classification of *T. araucae* and *T. chileae*, previously defined only by filament diameter, as not mere morphotypes, but separate species. However, filament diameter classes do not always correspond to genospecies or metabolic types; they may instead cover up unexpected genetic and metabolic diversity, as illustrated by the two clades of heterotrophic, freshwater *Beggiatoa* and marine, autotrophic *Beggiatoa* (Tree 1 of Fig. BXII.γ.79). With the exception of strain MS-81-

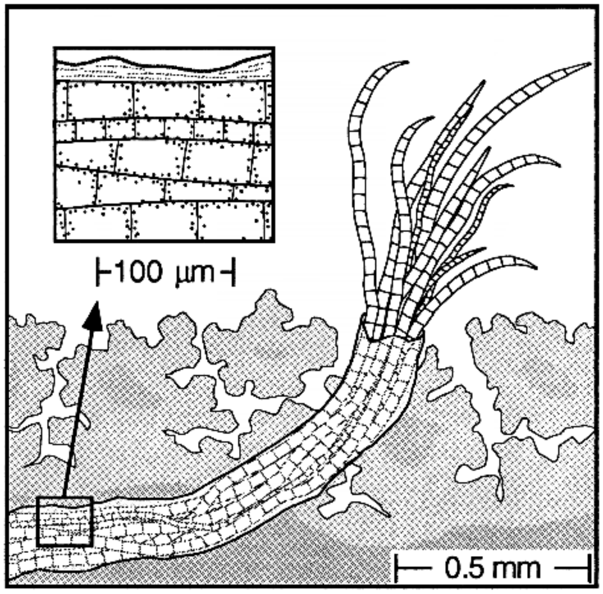

FIGURE BXII.γ.77. Schematic presentation of a bundle of marine thioplocas extending from their common sheath within the sediment and up into the overlying seawater. The insert shows the light-microscopic appearance of the trichomes, with crosswalls and fine sulfur globules along the cell periphery. (Drawing by Heide N. Schulz).

6, these *Beggiatoa* strains all share filament diameters of close to 2 μm. The genetic coherence of morphologically defined, widely distributed *Thioploca* species, for example *T. ingrica*, which is represented only by 16S rRNA sequences of specimens from a Danish brackish water habitat, is therefore not proven.

The thioplocas show some phenotypic similarities with cyanobacteria such as *Microcoleus*, both in morphology and in the formation of sheaths around bundles of filaments. The phylogenetic data clearly show, however, that the filamentous sulfide-oxidizing bacteria are unrelated to the cyanobacteria, which are not members of the *Proteobacteria*, but rather a separate monophyletic bacterial group.

Morphology and cell structure Each filament consists of a single row of cylindrical or barrel-shaped cells separated by septa. The septa may be difficult to observe microscopically in filaments rich in light-diffracting sulfur globules, but in those cases, their position is often indicated by the distribution pattern of sulfur globules (Fig. BXII.γ.78, D and F). For the smaller species with filament widths of <10 μm, the cell height is greater than the diameter, whereas the large marine species have more disk-shaped cells. Interestingly, the two diameter classes of *T. chileae* and *T. araucae* have been found to occur as two distinct populations of morphotypes: the normal type with a height-to-diameter ratio of 0.5:1.5 and a form with more rounded and flat cells having a height-to-diameter ratio of 0.3:1–0.5:1 (Schulz et al., 2000). The large, undescribed, marine thioplocas with diameters >50 μm all belong to this short-cell type. Each trichome contains a hundred to several thousand cells. The large, marine species are generally 1–2 cm long and may reach >5 cm in length (Huettel et al., 1996).

There is a distinct difference in cell structure between the small, freshwater species and the large, marine species of *Thioploca*. Each group shows many similarities to the small and large *Beggiatoa*, respectively (Maier and Murray, 1965; Strohl et al., 1982; Maier et al., 1990). In both groups, the 90–130 nm thick cell wall has a complex, four-layered structure, of which only the innermost layer and the cytoplasmic membrane continue across the septum wall separating the cells. Intracytoplasmic membranes and numerous cell inclusions form complex structures, which are apparent from TEM micrographs, and which have functions related to transport and storage. Most of these inclusions are situated in intrusions of the cytoplasmic membrane and are, therefore, extracytoplasmic (Maier et al., 1990). Most prominent are globules of S^0, which are also visible in the light microscope. Membrane-bound vacuoles, which in *Thioploca* contain electron-dense material, are distributed throughout the cytoplasm in *T. ingrica* as well as in the 4 μm wide *Beggiatoa* (Morita and Stave, 1963; Maier and Murray, 1965).

In *T. araucae* and *T. chileae*, the cytoplasm, with its sulfur inclusions, is confined to a 0.5-1.0 μm thick layer along the periphery of each cell (Maier et al., 1990). The whole inner cell volume is filled by a single liquid vacuole surrounded by a cytoplasmic membrane without apparent connection to the cell surface (Fig. BXII.γ.78B). Such a vacuole, which comprises >90% of the cell volume, is also found in the large, marine *Beggiatoa* spp. of >15 μm diameter (Lackey et al., 1965; Nelson et al., 1989b). It serves as a reservoir for nitrate, which the organisms use as an electron acceptor when oxidizing sulfide within the sediment (Fossing et al., 1995; McHatton et al., 1996; Zopfi et al., 2001). The peripheral distribution of cytoplasm, furthermore, provides short transport distances to the external medium and, thus, counteracts the diffusion limitation of these very large procaryotes.

Metabolism Since none of the thioplocas has been isolated in pure culture, information on their physiology is based mostly on observations of whole communities and on experiments with whole bundles of filaments. However, since the organisms are large and conspicuous, it has also been possible to physically isolate individual filaments and to observe their metabolic activity, e.g., by feeding them radiolabeled substrates and subsequently performing microautoradiography.

Thioploca oxidizes H_2S to sulfate and stores S^0 as an intermediate oxidation product in the form of globules in the cells. The S^0 serves as a transportable energy source that makes the organism independent of a continuous source of H_2S. All large, marine thioplocas and beggiatoas that have been examined so far contain high (100–500 mM) intracellular concentrations of nitrate, an accumulation four orders of magnitude over nitrate concentrations in the ambient sea water (Fossing et al., 1995; McHatton et al., 1996). The nitrate is stored in the large central vacuole, which functions as an anaerobic "lung" as the organisms move around in the sulfidic sediment. *Thioploca* uses nitrate as a respiratory electron acceptor for sulfide oxidation and reduces the nitrate principally to ammonium, as does *Beggiatoa* (Vargas and Strohl, 1985b; McHatton et al., 1996; Otte et al., 1999). It is unknown to what extent the smaller, freshwater or brackish water *Thioploca* species utilize nitrate as electron acceptor.

T. araucae and *T. chileae* are able to fix CO_2 and may be able to grow autotrophically but probably mostly grow mixotrophically, similar to *Beggiatoa* and *Thiothrix* (Nelson and Jannasch, 1983; Strohl and Schmidt, 1984; Otte et al., 1999). They can incorporate acetate, mixed amino acids, glycine, glucose, and thymidine in the presence of sulfide, as shown by autoradiog-

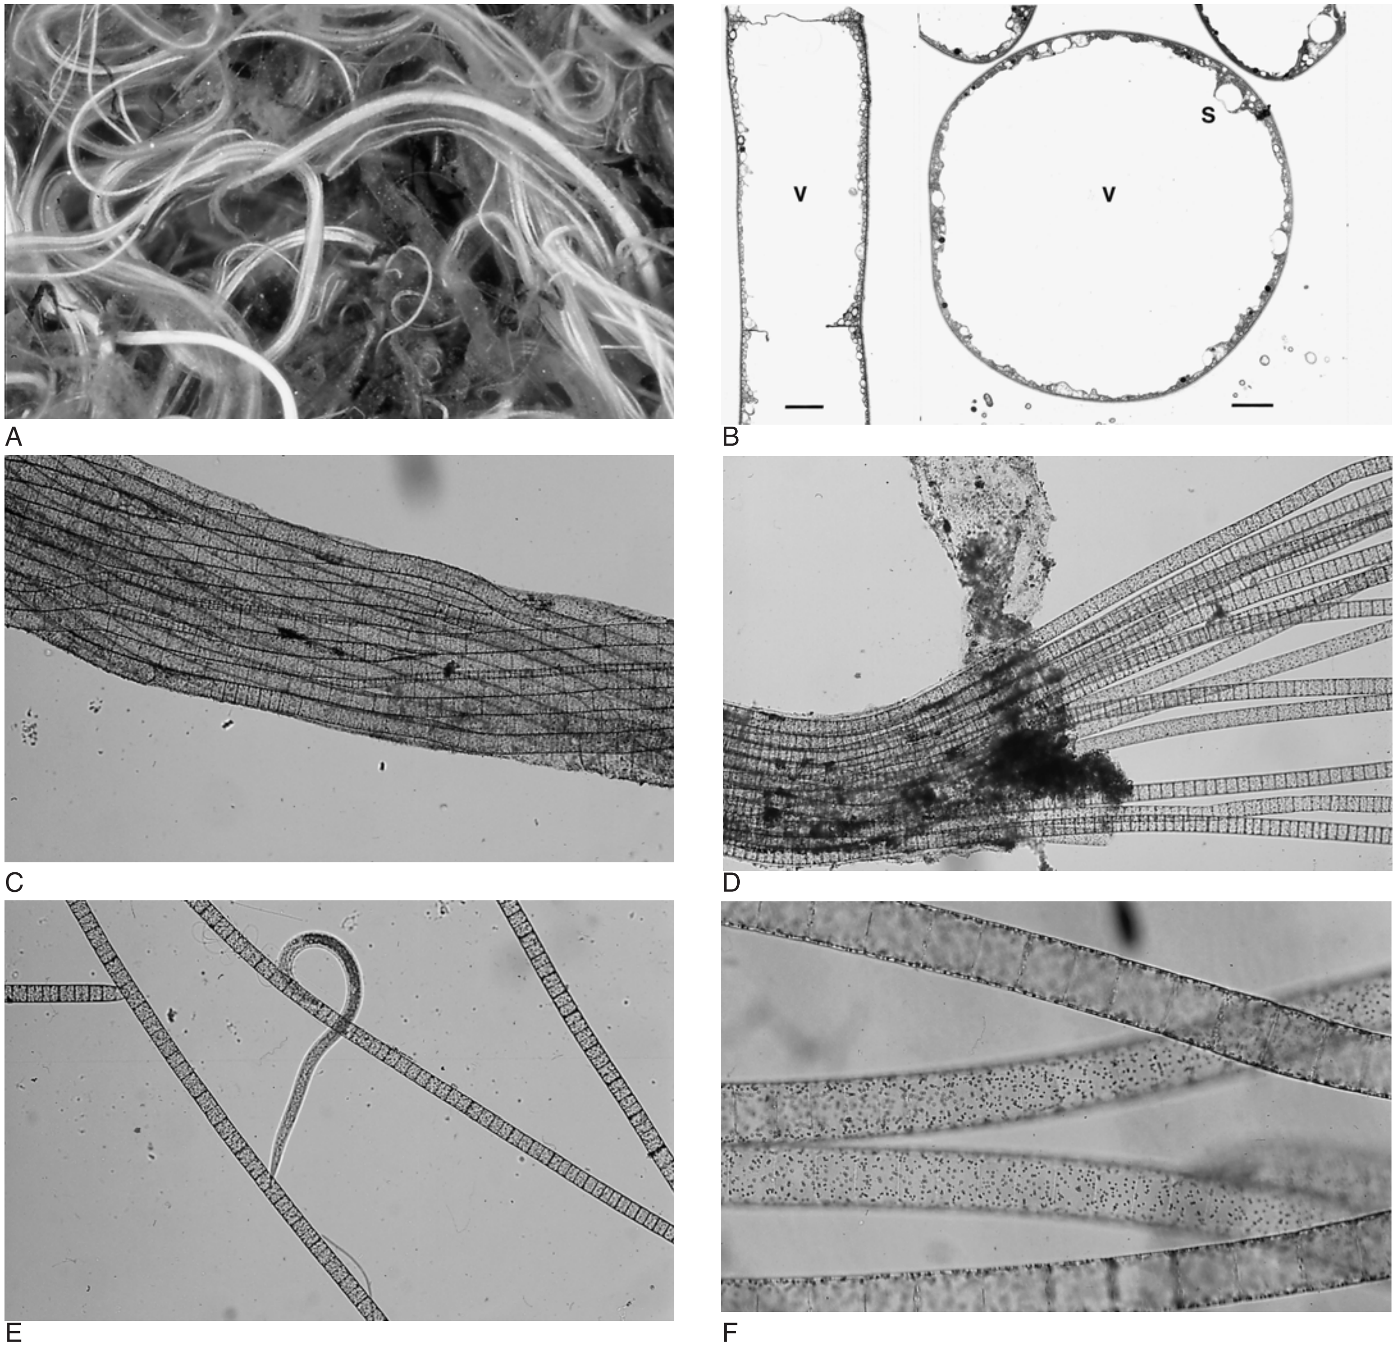

FIGURE BXII.γ.78. Marine thioplocas from the shelf off the coast of central Chile. (*A*) Thiplocas in gelatinous sheaths which were sieved out of the sediment. The frame is 8 mm wide. (*B*) Transmission electron micrographs of *Thioploca chileae* in cross-section (*left*) and longitudinal section (*right*). The cells appear empty due to the large central vacuole. Sulfur globules are stored in the thin peripheral layer of cytoplasm. The filaments are 20 μm in diameter. (*C*) *Thioploca* bundle densely packed in a sheath (not visible). The bundle has the appearance of a braid where the filaments cross over, hence the name *Thioploca,* meaning sulfur braid. (*D*) Bundle of *T. araucae* filaments extending out of their sheath. (*E*) Trichomes of *T. araucae* together with a marine nematode, illustrating the large size of these multicellular prokaryotes. (*F*) Light micrograph of *T. araucae* trichomes showing the dense sulfur globules as fine dots. In the central trichomes, the focus is on the surface, whereas in the outer trichomes, the focus is in the center, thus showing the hollow appearance with sulfur globules only along the periphery. (Part B reproduced with permission from S. Maier et al., Canadian Journal of Microbiology, *36:* 438–448, 1990, ©National Research Council of Canada; *A* courtesy of M. Hüttel; *C–F* courstesy of B.B. Jørgensen.)

raphy (Maier and Gallardo, 1984a). Methylotrophy has also been suggested (Morita et al., 1981), but this theory appears to be incorrect since *Thioploca* cannot assimilate methane or methanol. Furthermore, in the marine habitats of *Thioploca*, methane is produced in insufficient amounts to play a role as a carbon source (Ferdelman et al., 1997).

Ecology *Thioploca* occurs in freshwater, brackish, and marine sediments, mostly under oxygen-depleted water. The organisms seem to prefer low sulfide concentrations, although they are also found in sulfide-rich sediments along the Peruvian coast (Henrichs and Farrington, 1984). Classical localities of the freshwater species are lakes in central and northern Europe (Lauterborn, 1907; Wislouch, 1912; Koppe, 1924; Kolkwitz, 1955), but *Thioploca* is also reported from large lakes in North America, central Russia, and Japan (Maier and Preissner, 1979; Namsaraev et al., 1994; Nishino et al., 1998).

The marine species form dense and extensive communities in areas of coastal upwelling (Jørgensen and Gallardo, 1999). The largest *Thioploca* community is found associated with the Humboldt current on the Pacific continental shelf of South America (Gallardo, 1977). Biomasses here reach 120 g fresh weight/m^2, or up to 1 kg wet weight/m^2 when sheaths are included (Schulz et al., 1996). There is a seasonal variation in the population size, with the highest biomasses occurring during the summer, when the sedimentation of organic matter is highest and the overlying water is strongly depleted in oxygen (Schulz et al., 2000). The population size is strongly depressed during "El Niño," when upwelling is reduced and the overlying water remains oxygenated (V.A. Gallardo and H.N. Schulz, personal communication). Other reported marine habitats include the continental shelf underlying the Benguela current along the South Atlantic coast of Africa (Gallardo et al., 1998; H.N. Schulz, personal communication), the monsoon-driven upwelling area of the northwestern Arabian Sea (Levin et al., 1997), and hydrothermal vent sites in the eastern Mediterranean Sea (Dando and Hooper, 1996).

The upwelling habitats are characterized by very high plankton productivities, high nitrate and low oxygen concentrations in the bottom water, high sedimentation rates of organic matter, and high rates of sulfide production in the sediment (Thamdrup and Canfield, 1996; Ferdelman et al., 1997). The bacteria contribute significantly to the oxidation of sulfide in these sediments and are able to maintain very low H_2S concentrations. The winding sheaths have a mostly vertical position in the muddy sediment and may reach 2–5 cm depth for the freshwater species and 10–15 cm for the large marine species (Schulz et al., 1996; Nishino et al., 1998). The sheaths form vertical tunnels through which the filaments can migrate between the sediment-water interface and the bulk sediment (Fig. BXII.γ.80). The filaments glide with a speed of 1–3 μm/s and may thus move ~10 cm/day. Although they are not the only sulfide oxidizers in the sediment, their ability to transport intracellular nitrate reserves down into the sulfide production zone allows them to compete efficiently with other sulfide-oxidizing bacteria that require overlapping or frequently fluctuating gradients of sulfide and an appropriate electron acceptor (Jørgensen and Revsbech, 1983; Nelson et al., 1986a; Gundersen et al., 1992). Dense populations of *Thioploca* may form loose, gelatinous mats of 1–2 cm thickness at the sediment surface. Inhabited sheaths have been found to be densely covered by filamentous sulfate reducing bacteria of the genus *Desulfonema* (M. Fukui et al., 1999), thereby providing a short diffusion path between the H_2S producers and consumers.

Maintenance Procedures

Although thioplocas have not been isolated in pure culture, they may be maintained in undisturbed sediment in the laboratory for months or even years. Maier (1984) described the following procedures for freshwater *Thioploca*: They may be maintained in jars overlaid with tap water at 8–20°C in the dark. At approximately yearly intervals, a few stems of extracted grass (Scotten and Stokes, 1962) may be stuck into the sediment; *Thioploca* often colonizes these stems. Alternatively, 0.2–0.3 g pulverized extracted hay is autoclaved in 60 ml tap water in 125-ml Erlenmeyer flasks and inoculated with 4–10 ml sediment. After a month of undisturbed incubation at room temperature, *Thioploca* bundles are added and incubation continues for many weeks, with intermittent inspection.

Attempts to enrich marine *Thioploca* have met little success. They may be maintained for months in undisturbed cores sampled from the natural populations and kept near the *in situ* temperature of 13°C in a basin of anoxic seawater with nitrate added (H.N. Schulz, personal communication).

Differentiation of the genus *Thioploca* from other genera

Due to their conspicuous morphology and generally large size, members of the genus *Thioploca* can be easily distinguished from most other genera. However, they show a strong similarity and overlap in characteristics with *Beggiatoa* with respect to morphology, ultrastructure, physiology, ecology, and phylogeny. Tapered filament ends are characteristic of *Thioploca*, but these may also have rounded terminal cells with no tapering. Beggiatoas occasionally have a tapered terminal cell, though tapering is less than that for *Thioploca*. The best criterion of differentiation is the formation of bundles surrounded by a common sheath, which has so far been attributed only to the genus *Thioploca*. Sheath-inhabiting thioplocas tend to have a more vertical orientation in sediments than do beggiatoas, which often form whitish films covering solid–water interfaces. However, the reverse orientation may also be found for both species. When triggered by environmental stress, *Thioploca* filaments often glide partly or completely out of their sheaths, and they may perhaps even establish communities without apparent sheath formation, in which case they would be recognized as *Beggiatoa* (Schulz et al., 1996). *Thioploca* can be clearly differentiated from *Thiothrix* by their gliding movement and by the lack of a terminal holdfast or rosette formation. The closely related *Thiomargarita namibiensis* has separated, nonmotile, spherical cells.

Taxonomic Comments

Future changes in classification of *Thioploca* and *Beggiatoa* are likely. The range of strains over which the genus designation *Beggiatoa* is used is overly broad. More importantly, the differentiation between *Thioploca* and *Beggiatoa* is currently based on the formation of a common sheath surrounding filament bundles, a characteristic that might vary in response to environmental conditions. In the absence of pure cultures, it may be impossible to prove or disprove whether any natural population of vacuolated *Beggiatoa* will form sheath bundles in some specific environment. The clade (Tree 2 of Fig. BXII.γ.79) comprised of three *Thioploca* strains, two *Beggiatoa* strains, and a *Thiomargarita* strain is united by the possession of a large central vacuole. This feature currently appears to be the best morphological candidate to replace sheath formation as a marker in a revised taxonomy of the group *Beggiatoa*–*Thioploca*. This marker, in addition to being consistent with 16S rRNA phylogeny, appears to be universally connected to intracellular nitrate accumulation, presumably in the vacuole, for nitrate respiration enabling sustained anaerobic metabolism. This generalization regarding metabolic capacity remains to be confirmed for *T. ingrica*. A future revision of the

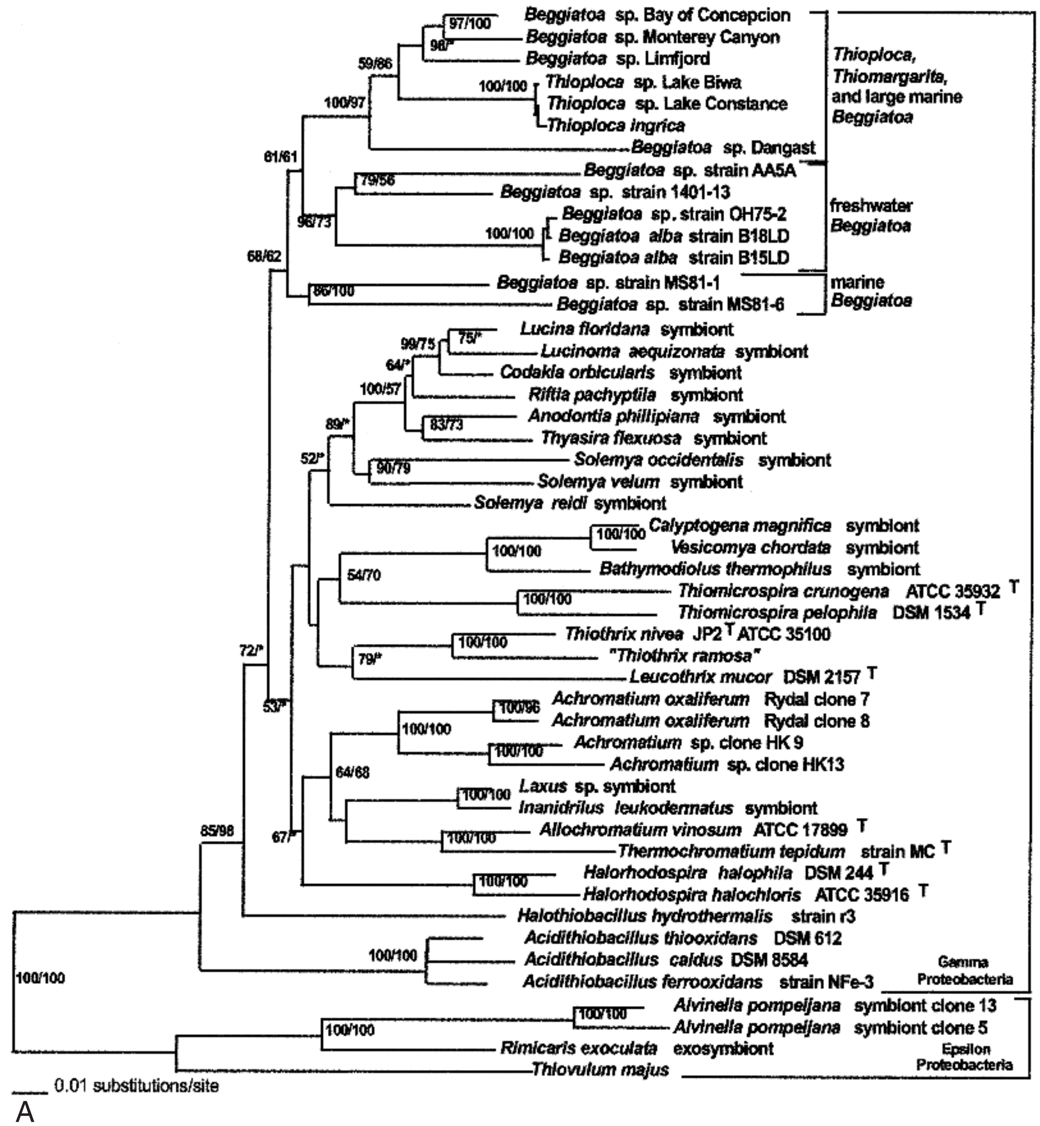

FIGURE BXII.γ.79. Phylogenetic relationships of *Thioploca*, *Beggiatoa*, and *Thiomargarita*, and representative sulfur-oxidizing bacteria of the *Gammaproteobacteria*. The trees are based on nearly complete 16S rDNA sequences (*E. coli* positions 28–1487), (*A*) and on partial sequences (*E. coli* positions 341–941), including those of marine *Thioploca* species and *Thiomargarita namibiensis*, for which only partial sequences are available. (*B*) The trees were routed

genus *Thioploca*, based on the vacuolated, nitrate-respiring phenotype and corresponding 16S rRNA clade, might include these gliding filaments regardless of whether they occur in sheathed bundles. For now, further investigations of natural populations of vacuolated *Beggiatoa* and *Thioploca*, as well as *Thiomargarita*, are required to check the consistency of this concept.

List of species of the genus Thioploca

1. **Thioploca schmidlei** Lauterborn 1907, 242[AL]
schmid' le.i. M.L. gen. n. *schmidlei* of Schmidle.

Identified from sediments of fresh and brackish water localities in Europe and from Lake Baikal, Russia. Originally found in Lake Constance, southern Germany.

The mol% G + C of the DNA is: not available.
Type strain: none isolated.

2. **Thioploca araucae** Maier and Gallardo 1984b, 417[VP]
a.rau' cae. M.L. gen. n. *araucae* of Arauco in Central Chile.

Identified from oxygen-poor upwelling areas of the

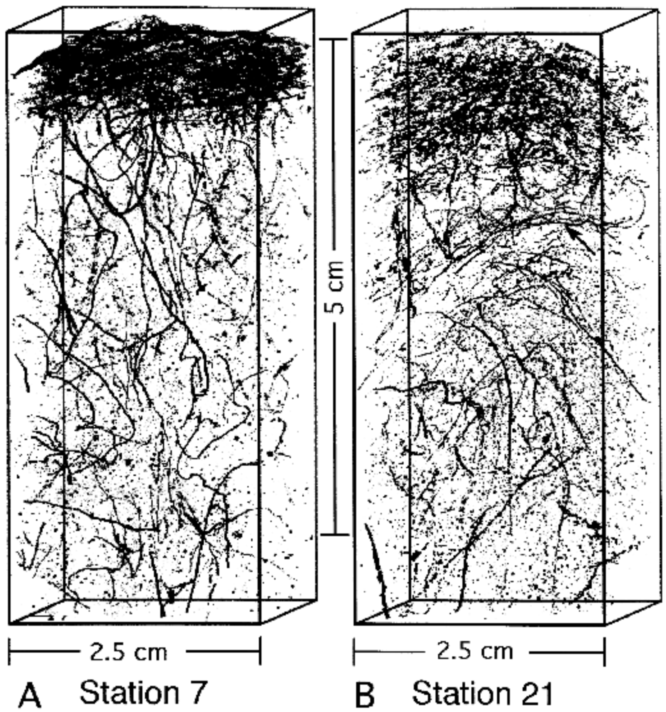

FIGURE BXII.γ.80. Three-dimensional reconstruction of marine *Thioploca* sheaths (black lines) in blocks of sediment from the Chilean coast at 40 m (*A*) and 100 m (*B*) water depth. The sediment blocks of 5 × 2.5 × 1 cm were rapidly frozen, cut vertically at 100 μm increments with a cryomicrotome, and photographed in polarized light. The 3-D image was developed from 100 sequential photographs. At the sediment surface, a grayish color shows a dense mat of more horizontally oriented sheaths, plus many free filaments of either *Beggiatoa* or *Thioploca* outside their sheaths. Below the mat, dark strands of *Thioploca* sheaths extend down through the sediment with a mostly vertical orientation. (Reproduced with permission from H.N. Schulz et al., Applied and Environmental Microbiology, *62:* 1855–1862, 1996, ©American Society for Microbiology.)

ocean, e.g., the Pacific continental shelf of South America, the Atlantic coast of southern Africa, and the northwest Arabian Sea.

The mol% G + C of the DNA is: not available.

Type strain: none isolated.

3. **Thioploca chileae** Maier and Gallardo 1984b, 417[VP]
chi' le' ae. M.L. gen. n. *chileae* of Chile.

Identified from oxygen-poor upwelling areas of the ocean, e.g., the Pacific continental shelf of South America, the Atlantic coast of southern Africa, and the northwest Arabian Sea.

The mol% G + C of the DNA is: not available.

Type strain: none isolated.

4. **Thioploca ingrica** Maier 1984, 344[VP]
in' gri.ca. M.L. adj. *ingrica* pertaining to Ingria, ancient district of Leningrad, Russia.

Identified from sediments of fresh and brackish water localities in central Europe and from Lake Erie, USA, and Lake Biwa, Japan.

The mol% G + C of the DNA is: not available.

Type strain: none isolated.

GenBank accession number (16S rRNA): L40998.

Other Organisms

1. *"Thioploca marina"*
ma.ri' na. L. adj. *marina* of marine.
Identified from oxygen-poor upwelling areas of the ocean, e.g., the Pacific continental shelf of South America (Maier and Gallardo, unpublished data).

2. *"Thioploca minima"* Koppe 1924, 630.
Identified from sediments of freshwater localities in Central Europe and Lake Erie.

Genus VIII. **Thiospira** *Visloukh 1914, 48*[AL]

J. Gijs Kuenen and Galina A. Dubinina

Thi'o.spi' ra. Gr. n. *thios* sulfur; Gr. n. *spira* a coil; M.L. fem. *Thiospira* sulfur coil or spiral.

Spirilla, usually with pointed ends, containing **sulfur inclusions**. **Motile** by monotrichous or polytrichous **polar flagella**. No resting stages known. Isolates conforming to the descriptions of the two "species" have now been obtained (Dubinina et al., 1993).

Type species: **Thiospira winogradskyi** (Omelianski 1905) Visloukh 1914, 48.

Further descriptive information

Cells are colorless spirilla, pointed at the ends and containing sulfur globules. Polar flagella, in some cases united in a tuft, are visible in the light microscope. *Thiospira winogradskyi* is 2–2.5 μm wide and up to 50 μm long. *"Thiospira bipunctata"* is 1.7–2.4 × 6.6–14 μm.

Thiospira spp. are microaerophilic and vigorously chemotactic with respect to oxygen and possibly H_2S.

They are found in sulfurous marine and freshwater environments, including wastewater treatment systems.

The validity of the genus *Thiospira* has, in recent years, been called into question. The primary diagnostic feature of the genus was the accumulation of sulfur within spiral cells, and the separation of the two species was primarily morphological. Now that some strains have been grown in axenic cultures, it seems likely

that members of the genus should actually be included within the genus *Aquaspirillum*, especially since *Aquaspirillum* species have been shown to accumulate sulfur in their cells (Dubinina et al., 1993). However, because the taxonomic position of the genus *Aquaspirillum* is itself under investigation (see, for example, Willems et al., 1991c; Pot et al., 1992), the genus *Thiospira* has not yet been formally removed, and because many authors still report observations of *Thiospira* species (e.g., Bernard and Fenchel, 1995), the description of the genus *Thiospira* will be maintained until the situation is clarified. What follows is adapted from the chapter by la Riviére and Kuenen in the last edition of *Bergey's Manual*.

Enrichment and Isolation Procedures

T. winogradskyi was enriched by Omelianski (1905) in Winogradsky columns kept for some months at room temperature in the dark. The cell mass was in the form of "bacterial plates", i.e., discrete dense layers of bacteria, and could be kept alive in the laboratory for 2 years. Molisch (1912) enriched *"T. bipunctata"* from Black Sea mud which, when mixed with decaying algae, was used as an H_2S-generating sediment in a seawater-filled cylinder 20–30 cm high.

Recent successful isolations (Dubinina et al., 1993) have been made from H_2S or thiosulfate-rich samples on a medium containing (g/l): $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.0; casein hydrolysate, 3.0; sodium succinate, 1.0; vitamins and trace elements (Pfennig and Lippert, 1966). The pH is 7.0, and the necessary redox gradient is generated by adding a FeS suspension, which also serves as a source of sulfide.

Taxonomic Comments

Although one of the species (*"T. bipunctata"*) does not appear on the Approved Lists, it is retained in the present description of the genus in view of its marked differences from the type species. It should be recalled that Bavendamm (1924) recognized five species.

Dubinina and Grabovich (1983) have described the isolation of heterotrophic spirilla morphologically similar to *Thiospira* and capable of forming internal sulfur granules in sulfide-containing media. Experiments indicate that the sulfur is formed through oxidation of sulfide by hydrogen peroxide.

Since other heterotrophs capable of forming sulfur inclusions in sulfide-containing media have also been found (Skerman et al., 1957), there is a distinct possibility that, on further examination, the spirilla isolated by Dubinina and Grabovich may turn out to be classifiable within the existing species of the genus *Spirillum* or, as now seems likely, *Aquaspirillum* (see above).

In spite of its present uncertain taxonomic position, the importance of the genus may prove to be considerable when further studies have been made of the population of sulfide oxidizers encountered at the deep-sea bottom around H_2S-emitting hydrothermal vents (Jannasch, 1984).

List of species of the genus Thiospira

1. **Thiospira winogradskyi** (Omelianski 1905) Visloukh 1914, 48[VP]

wi.no.grad'sky.i. M.L. gen. n. *winogradskyi* of Winogradsky; named for S.N. Winogradsky, a Russian microbiologist.

Found in freshwater and marine environments overlaying sulfurous muds. See Table BXII.γ.42 for differentiation of *T. winogradskyi* and *"T. bipunctata"*.

The mol% G + C of the DNA is: 38 (T_m).

Type strain: No culture available.

2. **"Thiospira bipunctata"** (Molisch 1912) Visloukh 1914, 48.

bi.punc.ta'ta. L. *bis* twice; L. part. adj. *pinctatus* punctate, dotted; M.L. fem. adj. *bipunctata* twice punctate.

Found in sulfurous marine and brackish waters (see Table BXII.γ.42).

TABLE BXII.γ.42. Differentiation of the species of the genus *Thiospira*

Characteristic	*T. winogradskyi*	*"T. bipunctata"*
Size	2–2.5 × up to 50 μm	1.7–2.4 × 6.6–14 μm
Number of sulfur inclusions	Numerous	Few
Volutin granules at both ends	−	+

Family II. **Piscirickettsiaceae** *fam. nov.*

John L. Fryer and Catharine N. Lannan

Pis' ci.ric.kett.si.a' ce.ae. M.L. fem. n. *Piscirickettsia* type genus of the family; *-aceae* ending to denote family, M.L. fem. pl. n. *Piscirickettsiaceae* the *Piscirickettsia* family.

Gram-negative, aerobic, coccoid, rod- or spiral-shaped bacteria, occasionally pleomorphic. Isolated predominantly from the marine environment. All belong to the *Gammaproteobacteria* with 16S rRNA similarities as the major unifying factor.

Type genus: **Piscirickettsia** Fryer, Lannan, Giovannoni and Wood 1992, 123.

Further Comments *"Piscirickettsiaceae"* includes six genera, *Piscirickettsia*, *Cycloclasticus*, *Hydrogenovibrio*, *Methylophaga*, *Thioalkalimicrobium*, and *Thiomicrospira*. These groups are related phylogenetically, but share a limited number of phenotypic characters. *Piscirickettsia* is a Gram-negative, nonmotile, highly fastidious, intracellular rickettsia-like pathogen of fish. The bacterium replicates within membrane-bound cytoplasmic vacuoles in cells of infected hosts and does not grow on any known artificial medium. *Piscirickettsia* contains a single species that is known to cause serious mortality among salmonids and other species of fish in the marine environment.

The remaining five genera are composed of rod-, comma-, or spiral-shaped bacteria. They are all motile by means of a single polar flagellum. All can be cultured on artificial media. None is pathogenic or replicates within the cells of hosts. Optimum temperatures are higher than those of *Piscirickettsia* and all were isolated from aquatic environments. *Cycloclasticus* utilizes aromatic hydrocarbons as the sole source of organic carbon; *Methylophaga* utilizes C_1 compounds; and *Hydrogenovibrio* and *Thiomicrospira* both use CO_2. Members of the genus *Thiomicrospira* are obligately autotrophic, sulfur bacteria and have been isolated from marine hydrothermal vents and mud flats. The genus *Thioalkalimicrobium* contains chemolithoautotrophs that are isolated from alkaline lakes and that oxidize sulfide and thiosulfate to sulfate.

Genus I. **Piscirickettsia** *Fryer, Lannan, Giovannoni and Wood 1992, 123*[VP]

John L. Fryer and Catharine N. Lannan

Pis' ci.ric.kett' si.a. L. n. *piscis* fish; generic name *Rickettsia*; N.L. fem. n. *Piscirickettsia* rickettsia-like organism affecting fish.

Pleomorphic, but predominantly coccoid organisms, ~0.5–1.5 µm in diameter. Gram negative, Gimenez negative, and stain dark blue with Giemsa's stain. Nonmotile. Aerobic. Characteristically replicate within cytoplasmic vacuoles in susceptible fish host cells. Cultivable in fish cell cultures but not on any known host-cell-free medium. Direct host-to-host transmission occurs in the aquatic environment without the requirement of a vector. The 16S rRNA gene sequence conforms to the secondary structural models for the *Gammaproteobacteria*. No signature sequence has been identified. **The etiological agent of the disease piscirickettsiosis in fishes.**

Type species: **Piscirickettsia salmonis** Fryer, Lannan, Giovannoni and Wood 1992, 123.

Further descriptive information

At present, *Piscirickettsia salmonis* is the only described species of the genus *Piscirickettsia*. This organism has a widespread geographic distribution, and causes disease in numerous salmonid host species (Table BXII.γ.43). *Piscirickettsia salmonis*-like bacteria have also been isolated from diseased sea bass, *Atractosion nobilis*, in California, USA (Chen et al., 2000a); and in Taiwan, from grouper, *Epinephelus melanostigma* (Chen et al., 2000b), and five species of cultured tilapia (Chern and Chao, 1994).

By electron microscopy, the organisms display the typical protoplasmic structure of a procaryote and the cell wall of a Gram-negative bacterium (Fig. BXII.γ.81). Although primarily coccoid, the organisms also appear as pairs of curved rods or rings (Fig. BXII.γ.82). They replicate by binary fission within membrane-bound cytoplasmic vacuoles in cells of susceptible fish hosts or fish cell lines (Fig. BXII.γ.83) where they produce a cytopathic effect (Fig. BXII.γ.84). *In vitro* replication is optimal at 15–18°C, retarded above 20°C and below 10°C, and does not occur above 25°C (Fryer et al., 1990).

Little genetic variation has been observed in *P. salmonis* isolated from differing salmonid host species or originating from diverse geographic locations. 16S rDNA sequence data are available for five *P. salmonis* isolates representing three salmonid host species and three widely separated geographic regions (North America, South America, and Europe; Fryer and Mauel, 1997). With 1527 bases compared, the five isolates form a tight monophyletic cluster. Four of the isolates show sequence similarities >99.4%. One of the five is less closely related with similarities ranging from 98.5–98.9% (Mauel et al., 1999). The genetic differences between this isolate and others in the study do not correlate with either host species or geographic region as these characters are shared among them.

monis recognizes four surface-exposed protein antigens with relative molecular sizes of 65, 60, 54, and 51 kDa and two low molecular weight carbohydrate antigens, the lipopolysaccharide and a component lipo-oligosaccharide with relative molecular weights of 16 kDa and ~11 kDa, respectively (Kuzyk et al., 1996). Nevertheless, the humoral response elicited by *P. salmonis* infection in fish is apparently low. In the study by Kuzyk et al. (1996) convalescent serum from infected salmonid fish reacted with several minor immunoreactive protein antigens between 10 and 70 kDa in size as well as with a carbohydrate antigen with a relative molecular weight of ~11 kDa, but the antigens recognized by the convalescent salmonid fish serum differed greatly from those

identified by rabbit antiserum, suggesting a modest humoral response in the fish.

Piscirickettsia salmonis replication is inhibited *in vitro* by numerous antibiotics normally used in cell culture or in human and veterinary medicine. These include gentamicin, streptomycin, erythromycin, rifampin, tetracycline, doxycycline, oxolinic acid, and chloramphenicol (Fryer et al., 1992). Penicillin appears to have little effect. In spite of the broad antibiotic sensitivity of this organism, *in vivo* antibiotic therapy has had limited success. Intracellular concentrations of these preparations may not reach lethal levels *in vivo*, permitting replication to continue within host cells despite therapy.

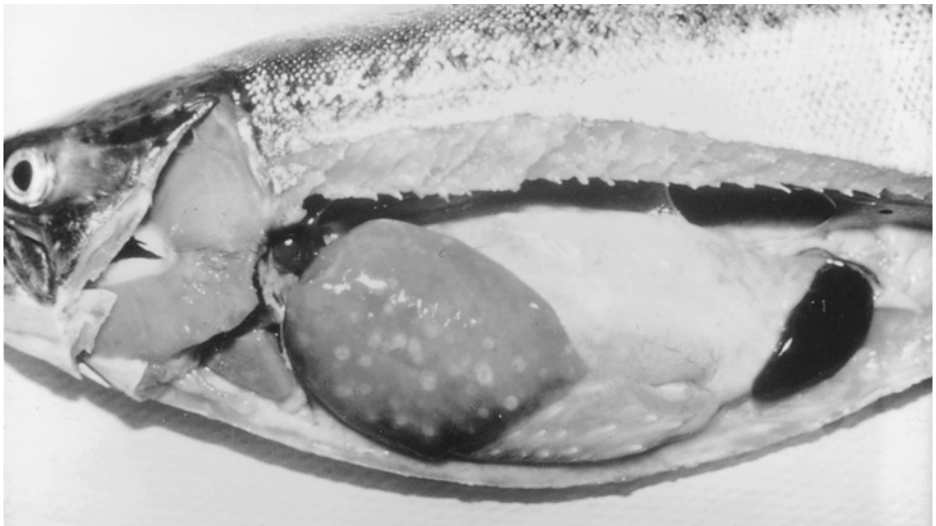

FIGURE BXII.γ.85. *Oncorhynchus kisutch* infected with *Piscirickettsia salmonis*. Note the diagnostic, ring-shaped lesions on the liver. (Reprinted with permission from J.L. Fryer and M.J. Mauel, Emerging Infectious Diseases *3:* 137–144, 1997, ©Centers for Disease Control and Prevention, Atlanta, Georgia, USA.)

Piscirickettsial infection results in a systemic, epizootic fish disease, piscirickettsiosis, which can occur in chronic or acute form. Mortality may range from low to extremely high (≥90% of a naturally exposed population.) Marked difference in virulence has been reported among three isolates of *P. salmonis* each obtained from a different geographic location (House et al., 1999). Frequently, skin hemorrhages and lesions ranging from small areas of raised scales to shallow ulcers up to 2 cm in diameter are the first disease signs to appear (Branson and Diaz-Munoz, 1991). Pathological changes that include necrosis and inflammation, frequently found adjacent to blood vessels, may be observed in most internal organs of infected fish, especially in kidney, liver, spleen, and intestine (Cvitanich et al., 1991). At times, epithelial hyperplasia results in lamellar fusion of the gills. Organisms are found within macrophages and in the cytoplasm of other host cells. Diagnostic, ring-shaped, cream-colored lesions are present on the livers of chronically infected fish (Fig. BXII.γ.85), but in acute cases, mortality may be the only gross sign of disease observed.

The means of transmission of *P. salmonis* in natural infections is by direct fish-to-fish passage and occurs without the need of a vector. The reservoir for the pathogen has not been determined but may include one or more species of fish or other aquatic animals. Almendras et al. (1997) demonstrated direct horizontal transmission of *P. salmonis* under experimental conditions in both fresh and salt water. Vertical transmission from parent to offspring may also occur. The organisms can be found in the gonad of infected fish, and Larenas et al. (1996) reported *P. salmonis* organisms in the fertilized ova from experimentally infected parents. Despite this, piscirickettsiosis is less frequently observed in anadromous salmonids during the freshwater stage of their life cycle than after entry into the marine environment, suggesting that vertical transmission may be an uncommon occurrence.

Enrichment and Isolation Procedures

Piscirickettsia salmonis can be isolated from the internal organs of infected fish by inoculation of homogenized tissues onto cell cultures derived from susceptible fish hosts. The cultures are incubated at 15–18°C for up to 28 d and microscopically observed for development of the characteristic cytopathic effect. However, isolation of these agents from clinical specimens presents a considerable challenge. Aseptic collection of diagnostic specimens in the field is difficult, enhancing the likelihood of adventitious bacterial contamination of the inoculum. In spite of this, the broad antibiotic sensitivity of *P. salmonis* dictates that the cultures be maintained in antibiotic-free medium. For this reason, preliminary diagnosis of piscirickettsiosis is normally made by examination of Gram stain, Giemsa stain, methylene blue, or acridine orange-stained kidney imprints or smears, with confirmation of identity provided by serological methods, e.g., immunofluorescence (Lannan et al., 1991) or immunohistochemistry (Alday-Sanz et al., 1994).

Maintenance Procedures

Piscirickettsia salmonis can be subcultured with the inoculation of spent growth medium from infected cultures onto fresh fish cell cultures in antibiotic-free medium. Infectious organisms can be recovered from spent culture medium stored for up to 3 weeks at 5°C (Lannan and Fryer, 1994). Long-term survival in culture medium requires the addition of 10% DMSO as a cryopreservative followed by storage at −70°C or in liquid nitrogen.

Differentiation of the genus *Piscirickettsia* from other genera

Piscirickettsia salmonis might be confused with *Neorickettsia helminthoeca*, the coccoid, Gram-negative, intracellular bacterium that is the etiologic agent of salmon-poisoning disease in canids. Although *N. helminthoeca* is not a parasite of salmonid fishes, salmonids are one host in the complex life cycle of *Nanophyetus salmincola*, the trematode vector of *N. helminthoeca*. Unlike *P. salmonis*, geographic distribution of *N. helminthoeca* is restricted to a portion of the Pacific coast of the United States. The differential characteristics of these two genera are listed in Table BXII.γ.44.

Taxonomic Comments

The genus *Piscirickettsia* currently contains one species. Additional microorganisms assigned to this genus must be intracel-

TABLE BXII.γ.44. Differential characteristics of *Piscirickettsia salmonis* and *Neorickettsia helminthoeca*

Characteristic	*P. salmonis*	*N. helminthoeca*
Replicates within fish cells	+	−
Replicates at 37°C	−	+
Widespread geographic distribution	+	−
Pathogenic for *Canidae*	−	+
Reacts with convalescent serum from canine salmon poisoning disease	−	+
Alphaproteobacteria	−	+
Gammaproteobacteria	+	−

lular, Gram-negative, procaryotic parasites of fishes and perhaps other aquatic animals. These bacteria must be specifically related to *P. salmonis*. Members of the species *P. salmonis* are those recognized by specific antiserum against the type strain, LF-89.

Based on the intracellular location of *P. salmonis* and phenotypic similarities between this organism and the genus *Ehrlichia*, it was originally proposed that *Piscirickettsia* should be placed with *Ehrlichia* in the family *Rickettsiaceae* (Fryer et al., 1992). However, microorganisms historically included in the *Rickettsiaceae* appear to be polyphyletic (Weisburg et al., 1989). The majority fall in the *Alphaproteobacteria*, but certain of these intracellular bacteria, including *P. salmonis*, *Rickettsiella grylli* (Roux et al., 1997), *Coxiella burnetii*, and the bacterium designated *Wolbachia persica* (Weisburg et al., 1989), belong to the *Gammaproteobacteria*. Therefore, these organisms are phylogenetically remote from others in the family. *Piscirickettsia* appears to group with the genera *Cycloclasticus*, *Hydrogenovibrio*, *Methylophaga*, and *Thiomicrospira*, and is somewhat more distantly related to the *Legionella*, *Francisella*, and *Coxiella*. *Piscirickettsia* is now assigned to a new family, the *"Piscirickettsiaceae"*.

Gram-negative obligate intracellular bacteria were not recognized as pathogens of fish before 1989, when *P. salmonis* was isolated from diseased salmonid fish in Chile (Fryer et al., 1990). Since that time, bacteria of this type have been observed or isolated from other species of salmonid and nonsalmonid fish at numerous locations (Brocklebank et al., 1992; Rodger and Drinan, 1993; Chern and Chao, 1994; Olsen et al., 1997; Chen et al., 2000a, b). Many of the isolates from salmonid fish have been serologically identified as *P. salmonis*, but the taxonomic placement of those found in other fishes has not been determined. Whether these organisms can be classified as *P. salmonis*, or as additional species in the genus *Piscirickettsia*, or whether they more properly belong to other genera as yet undescribed remains unresolved.

Acknowledgments

We thank Sandra Bravo of Puerto Montt, Chile, who first reported the disease that was later identified as piscirickettsiosis, and L. H. Garcés, J. J. Larenas, and P. A. Smith of the Veterinary Sciences Faculty of the University of Chile, Santiago, all of whom have provided specimens, counsel, and technical help in the identification and characterization of *P. salmonis*. In addition, we thank Ena Urbach of the Department of Microbiology, Oregon State University, for aid in the phylogenetic description of this organism. This is Oregon Agricultural Experiment Station technical paper no. 11325.

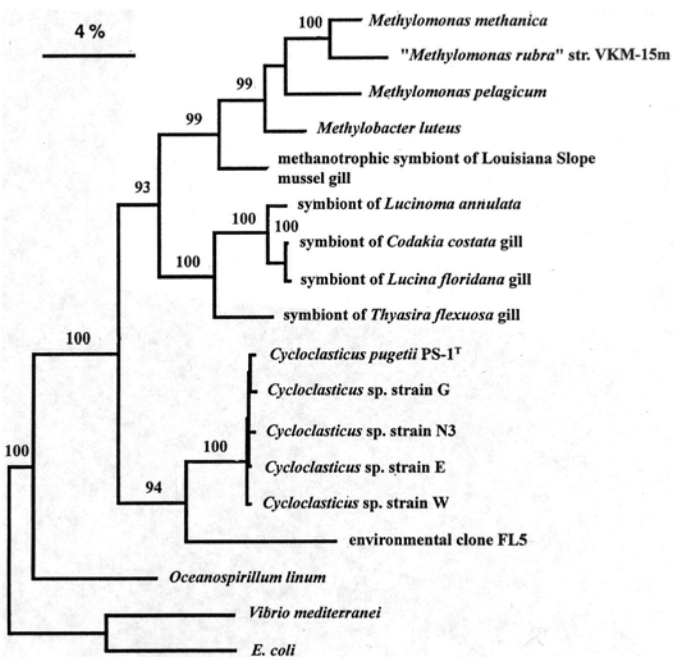

FIGURE BXII.γ.86. Phylogenetic relationships based on 16S rDNA sequences of *Cycloclasticus* and closely related species found in the Ribosomal Database Project, release 6.0 (Maidak et al., 1999). Environmental clone FL5 is an rDNA clone amplified from free-living bacteria in the marine water column (DeLong et al., 1993). This tree was the most parsimonious tree generated with PAUP, version 3.0s (Swofford, 1993). Heuristic unweighted bootstrap values are shown near the clades; only values greater than 50% are shown. Bar = ~0.04 change per nucleotide position.

Further descriptive information

The genus *Cycloclasticus* comprises a collection of marine strains with one validly named species. Phylogenetically, the closest relatives of these organisms are members of the methane-oxidizing genera *Methylomonas* and *Methylobacter*, a group of uncultured sulfur-oxidizing symbionts found in marine invertebrates, and a 16S rRNA environmental clone designated FL5. However, the mol% G + C DNA base composition of *Cycloclasticus* and *Methylomonas methanica* differ substantially (37 and 52, respectively), and *Cycloclasticus* cannot utilize methane or other C_1 compounds as carbon sources. In addition, *Cycloclasticus* does not utilize thiosulfate as an energy source. Furthermore, existing strains are not phylogenetically closely related to other marine genera of aerobic, heterotrophic, motile, rod-shaped bacteria belonging to the *Gammaproteobacteria* (see Table BXII.γ.45 and Fig. BXII.γ.86) (Dyksterhouse et al., 1995).

TABLE BXII.γ.46. Predominant whole-cell fatty acids and percent composition of *Cycloclasticus* strains[a]

Fatty acid	% total fatty acids in:	
	C. pugetii PS-1[b]	*Cycloclasticus* sp. N3[c]
Unknown[d]	6	6
$C_{12:0}$	2.5	3
$C_{12:0\ 3OH}$	2.8	3
$C_{16:0\ iso}$	nd[e]	3
$C_{16:1\ \omega7c}$	61.5	53
$C_{16:0}$	23	21
Total identified	95.7	89

[a]Only fatty acids representing 2.5% or more of the total fatty acid composition of each strain are listed. Cellular fatty acids were extracted, methylated, and detected with a Hewlett Packard model 5890 series II gas chromatograph as previously described (MIDI Inc., 1993).

[b]Data from Dyksterhouse et al. (1995). Strains were grown in liquid culture on 50 ml of Bacto Marine 2216 broth containing biphenyl crystals for 3 d with agitation, centrifuged, washed twice with ONR7a. 40 mg (wet weight) of the cell pellet was used for the analysis.

[c]Data from Geiselbrecht et al. (1998). Strains were grown on ONR7a plus Casamino acids (Difco) and salicylate (0.01% each) plates for 2 weeks at 20°C. Cells were harvested by scraping the entire plate surface.

[d]Unidentified peak at an equivalent carbon length of 11:798.

[e]nd, not detected.

Transmission electron microscopy of whole cells shows a single polar flagellum with several fimbriae originating from the cell surface and a cell envelope structure typical of Gram-negative bacteria, with a cell size of 0.5 × 1.0–2.0 μm. Colonies are small, smooth, round, and raised, with slow growth on solid media, and in some cases requiring up to 2 weeks for visible colony formation. Cultures have been shown to grow at temperatures ranging from 4–28°C, in the presence of salinity ranging from 1–7% (Dyksterhouse et al., 1995).

Whole cell fatty acid analyses show similar compositions between strains (Table BXII.γ.46). The predominant fatty acids in these and two additional strains tested were similar; $C_{16:1\ \omega7c}$ was the most prevalent fatty acid.

A characteristic of this genus is an apparent preference for aromatic compounds as carbon sources. Carbon source utilization studies indicate that only a few additional carbon sources, including selected fatty acids and amino acids, can be used as sole carbon sources (Table BXII.γ.47). The concentrations of the carbon sources are crucial in determining carbon source utilization: strains responded differently to 0.01% and 0.1% w/v amounts of carbon source (Geiselbrecht, 1998).

Polyaromatic hydrocarbon (PAH) degradation studies performed with *Cycloclasticus* strains indicate similar, broad PAH-substrate ranges including naphthalene, substituted naphthalenes, phenanthrene, fluorene, biphenyl, and acenaphthene (Table BXII.γ.48) (Geiselbrecht et al., 1998). *"Cycloclasticus oligotrophus"* RB1 is capable of using a variety of aromatic compounds, such as toluene and *o*-, *m*-, and *p*-xylenes, as sole carbon sources (Wang et al., 1996).

Wang et al. (1996) cloned and sequenced a 5.7-kb DNA fragment from *"C. oligotrophus"* RB1. This DNA region contains genes that encode proteins somewhat homologous to the large-subunit (XcylC1) and small-subunit (XylC2) biphenyl dioxygenase of ter-

[c]PAH was only partially removed.

restrial bacteria, although these sequences are quite divergent from the sequences of known dioxygenases. By utilizing degenerate PCR primers, partial ISP sequences were obtained from *C. pugetii* and *Cycloclasticus* strain W that indicated the presence of *bph*-type dioxygenase ISP sequences similar to the region cloned in *"C. oligotrophus"* RB1, as well as a sequence corresponding to an additional PAH dioxygenase type more closely related to naphthalene type dioxygenases (Geiselbrecht et al., 1998). Although this study did not examine the functionality of these sequences, these data may indicate that *Cycloclasticus* contains multiple dioxygenases.

16S rDNA sequence analysis performed on three strains of *Cycloclasticus pugetii* revealed that 16S rDNA sequences from strain PS-1[T], -2, and -3 are nearly identical. Furthermore, *Cycloclasticus* sp. N3 contains only 3 base pair differences from *C. pugetii*[T] (Geiselbrecht et al., 1996). *"C. oligotrophus"* RB1 is also phylogenetically very closely related to *C. pugetii* [T]. All of these isolates share a distinctive 16S rDNA sequence at approximately base pair position 825, relative to *E. coli* (Gutell, 1993) of 5′-CUAACUG-UUGGGCGGGUUUCCGC-3′. No DNA–DNA reassociation data exist for strains of the genus.

Cycloclasticus strains have been isolated from coastal marine sediments and waters in Puget Sound, the Gulf of Mexico, and Resurrection Bay, Alaska (Button et al., 1993, 1998; Dyksterhouse et al., 1995; Geiselbrecht et al., 1996, 1998). In Puget Sound, *Cycloclasticus* is widespread in both contaminated and uncontaminated sediments (Geiselbrecht et al., 1996). Furthermore, they occur in the Puget Sound water column (Geiselbrecht, 1998). *"C. oligotrophus"* RB1 was isolated from the water column in Resurrection Bay, Alaska, following a 10^8 dilution, indicating that they can potentially be numerous in the marine water column (Button et al., 1993). In the Gulf of Mexico, they have been isolated from offshore and near-shore sites at sediment dilution numbers ranging from 2×10^3 to 2×10^5, indicating that they are somewhat numerous in these sediments (Geiselbrecht et al., 1998).

Enrichment and Isolation Procedures

An artificial seawater mineral salts medium called ONR7a has been used for most *Cycloclasticus* isolations. This medium contains all of the major cations and anions that are present in concentrations greater than 1 mg/l in seawater. ONR7a contains (per liter of distilled or deionized water): NaCl, 22.79 g; $MgCl_2 \cdot 6H_2O$, 11.18 g; Na_2SO_4, 3.98 g; $CaCl_2 \cdot 2H_2O$, 1.46 g; TAPSO (3-[N-tris(hydroxymethyl)methylamino]-2-hydroxypropanesulfonic acid), 1.3 g; KCl, 0.72; NH_4Cl, 0.27 g; $Na_2HPO_4 \cdot 7H_2O$, 89 mg; NaBr, 83 mg; $NaHCO_3$, 31 mg; H_3BO_3, 27 mg; $SrCl_2 \cdot 6H_2O$, 24 mg; NaF, 2.6 mg; $FeCl_2 \cdot 4H_2O$, 2.0 mg. To prevent precipitation of ONR7a during autoclaving, three separate solutions are prepared and then mixed together after autoclaving when the solutions are cooled to at least 50°C: one solution contains NaCl, Na_2SO_4, KCl, NaBr, Na_2HPO_4, H_3BO_3, NaF, NH_4Cl, Na_2HPO_4, and TAPSO (pH adjusted to 7.6 with NaOH, then autoclaved); the second solution contains $MgCl_2$, $CaCl_2$, and $SrCl_2$ (divalent

cation salts made as a 50× stock and autoclaved); and the third solution contains $FeCl_2$ (made as a 200× stock and then preferably filter-sterilized). For solid media, Bacto Agar (Difco) or agarose (Sigma) is used as a solidifying agent. ONR8a contains all the compounds listed above for the ONR7a plus 10 ml/l of a vitamin solution (Staley, 1968) and 10 ml/l of a trace element solution (Dyksterhouse et al., 1995). The type strain of the genus *Cycloclasticus*, *C. pugetii*, was isolated by blending Puget Sound sediments, diluting these sediments 1:5, and spreading the dilution onto ONR8a containing 0.2 g of biphenyl on the Petri dish lid. Colonies surrounded by a diffusible yellow zone indicative of PAH degradation were selected for further isolation (Dyksterhouse et al., 1995). The vitamin and trace element solutions were later found to be unnecessary for growth, and were eliminated.

Cycloclasticus has also been isolated following enrichment in dilute most probable number (MPN) tubes specific for PAH-degrading marine bacteria. Surficial (aerobic) 1-cm portions of sediments were used as the inocula for these MPN preparations. Briefly, this technique involved serially diluting wet sediments with ONR7a containing PAHs as sole carbon sources. Tubes were scored positive or negative based on PAH degradation. After incubation for approximately 5 months at 15°C, the most dilute tubes that showed color changes indicative of PAH degradation were used for isolation. Samples from positive MPN tubes were streaked onto plates containing ONR7a solidified with 0.8% agarose. Phenanthrene or naphthalene were used as the sole carbon sources; these PAHs are provided in the vapor phase by placing approximately 1 mg of PAH in the lid of each plate and storing the plates inverted and wrapped in Parafilm™. Colonies that were capable of growing with either of these PAHs as sole carbon sources are picked and inoculated into an ONR7a solution containing the appropriate PAH in crystal form at a concentration of approximately 1 mg/ml (Geiselbrecht et al., 1998). *Cycloclasticus* spp. have also been isolated from enrichments made by inoculating ONR7a + PAHs with fresh sediments, incubating for 2 weeks at room temperature, and plating onto ONR7a solidified with 0.8% agarose (Geiselbrecht et al., 1996).

"C. oligotrophus" RB1 was isolated following a 10^8 dilution of Resurrection Bay seawater into unamended seawater prepared by filtration through fired Gelman 1/E 47-mm-diameter filters, autoclaving, refiltering through other fired Gelman filters, and aseptically siphoning the sterile filtrate into incubation chambers (Button et al., 1993).

Maintenance Procedures

Although initial isolations were at 15°C, subsequent studies indicated a temperature growth range of 4–28°C, with strong growth at room temperature. Routine growth occurs in either ONR7a with PAHs as a sole carbon source, or in a seawater medium amended with acetate (Button et al., 1998). Strains have also been grown on Bacto Marine 2216 Petri plates with biphenyl in the vapor phase (Dyksterhouse et al., 1995). Cultures can be frozen and stored at −80°C using either DMSO or glycerol.

Procedures for Testing Special Characters

The use of PAHs as a sole carbon source is a characteristic of this genus. PAH degradation can be confirmed by several methods, but a simple method involves growing cultures with individual PAHs as sole carbon sources and monitoring the disappearance of the PAHs with a gas chromatograph equipped with a flame ionization detector in comparison to sterile controls. Briefly, 20-ml Balch tubes fitted with Teflon-lined stoppers can be used, and PAHs added as concentrated solutions in methylene chloride. After the methylene chloride is evaporated, 5 ml of a seawater medium (such as ONR7a) is added. Tubes are vortexed and shaken to allow the PAHs to solubilize. The tubes are inoculated with an exponential-phase culture of *Cycloclasticus*, grown on either acetate or a different PAH. Control tubes receive no inoculum. The tubes are incubated in the dark with shaking (for aeration), and then the cultures are extracted with hexane. Each extract can be analyzed with a gas chromatograph equipped with a 30-m DB-5 column (diameter, 0.5 mm) or comparable column, and the recovery of parent compound recovered versus controls indicate PAH degradation (Geiselbrecht et al., 1998).

Differentiation of the genus *Cycloclasticus* from other genera

The ability to utilize PAHs is not unique to this genus; other marine PAH-degrading, Gram-negative rods have been isolated and include members of the genus *Pseudomonas* (Shiaris and Cooney, 1983; Tagger et al., 1990), *Flavobacterium* (Shiaris and Cooney, 1983; Okpokwasili et al., 1984), *Moraxella* (Tagger et al., 1990), *Marinobacter* (Gauthier et al., 1992), *Vibrio* (West et al., 1984), *Sphingomonas* (Zylstra et al., 1997), and a new genus *Neptunomonas* (Hedlund et al., 1999a). *Cycloclasticus* can be distinguished from some of these genera by its 1% salt requirement. *Cycloclasticus* can be distinguished from all of these genera as well as other aerobic, heterotrophic, motile, rod-shaped marine bacteria by its distinct phylogenetic location.

Taxonomic Comments

As noted, several strains of *Cycloclasticus* have been isolated. *"Cycloclasticus oligotrophus"* RB1 has been described as a distinct species based on its small size and inability to utilize polar substrates such as amino acids (Button et al., 1993, 1998). Although *"C. oligotrophus"* RB1 is phylogenetically closely related to *C. pugetii*^{T} (Button et al., 1998), it has not yet been validly named.

Dyksterhouse, S.E., J.P. Gray, R.P. Herwig, J.C. Lara and J.T. Staley. 1995. *Cycloclasticus pugetii* gen. nov., sp. nov., an aromatic hydrocarbon-degrading bacterium from marine sediments. Int. J. Syst. Bacteriol. *45*: 116–123.

List of species of the genus Cycloclasticus

1. **Cycloclasticus pugetii** Dyksterhouse, Gray, Herwig, Lara and Staley 1995, 120^{VP}
pu.get'i.i. M.L. gen. n. *pugetii* of Puget, named in honor of Peter Puget, a British naval officer who participated in the Vancouver Expedition and for whom Puget Sound was named.

The characteristics are as described for the genus.

Isolated from surficial sediments of Sinclair Inlet, which is located on Puget Sound near the city of Bremerton, Washington.

The mol% G + C of the DNA is: 37 (HPLC).

Type strain: PS-1, ATTC 51542.

GenBank accession number (16S rRNA): U12624, L34955.

Other Organisms

A collection of 15 strains of *Cycloclasticus* was isolated from several Puget Sound locations subsequent to the isolation of *Cycloclasticus pugetii*. These were grouped on the basis of fatty acid analyses and a representative strain's 16S rDNA was sequenced, *Cycloclasticus* sp. strain N3 (GenBank U57920) (Geiselbrecht et al., 1996). This strain differs from *C. pugetii* at only 3 base pair positions in the 16S rDNA. Twenty-three strains of *Cycloclasticus* spp. were isolated from offshore and near-shore Gulf of Mexico sediments (Geiselbrecht et al., 1998). Partial 16S rDNA sequencing revealed that all 23 were members of the *Cycloclasticus* genus, and the 16S rDNA was sequenced in entirety from three strains: *Cycloclasticus* sp. strain G (GenBank AF093002), *Cycloclasticus* sp. strain E (GenBank AF093003), and *Cycloclasticus* sp. strain W (GenBank AF093004). All three are closely related to *C. pugetii*. At this time, it is unclear whether any of these strains are potentially new species of *Cycloclasticus*.

Genus III. **Hydrogenovibrio** *Nishihara, Igarashi and Kodama 1991b, 132*[VP]

Hirofumi Nishihara

Hy.dro.ge.no.vib' ri.o. Gr. n. *hydro* water; Gr. n. *genus* offspring; M.L. masc. n. *hydrogenium* hydrogen, that which produces water; M.L. masc. n. *vibrio* that which vibrates; M.L. masc. n. *Hydrogenovibrio* hydrogen vibrio.

Cells are **comma-shaped rods** (0.2–0.5 × 1–2 μm) that occur singly (Fig. BXII.γ.87). **Gram negative.** Motile by means of a polar flagellum. No resting stages are known. **Aerobic. Chemolithoautotrophic, using H_2 or reduced inorganic sulfur compounds**, such as S^0, thiosulfate, and tetrathionate, as the electron donor **and CO_2** as the carbon source. CO_2 is fixed via the **Calvin-Benson cycle**. Chemoorganotrophic growth has not been observed. The optimum temperature for growth is ~37°C. The optimum pH for growth is ~6.5. NaCl is required for growth with an optimum concentration of 0.5 M.

Straight chain saturated $C_{16:0}$ and $C_{18:0}$ acids and a straight-chain unsaturated $C_{16:1}$ acid are the major components of the cellular fatty acids. Ubiquinone-8 is the major component of the quinone system.

The mol% G + C of the DNA is: 44.1.

Type species: **Hydrogenovibrio marinus** Nishihara, Igarashi and Kodama 1991b, 132.

Further descriptive information

Reddish-brown, smooth colonies are formed on inorganic basal medium solidified with agar in an atmosphere of $H_2/O_2/CO_2$ (85:5:10) (1 atm at room temperature). Colonies are not formed when the partial pressure of oxygen is more than 10%. The colonies grow up to approximately 1 mm in diameter after a week of incubation at 26.5°C. No colony is formed heterotrophically on nutrient broth medium supplemented with 0.5 M NaCl.

H. marinus grows rapidly and vigorously in the presence of

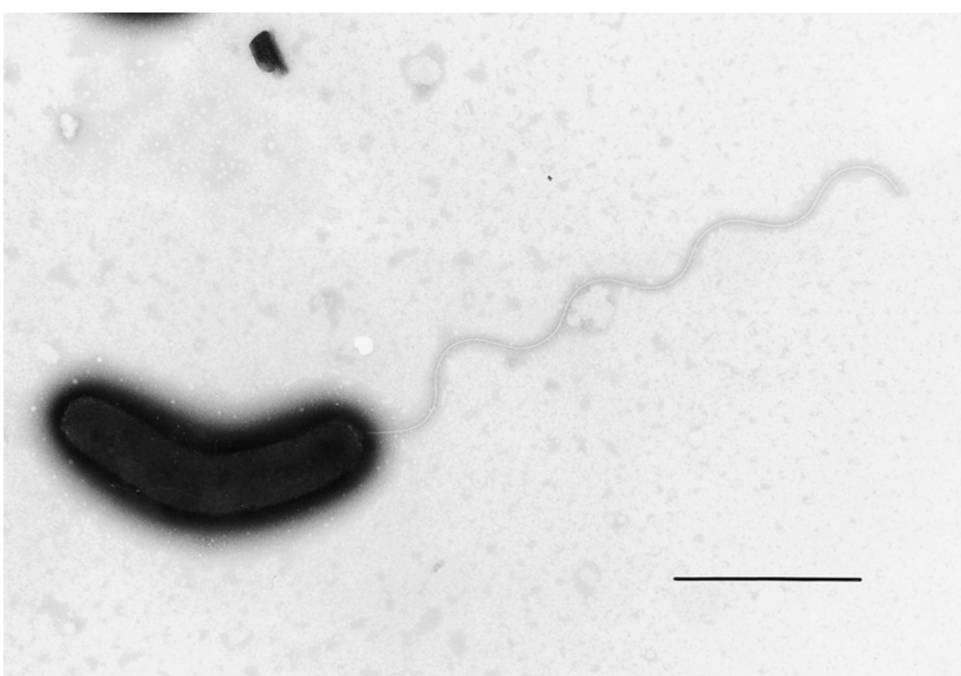

FIGURE BXII.γ.87. Electron micrograph of *H. marinus* strain MH-110 fixed with glutaraldehyde and negatively stained. Bar = 1 μm.

H_2 and CO_2 as the sole energy and carbon sources, respectively. Lag time of growth is not observed at any tension of oxygen (1–40%), nevertheless hydrogen-oxidizing bacteria are usually microaerophilic. Specific growth rate in the initial stage of growth is very high (0.60–0.67 h^{-1} at 37, pH 6.5) irrespective of any oxygen tension. The cell density reaches more than 20 g/l dry weight after 24 h cultivation under a continuous gas flow of $H_2/O_2/CO_2$ in a jar fermentor (Nishihara et al., 1991a). A reduced inorganic sulfur compound such as S^0, thiosulfate, or tetrathionate is also utilized as the sole energy source under both aerobic (shaking, pO_2 = 20%, pCO_2 = 10%) and microaerobic (standing, pO_2 = 5%, pCO_2 = 10%) conditions in flask cultures, but the growth is very poor. A decrease in pH value occurs when *H. marinus* is cultivated on these sulfur compounds. S^0 is deposited extracellularly when cultivated with thiosulfate or tetrathionate. Ferrous, manganous, ammonium, or nitrite ions are not utilized as an energy source under both aerobic and microaerobic conditions (Nishihara et al., 1989).

Chemoorganotrophic growth is not observed on the following organic compounds (0.1%, w/v) or media: acetate, propionate, oxalate, succinate, maleate, fumarate, DL-malate, α-ketoglutarate, DL-lactate, citrate, pyruvate, formate (5–100 mM), glycollate, DL-β-hydroxybutyrate, *p*-hydroxybenzoate, gluconate, D-xylose, D-galactose, sucrose, D-glucose, D-mannose, D-fructose, maltose, L-rhamnose, trehalose, D-raffinose, soluble starch, methanol, ethanol, mannitol, glycine, L-glutamate, L-aspartate, L-serine, L-leucine, L-valine, L-lysine, L-tryptophan, L-histidine, L-alanine, L-proline, L-arginine, L-threonine, L-phenylalanine, nutrient broth medium, yeast extract-peptone-glucose medium, brain heart infusion medium, and ZoBell 2216E medium (Nishihara et al., 1989).

Ammonium ions and urea are utilized as sole nitrogen sources, but nitrate ions, nitrite ions, and gaseous nitrogen are not. Nitrite inhibits growth. No growth is observed in the absence of NaCl, and Na^+ is not replaceable by K^+ or Li^+. The optimum NaCl concentration is 0.5 M. No growth factors are required (Nishihara et al., 1989).

Glycogen is accumulated when *H. marinus* is autotrophically cultivated on hydrogen and CO_2 under nitrogen or magnesium starvation or oxygen limitation. The maximum absorption of the iodine complex is observed at 453 nm (Nishihara et al., 1993).

The major hydrogenase is membrane-bound type. The natural electron carrier has not been identified. Pyridine nucleotides reducing activity is not observed in either the membrane or the soluble fraction. Type *b*, *c*, and *o* cytochromes have been found. The membrane-bound hydrogenase is characterized as highly oxygen-tolerant and thermostable. The optimum temperature for hydrogen-oxidation activity using methylviologen as an electron acceptor is 90°C (Nishihara et al., 1997).

CO_2 is fixed via the Calvin-Benson cycle. Three different molecules of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCo) have been found in *H. marinus* cells. Two of them are form I RuBisCos (CbbLS-1 and CbbLS-2), which are composed of eight large and eight small subunits, and the other is form II RuBisCo (CbbM), which is composed of only large subunits (Chung et al., 1993a). The specific factors (τ values) of CbbLS-1 and CbbLS-2 are higher than that of CbbM, but lower than those of other form I RuBisCos from various organisms (Hayashi et al., 1998). The gene sequences of CbbLS-1, CbbLS-2, and CbbM from *H. marinus* are deposited in the DDBJ database under accession numbers D43621, D43622, and D28135, respectively. The deduced amino acid sequences of both CbbLS-1 and CbbLS-2 exhibited particularly high similarities to those of *Chromatium vinosum* and sulfur-oxidizing bacteria (*Thiobacillus*) (Nishihara et al., 1998). Large subunits of form I RuBisCos (CbbLs) from these bacteria formed a monophyletic group in the maximum parsimony tree of *cbbL* amino acids (Delwiche and Palmer, 1996).

The 16S rRNA gene sequence of *H. marinus* is deposited in the DDBJ database under accession number D86374. According to the sequence, *H. marinus* is affiliated with purple sulfur bacteria and sulfur-oxidizing bacteria belonging to the *Gammaproteobacteria*, members of *Thiomicrospira* being the closest relatives (Nishihara et al., 1998). Sequence similarities of the 16S rRNA genes and of the *cbbL* genes among these *Gammaproteobacteria* suggest a common autotrophic ancestry.

H. marinus was isolated from seawater (surface or shallow water) collected at a coastal region in Japan.

Enrichment and Isolation Procedures

The following inorganic medium was used for the enrichment of *H. marinus*: K_2HPO_4, 2.5 g/l; KH_2PO_4, 0.5 g/l; $(NH_4)_2SO_4$, 2.0 g/l; NaCl, 29.3 g/l; $MgSO_4 \cdot 7H_2O$, 0.2 g/l; $CaCl_2$, 10.0 mg/l; $FeSO_4 \cdot 7H_2O$, 10.0 mg/l; and $NiSO_4 \cdot 7H_2O$, 0.6 mg/l; plus trace elements (pH 7.0) (Nishihara et al., 1989). The flasks were gassed with a gas mixture of $H_2/O_2/CO_2$ (75:15:10) (1 atm at room temperature) and shaken at 25°C. Single colony isolation was performed on plate medium solidified with 1.5% agar. The inoculated plates were placed in a desiccator and the gas phase was replaced by a gas mixture of $H_2/O_2/CO_2$ (85:5:10) (1 atm at room temperature).

Maintenance Procedures

H. marinus can be preserved by a freeze-drying method. 50 mM phosphate buffer (pH 7.0) containing 2% sodium glutamate was used as the suspending medium. The cultures can also be stored in 10–15% (v/v) glycerol at −80°C or in liquid nitrogen.

Differentiation of the genus *Hydrogenovibrio* from other genera

Hydrogenovibrio is the only taxon for mesophilic and obligately chemolithoautotrophic hydrogen bacteria. *Thiomicrospira* is the closest relative of *Hydrogenovibrio* according to the 16S rRNA gene sequence analysis. Hydrogen autotrophy is the main feature that differentiates these two genera.. *H. marinus* grows best on hydrogen as an energy source. On the other hand, growth of *Thiomicrospira* on hydrogen has not been observed (Nishihara et al. 1991b) (see also the table in the description of the genus *Thiomicrospira*).

List of species of the genus Hydrogenovibrio

1. **Hydrogenovibrio marinus** Nishihara, Igarashi and Kodama 1991b, 132[VP]

ma.ri′ nus. L. adj. *marinus* marine, of the sea.

The description of this species is the same as that of the genus.

The mol% G + C of the DNA is: 44.1 (HPLC).

Type strain: MH-110, DSM 11271; JCM 7688.

GenBank accession number (16S rRNA): D86374.

Genus IV. **Methylophaga** *Janvier, Frehel, Grimont and Gasser 1985, 138*[VP]

JOHN P. BOWMAN

Me.thyl.o'pha.ga. Fr. n. *methyl* methyl radical; Gr. v. *phagein* to eat; M.L. n. *Methylophaga* methyl eating.

Rod-shaped cells 0.2 × 0.9-1.0 μm, occurring singly or in pairs. **Motile by means of a single polar flagellum. Gram negative.** Spores and other resting stages are not formed. **Chemoheterotrophic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Restricted methylotroph**, able to utilize only a limited range of substrates, mostly C_1 substrates including methanol, methylamine, dimethylamine, and trimethylamine. The only C_{2+} compounds used for growth are D-fructose and sucrose. The **ribulose monophosphate pathway** is used for assimilation of C_1 compounds. One species can utilize dimethylsulfide and grow mixotrophically by oxidizing H_2S to thiosulfate. Catalase and oxidase positive. **Na^+ and Mg^{2+} are required for optimum growth**. Requires vitamin B_{12} for growth. Major fatty acids are $C_{16:0}$ and $C_{16:1\ \omega7c}$. The major coenzyme Q is ubiquinone-8 (Q-8). Belongs to the *Gammaproteobacteria*. Isolated from seawater, brackish waters and marine benthic mats.

The mol% G + C of the DNA is: 42–45.

Type species: **Methylophaga marina** Janvier, Frehel, Grimont and Gasser 1985, 138.

FURTHER DESCRIPTIVE INFORMATION

Morphology Cells lack differentiated resting cells, prostheca, and other ultrastructural peculiarities except for having a somewhat wide periplasmic space with a width of 20–30 nm (Janvier et al., 1985). Cell walls are of the usual type for Gram-negative cells.

Cultural characteristics *Methylophaga* strains grow well on artificial seawater (ASW)-methanol medium[1] but do not grow on most standard complex marine media such as marine agar (ZoBell, 1941). The colonies of *Methylophaga* strains are circular and convex, possess entire edges and a butyrous consistency, and have a white to pale pink color.

Methylophaga strains require Na^+ and Mg^{2+} ions (20 mM and 5 mM, respectively) for optimal growth (Janvier et al., 1985), though some strains still grow weakly in their absence (Urakami and Komagata, 1987). Most *Methylophaga* strains are able to tolerate up to 9–10% NaCl. *"M. limanica"* exhibits optimum growth with 0.5–1.0 M NaCl (Doronina and Trotsenko, 1997). Strains usually possess a requirement for cyanocobalamin (vitamin B_{12}). The optimal pH for growth is equivalent to that of seawater (7.4–7.8) and the optimal growth temperature is 30–37°C. *M. thalassica* is slightly more thermotolerant than *M. marina* and can grow at 42°C (Urakami and Komagata, 1987).

Carbon and energy sources Only a few substrates are utilized for carbon and energy. These are mainly C_1 compounds including methanol and methylamine, which are utilized by all *Methylophaga* strains (Table BXII.γ.49). No strains grow on methane or methanesulfonate. Among a large number of C_{2+} compounds tested, only D-fructose supports growth, except for *"M. limanica"*, which can also use sucrose (Janvier et al., 1985; de Zwart et al., 1996; Doronina et al., 1997).

M. sulfidovorans has the unusual ability to grow on dimethylsulfide (DMS) and oxidize it to thiosulfate. The doubling time is approximately 15 h compared with 2–3 h on methanol. This species can also grow mixotrophically by oxidizing H_2S to thiosulfate when in the presence of a carbon substrate such as DMS, which acts as a source of sulfide and carbon (de Zwart and Kuenen, 1997). Sulfide concentrations of 200 μmol/l reduce DMS oxidation by about 50%. The sulfide oxidation rate of *M. sulfidovorans* is equivalent to that in other sulfide-oxidizers such as *Thiobacillus thioparus* (de Zwart et al., 1997).

C_1 metabolism *Methylophaga* strains possess a dissimilatory pathway for methanol oxidation like that found in other methylotrophic bacteria. In this pathway, methanol is oxidized to formaldehyde by methanol dehydrogenase; then the formaldehyde is either oxidized to formate (and then to CO_2) or is fixed as cellular carbon. The methanol dehydrogenase in *Methylophaga marina* has a structure similar to that found in other methylotrophic bacteria (Janvier and Gasser, 1987). Mutagenesis studies indicate that apo-methanol dehydrogenase and pyrroloquinol quinone—the cofactor typically associated with methanol dehydrogenase—are insufficient to constitute an active enzyme and that another unknown factor is required (Janvier et al., 1992). *Methylophaga* strains use the 2-keto-3-deoxy-6-phosphogluconate aldolase variant of the ribulose monophosphate (RuMP) pathway for formaldehyde fixation (Doronina et al., 1997). The assimilation of methylamine, however, uses a variety of enzymes that differ between strains. Methylamine dehydrogenase is the primary methylamine-oxidizing enzyme in *M. marina* and *"M. limanica"* (Doronina et al., 1997), whereas in *M. thalassica* the predominant enzyme is *N*-methylglutamate dehydrogenase (Janvier et al., 1985). This differentiation is not absolute, however, because *"M. limanica"* and some strains of *M. marina* also exhibit *N*-methylglutamate dehydrogenase activity (Janvier et al., 1985; Doronina et al., 1997). Methylamine dehydrogenase converts methylamine directly to formaldehyde and ammonia using cytochrome *c* as an electron acceptor (Mehta, 1977). Methylamine can also be converted to γ-glutamylmethylamide (γ-GMA) by the addition of glutamate via γ-GMA synthetase. γ-GMA is then cleaved by γ-GMA lyase to yield ammonia and *N*-methylglutamate, and the latter is oxidized by *N*-methylglutamate dehydrogenase to produce formaldehyde and glutamate (Hou, 1984; Doronina et al., 1997). An alternative pathway has been discovered for *Methylophaga* strain AA-30 in which γ-GMA is cleaved into ammonia, formaldehyde, and 2-oxoglutarate; the latter compound is then transaminated to form glutamate (Kimura et al., 1990b, 1995). As in other methylotrophs possessing the RuMP pathway, the tricarboxylic acid cycle lacks 2-oxoglutarate dehydrogenase; moreover, strains lack pyruvate kinase and glyoxylate cycle enzymes (Doronina et al., 1997).

1. Artificial seawater (ASW)-methanol medium contains (g/l of natural or artificial seawater) KH_2PO_4, 0.14; Bis-Tris, 2.0; and ferric ammonium citrate, 0.06. The pH is adjusted to ~7.5 and 1.6% agar is added (optional). After autoclaving and cooling to ~50°C, methanol and vitamin B_{12} are added to final concentrations of 0.2% and 1 μg/ml, respectively. Artificial seawater consists of (g/l distilled water) NaCl, 24; $MgCl_2·6H_2O$, 3; $MgSO_4·7H_2O$, 2; KCl, 0.5; $CaCl_2·2H_2O$, 1; Bis-Tris, 0.5; and 1 ml of trace element solution. The trace element solution (Widdel and Pfennig, 1981) consists of (per liter of distilled water) 25% HCl, 10 ml; $FeCl_2·4H_2O$, 1.5 g; $CoCl_2·6H_2O$, 0.19 g; $MnCl_2·4H_2O$, 0.1 g; $ZnCl_2$, 0.07 g; H_3BO_3, 0.062 g; $Na_2MoO_4·2H_2O$, 0.036; $NiCl_2·6H_2O$, 0.024 g; and $CuCl_2·2H_2O$, 0.017 g. The ferrous chloride is dissolved in HCl and then added to the distilled water with the other reagents.

TABLE BXII.γ.49. Phenotypic characteristics of the species of the genus *Methylophaga*[a]

Characteristic	1. *M. marina*	2. *M. sulfidovorans*	3. *M. thalassica*	4. *"M. limanica"*
Nitrate reduction	−	−	d (weak)	−

[a]For symbols see standard definitions; nd, no data.

Nitrogen metabolism *Methylophaga* strains utilize a variety of nitrogen sources including ammonia, nitrate, short chain amines (Kimura et al., 1990a), amino acids, and yeast extract. In general, strains cannot reduce nitrate to nitrite, though some *Methylophaga thalassica* strains have been reported to produce weak positive results in this test (Urakami and Komagata, 1987). Ammonia is assimilated by the glutamate cycle (glutamate synthase and glutamine synthetase) (Doronina et al., 1997).

DNA composition The mol% G + C of the DNA has been analyzed for several *Methylophaga* strains. In *M. marina* the values range from 43–44. *M. thalassica* has slightly higher values of 44–45. Additional *Methylophaga*-like strains analyzed by Urakami and Komagata (1987) have values as high as 48.

Fatty acids and quinones Chemotaxonomically the strains of *Methylophaga* form a homogeneous group. The major fatty acids include $C_{12:0}$ (4–5%), $C_{14:0}$ (3–4%), $C_{16:0}$ (33–35%), $C_{16:1\ \omega 7c}$ (37–44%), $C_{18:1\ \omega 7c}$ (4–11%) and $C_{10:0\ 3OH}$ (3–5%). The major isoprenoid quinone is ubiquinone-8 and all strains contain significant levels of squalene (Urakami and Komagata, 1986c, 1987).

Ecology Limited information is available on the distribution and ecology of *Methylophaga*. Studies using indirect immunofluorescence have shown that *M. marina* strains can be most frequently isolated from open seawater rather than estuarine waters (Sieburth et al., 1993). The ability of *M. sulfidovorans* to utilize dimethylsulfide and use H_2S for energy suggests the species has a significant role in cycling of DMS and sulfide in marine ecosystems (de Zwart et al., 1997). DMS is the breakdown product of dimethylsulfoniopropionate (DMSP), an important osmolyte produced copiously by various phytoplankton species (Ledyard et al., 1993; Visscher and Taylor, 1994). Other bacteria that can metabolize DMS, such as *Hyphomicrobium* and *Thiobacillus* spp. (Kanagawa and Mikami, 1989; Visscher and Taylor, 1994), have been isolated from freshwater sites. *"M. limanica"* was isolated from the hypersaline waters of a liman adjoining the Black Sea (Doronina and Trotsenko, 1997).

Enrichment and Isolation Procedures

M. marina and *M. thalassica* can be isolated following initial enrichment of marine samples in ASW-methanol broth for 3–6 d at about 30°C (Janvier et al., 1985). Enrichment cultures are then serially diluted onto ASW-methanol agar and incubated at 30°C for about 1 week. The appearance of pale pink colonies 0.5–2 mm in size are usually indicative of *Methylophaga* strains. A similar approach can be taken for *"M. limanica"* except NaCl levels used should match sample salinity levels (from 1.0–2.0 M). *M. sulfidovorans* can be isolated from benthic mats and sediment by enriching samples in ASW-dimethylsulfide (DMS)[2] broth at 20–25°C (de Zwart et al., 1996). A sample slurry is serially diluted in ASW-DMS broth and growth from the highest dilution is then transferred to fresh medium. Isolation must be performed in liquid medium because no growth occurs on DSM agar media. The DMS-utilizing culture is passaged until it becomes morphologically homogeneous. Alternatively, purification can be achieved on ASW-methanol agar, with checks made to ensure DMS utilization is maintained.

Maintenance Procedures

Methylophaga can be preserved at −80°C in ASW-methanol media supplemented with 30% DMSO. Strains can also be freeze-dried using 20% skim milk as a cryoprotectant.

Differentiation of the genus *Methylophaga* from other genera

To date, *Methylophaga* is the only known restricted methylotroph isolated from marine habitats. A requirement for Na^+ ions differentiates this genus from other metabolically similar restricted methylotrophs belonging to the *Betaproteobacteria*, i.e., *Methylophilus*, *Methylobacillus*, and *Methylovorus*.

Taxonomic Comments

16S rRNA sequences are available for *Methylophaga marina*, *Methylophaga thalassica*, and *Methylophaga sulfidovorans*, and these species form a tightly knit group with an overall sequence divergence of approximately 4–5%. *Methylophaga* forms a distinct lineage within the *Gammaproteobacteria* (Ando et al., 1989; Janvier and

2. ASW-dimethylsulfide (DMS) broth consists of (g/l) NaCl, 15–25; NH_4SO_4, 0.5; $CaCl_2 \cdot 6H_2O$, 0.33; KCl, 0.2; $MgSO_4 \cdot 7H_2O$, 1; KH_2PO_4, 0.02; Na_2CO_3, 2; $FeSO_4 \cdot 7H_2O$, 1 mg; trace element solution (similar to that given for ASW-methanol medium except that it is supplemented with 6 mM Na_2SeO_4), 1 ml. The pH is adjusted to ~7.5 and 10- or 20-ml portions of the medium are dispensed into 60- or 100-ml serum vials, sealed by butyl-rubber stoppers, and autoclaved. After the medium is cooled, DMS and vitamin B_{12} are added to final concentrations of 1 mM and 1 μg/ml, respectively.

Grimont, 1995; de Zwart et al., 1996). The closest relatives include the marine genus *Cycloclasticus* and various type I methanotrophs including *Methylomonas* and *Methylobacter*. *Methylophaga* are unrelated to other restricted methylotrophic bacteria, including *Methylophilus* (Jenkins et al., 1987), *Methylobacillus* (Urakami and Komagata, 1986b), and *Methylovorus* (Govorukhina and Trotsenko, 1991), which belong to the *Betaproteobacteria* and which are nonhalophilic.

"Alteromonas thalassomethanolica" (e.g., ATCC 33145 and NCIMB 2160) and *"Methylomonas thalassica"* (e.g., NCIMB 2162, ATCC 33146) described originally by Yamamoto et al. (1980) were renamed *Methylophaga thalassica* by Janvier et al. (1985). Further phenotypic analysis by Urakami and Komagata (1987) indicates that *M. marina* and *M. thalassica* are very similar phenotypically and that they can only be identified definitively by a limited number of biochemical characteristics (Table BXII.γ.49), 16S rRNA analysis, and DNA–DNA hybridization. DNA–DNA hybridization studies indicate that *M. marina* strains share 81 to >100% hybridization, *M. thalassica* strains share 61–74% hybridization, and that no significant DNA hybridization occurs between the species.

The putative species *"M. limanica"* has yet to be validated. Doronina et al. (1997) reported that *"M. limanica"* strain hal-6 exhibited 30–40% DNA hybridization with *M. marina* and *M. thalassica*.

Differentiation of the species of the genus *Methylophaga*

Phenotypic characteristics differentiating *Methylophaga* species are shown in Table BXII.γ.49. Electrophoresis of enzymes has also been used to distinguish *Methylophaga* species. For example, the electrophoretic mobility of glucose-6-phosphate dehydrogenase is slightly greater for *M. thalassica* strains vs. *M. marina* strains. The methanol dehydrogenases of these species also differ in terms of mobility (Janvier et al., 1985).

List of species of the genus Methylophaga

1. **Methylophaga marina** Janvier, Frehel, Grimont and Gasser 1985, 138[VP]

ma.ri′ na. L. adj. *marinus* of the sea.

Short, slender, Gram-negative rods 0.2 × 1 μm. Colonies on artificial seawater-methanol agar are white to pale pink, convex, and circular with an entire edge and a creamy consistency. Na^+ ions, Mg^{2+} ions, and vitamin B_{12} are required for growth.

Optimal growth temperature, 30–37°C; range, 10–40°C. Optimal pH, ~7.5.

Other characteristics are as given in the genus description and are presented in Table BXII.γ.49.

Isolated from seawater and marine sediment.

The mol% G + C of the DNA is: 43–44 (T_m).

Type strain: 222, ATCC 35842, DSM 5989, NCIMB 2244.

GenBank accession number (16S rRNA): X87338, X95459.

2. **Methylophaga sulfidovorans** de Zwart, Nelisse and Kuenen 1998, 1083[VP] (Effective publication: de Zwart, Nelisse and Kuenen 1996, 266.)

sul.fi.do′ vo.rans. L. n. *sulfur* sulfur; L. prefix *sulf-* + *ide* probably originally formed from German *sulfid;* L. v. *voro* to devour; M.L. part. adj. *sulfidovorans* sulfide-devouring.

Short, slender, Gram-negative motile rods, approximately 0.9 × 0.2 μm. Na^+ ions, Mg^{2+} ions, and vitamin B_{12} are required for growth. Other characteristics are as given in the genus description and are presented in Table BXII.γ.49.

Isolated from a marine benthic mat off the coast of the Netherlands.

The mol% G + C of the DNA is: 42 (T_m).

Type strain: YK-4015, ATCC 33146, DSM 5690, IAM 12458, LMG 4055, NCIMB 2163.

GenBank accession number (16S rRNA): X87339, X95460.

3. **Methylophaga thalassica** Janvier, Frehel, Grimont and Gasser 1985, 138[VP]

tha.las′ si.ca. Gr. n. *thalassica* of the sea.

Short, slender, Gram-negative rods, 0.2 × 1 μm. Colonies on artificial seawater-methanol agar are white to pale pink, convex, and circular with an entire edge and a creamy consistency. Na^+ ions, Mg^{2+} ions, and vitamin B_{12} are required for growth.

Optimal temperature, 30–37°C; range, 10–42°C. Optimal pH, ~7.5.

Other characteristics are as given in the genus description and are presented in Table BXII.γ.49.

Isolated from seawater.

The mol% G + C of the DNA is: 44–45 (T_m).

Type strain: YK-4015, ATCC 33146, DSM 5690, IAM 12458, LMG 4055, NCIMB 2163.

GenBank accession number (16S rRNA): X87339, X95460.

Species Incertae Sedis

1. **"Methylophaga limanica"** Doronina, Krauzova and Trotsenko 1997, 438.

li.ma′ ni.ca. M.L. n. *limanica* of a liman (a salty lagoon-like water body).

Short Gram-negative rods possessing a single polar flagellum. Do not form spores or prostheca.

Colonies on artificial seawater salts–methanol agar appear opaque, white, and circular, with an entire edge and a creamy consistency. No growth occurs on nutrient agar.

Requires vitamin B_{12} and Na^+ ions for growth (0.5–1.0 M is optimal). Optimal temperature and pH for growth are 30–37°C and pH 6.7–7.2, respectively.

Isolated from a Black Sea liman.

Other characteristics are as given in the genus description and are presented in Table BXII.γ.49.

The mol% G + C of the DNA is: 43.5 (T_m).

Deposited strain: hal 6.

Genus V. **Thioalkalimicrobium** *Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 576*[VP]

THE EDITORIAL BOARD

Thi.o.al.kal.i.mi.cro' bi.um. Gr. n. *thios* sulfur; N.L. n. *alkali* Arabic *al* the; *qaliy* soda ash; Gr. adj. *micros* small; Gr. masc. n. *bios* life; M.L. n. *Thioalkalimicrobium* sulfur alkaline microbe.

Motile Gram-negative rods, curved rods, or spirilla (0.4–0.5 × 0.8–1.5 μm). 1–3 monopolar flagella. Possess **carboxysomes**. **Chemolithoautotrophs; obligate aerobes. Oxidize sulfide and thiosulfate to sulfate**; do not oxidize sulfite. Carbon assimilation via Calvin cycle. Halotolerant up to 1.2–1.5 M Na^+; require at least 0.2–0.3 M NaCl.

The mol% G + C of the DNA is: 48–51.2.

Type species: **Thioalkalimicrobium aerophilum** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578 (**Thioalkalimicrobium aerophilum** (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578.)

FURTHER DESCRIPTIVE INFORMATION

These organisms were found in the water and sediments of alkaline lakes in which sulfide is produced in the underlying sediments. Growth in the laboratory was studied in carbonate/bicarbonate buffered medium containing sulfide, thiosulfate, and polysulfide. Tetrathionate and elemental sulfur were not used by most strains. The pH optimum was 9–10. Ammonia, nitrite, nitrate, and thiocyanate were used as nitrogen sources (Sorokin et al., 2001a).

Analysis of the 16S rDNA sequence of the type strains of *T. aerophilum* and *T. sibiricum* revealed a close relationship with the genus *Thiomicrospira*, particularly with *Thiomicrospira pelophila*. Thus, the genus *Thioalkalimicrobium* is a member of the family *"Piscirickettsiaceae"* in the *Gammaproteobacteria* (Sorokin et al., 2001a).

ENRICHMENT AND ISOLATION PROCEDURES

These bacteria were obtained by enrichment and isolation in a carbonate/bicarbonate buffered liquid salts medium containing thiosulfate. For some strains, the amount of NaCl in the base medium had to be increased (Sorokin et al., 2001a).

MAINTENANCE PROCEDURES

Thioalkalimicrobium spp. can be stored at 4°C for 2 months between transfers in liquid salts medium (pH 10) containing 5mM $MgCl_2$ to stabilize the cell walls. They can also be stored in 10% glycerol (v/v) at –80°C (Sorokin et al., 2001a).

List of species of the genus Thioalkalimicrobium

1. **Thioalkalimicrobium aerophilum** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578[VP] (*Thioalkalimicrobium aerophilum* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578.)
ae.ro.phi' lum. Gr. masc. n. *aër* gas Gr. adj. *philus* loving; M.L. n. *aerophilum* air-loving.

Description as for the genus with the following additional characteristics. Grow preferentially in atmospheric O_2 levels. Tetrathionate oxidized by most strains. Colonies flat and spreading.

The mol% G + C of the DNA is: 48–51.2 (T_m).
Type strain: AL 3, DSM 13739.
GenBank accession number (16S rRNA): AF126548.

2. **Thioalkalimicrobium sibiricum** Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578[VP] (*Thioalkalimicrobium sibiricum* (sic) Sorokin, Lysenko, Mityushina, Tourova, Jones, Rainey, Robertson and Kuenen 2001a, 578.)
si.be' ri.cum. M.L. masc. adj. *sibericus* from Siberia.

Description as for the genus with the following additional characteristics. Grow preferentially at less than atmospheric O_2 levels. Tetrathionate not oxidized by most strains. Colonies compact.

The mol% G + C of the DNA is: 48.2–49.5 (T_m).
Type strain: AL 7, DSM 13740.
GenBank accession number (16S rRNA): AF126549.

Genus VI. **Thiomicrospira** *Kuenen and Veldkamp 1972, 253*[AL]

THORSTEN BRINKHOFF, JAN KUEVER, GERARD MUYZER AND HOLGER W. JANNASCH

Thi.o.mi.cro.spi' ra. Gr. n. *thios* sulfur; Gr. adj. *micros* small, little; Gr. n. *spira* spiral; M.L. fem. n. *Thiomicrospira* small sulfur spiral.

Small **spiral-, comma-, or rod-shaped cells** (0.2–0.5 × 0.8–3.0 μm) that occur singly. Gram negative. Motile by means of a polar flagellum or nonmotile. No resting stages are known. **Aerobic. Chemolithoautotrophic, using reduced inorganic sulfur compounds, such as S^0, sulfide, tetrathionate, thiosulfate** (but not sulfite or thiocyanate), **and CO_2 as carbon source.** CO_2 is fixed via the **Calvin-Benson cycle** (ribulose 1,5-bisphosphate carboxylase is present). The final oxidation product is sulfate, but S^0 may accumulate in the medium. During growth acid is produced. Ammonium salts serve as nitrogen source. Na^+ ions are required for growth. The temperature optimum lies between 28°C and 40°C. The optimal pH varies from 6.0 to 8.0. Metabolic properties are very similar to those of the genus *Thiobacillus*.

Q-8 is the major ubiquinone. Members of a **monophyletic group** within the *Gammaproteobacteria*.

The mol% G + C of the DNA is: 39.6–49.9.

Type species: **Thiomicrospira pelophila** Kuenen and Veldkamp 1972, 253.

FURTHER DESCRIPTIVE INFORMATION

All described *Thiomicrospira* spp. are obligate chemolithotrophs, and thus use CO_2 as their main carbon source. They do not have

functional citric acid or glyoxylate cycles. However, *Thiomicrospira pelophila* can assimilate small amounts of organic substrates, such as acetate, while growing autotrophically under thiosulfate limitation (Kuenen and Veldkamp, 1972). Heterotrophic growth, as reported for *Thiomicrospira thyasirae* (Wood and Kelly, 1989) could not be confirmed with a culture obtained from the Deutsche Sammlung für Mikroorganismen und Zellkulturen (DSMZ) (Kuever, unpublished results). Strains of *Thiomicrospira crunogena* can use polymetal sulfides as electron donors (Eberhard et al., 1995; Wirsen et al., 1998). Members of the genus *Thiomicrospira* require oxygen as terminal electron acceptor for respiration. Good growth occurs at low to saturated oxygen conditions.

Temperature ranges of species of this genus are from 3.5 to 40°C. At optimal pH the maximum growth rates on TP or T-ASW medium[1] at 30°C ranged from 0.3 to 0.8 h^{-1}. The optimal pH values are between 6.0 and 8.0; however, growth of particular species was reported down to values of 4.0 or up to 9.0.

On 1% (w/v) agar plates with TP medium small, smooth, whitish colonies are first obtained. Later, bigger yellowish colored colonies with a rough surface are formed due to intensive sulfur precipitation. Production and consumption of S^0 globules is both pH and thiosulfate dependent (Javor et al., 1990). Under stress conditions, pleomorphism and spirals up to 5–15 μm length were observed for *T. thyasirae* (Wood and Kelly, 1993).

Although *Thiomicrospira* was present in one freshwater habitat (Brinkhoff and Muyzer, 1997), so far, all described species and strains were isolated from marine environments. Na^+ ions are required, with an optimal concentration of around 470 mM. The named species were obtained from intertidal mud flats, a continental shelf, and deep-sea hydrothermal vents. Deep-sea strains are barotolerant, but not barophilic, and are known to excrete approximately 10% of their fixed carbon as low molecular weight organic compounds (Ruby and Jannasch, 1982; Jannasch et al., 1985; Wirsen et al., 1998).

Thiomicrospira appears to be ecologically very significant in hydrothermal vent systems (e.g., Muyzer et al., 1995; Brinkhoff et al., 1999c), while in an intertidal mud flat habitat the genus was found in much lower densities than other sulfur-oxidizing bacteria (Brinkhoff et al., 1998).

Enrichment and Isolation Procedures

Procedures for the enrichment and isolation of these organisms were described several times (Ruby et al., 1981; Kuenen et al., 1992; Brinkhoff and Muyzer, 1997). *Thiomicrospira* can be obtained after inoculation of a general marine medium for chemolithoautotrophic bacteria containing thiosulfate as the sole electron donor with a water or sediment sample. Incubation is aerobic at room temperature. After growth is obtained, indicated by a decreasing pH value, and often sulfur precipitation, an aliquot should be transferred to a 1–1.5% (w/v) agar plate, containing the same medium, to promote formation of the distinctive colony types. For some isolates enrichment by filtration of the sample before inoculation of the medium was described. A pore size of 0.22 μm was recommended for *T. pelophila* (Kuenen and Veldkamp, 1972) and one of 0.45 μm for *T. chilensis* (Brinkhoff and Muyzer, 1997).

Maintenance Procedures

Active cultures can be stored at 4°C for 2 weeks, but should then be transferred in fresh medium, to prevent acid formation that might easily result in irreversible inhibition of growth. For long-term storage, members of this genus are best maintained in liquid nitrogen or at −80°C in TP medium containing 20% (v/v) glycerol or 5% (v/v) DMSO (final concentration). They can be subcultured on mineral salts medium with sulfide, thiosulfate, or S^0.

Procedures for Testing Special Characters

Two oligonucleotide probes specific for the genus *Thiomicrospira* were designed targeting the 16S rRNA gene (Brinkhoff and Muyzer, 1997). The probes are located at positions 128–145 (TMS128F: 5′-GAA TCT RCC CTT TAG TTG-3′) and 830–849 (TMS849R: 5′-CTT TTT AAT AAG RCC AAC AG-3′) according to *Escherichia coli* numbering (Brosius et al., 1981). They were checked against the small-subunit rRNA sequences stored in the Ribosomal Database Project (RDP) using the Check Probe software program (Maidak et al., 1997) and contained at least two mismatches to all non-*Thiomicrospira* sequences. The probes require a hybridization temperature of 52°C for specific dot-blot hybridization with nearly complete PCR-amplified 16S rRNA gene fragments. If both probes are used combined as PCR primers, an annealing temperature of 44°C is required for specific amplification of *Thiomicrospira* 16S rRNA genes (Brinkhoff and Muyzer, 1997).

Two slightly different versions of probe TMS849R, which differ by an A/G mismatch, were developed for use in rRNA slot-blot hybridization (TMS849A: 5′-CTT TTT AAT AAG ACC AAC A-3′; TMS849G: 5′-CTT TTT AAT AAG GCC AAC A-3′) (Brinkhoff et al., 1998). Both probes contain one mismatch to several *Thiomicrospira* sequences. The combination of both probes matches all known species. Specificity was tested with rRNA isolated from *Thiomicrospira* species having either no mismatch or one. Both probes have a T_d of 41°C. Hybridization is done at 30°C, and washing at 41°C (Brinkhoff et al., 1998).

Differentiation of the genus *Thiomicrospira* from other genera

Thiomicrospira species can be differentiated from the related genus *Thiobacillus* by their lower mol% G + C content and their higher sulfide tolerance (800–1000 μM) (Kuenen and Veldkamp, 1972; Ruby and Jannasch, 1982; Jannasch et al., 1985). Not all *Thiomicrospira* species have a spiral cell form; *T. chilensis* and *T. frisia* are rod-shaped. Therefore, morphology should not be used for distinguishing *Thiomicrospira* from thiobacilli. The most reliable method for a clear identification is the use of the genus-specific probes, as described above, or sequencing of the 16S rRNA gene followed by phylogenetic analysis.

---

1. TP (*Thiomicrospira pelophila*) medium (Kuenen and Veldkamp, 1972, modified by Brinkhoff et al., 1999b): synthetic seawater medium contained (g/l deionized water) NaCl, 25.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.5; $CaCl_2 \cdot 2H_2O$, 0.42; K_2HPO_4, 0.5; $Na_2 S_2O_3 \cdot 5H_2O$, 5.0. One ml of a trace element solution containing EDTA (Widdel and Bak, 1992) was used. Vitamin B_{12} is added after sterile filtration (final concentration 50 ng/l). Bromothymol blue (4 mg/l) is used as pH indicator. K_2HPO_4 and $Na_2S_2O_3 \cdot 5H_2O$ are autoclaved separately, each in 10% of the final volume. After autoclaving the pH is adjusted to 7.2 with sterile 0.4% (w/v) Na_2CO_3 solution.

T-ASW (thiosulfate artificial seawater) medium (Jannasch et al., 1985): synthetic seawater medium contained (g/l deionized water) NaCl, 25.0; $(NH_4)_2SO_4$, 1.0; $MgSO_4 \cdot 7H_2O$, 1.5; $CaCl_2 \cdot 2H_2O$, 0.3; KH_2PO_4, 0.42; $NaHCO_3$, 0.2; Trizma hydrochloride, 3.0; $Na_2S_2O_3$, 1.58. One ml trace element solution SL-8 (Biebl and Pfennig, 1978) was used. Phenol red (2 ml of a 0.5% [w/v] solution) is used as pH indicator. KH_2PO_4 and $Na_2S_2O_3$ are autoclaved separately, each in 10% of the final volume. After autoclaving the pH is adjusted to 7.5 with sterile 0.4% (w/v) Na_2CO_3 solution.

Taxonomic Comments

Phylogenetic analysis of nearly complete 16S rRNA gene sequences showed that all *Thiomicrospira* spp., with the exception of *Thiomicrospira denitrificans* (Timmer-ten Hoor, 1975), form a monophyletic group (bootstrap value of 100%) within the *Gammaproteobacteria* (Fig. BXII.γ.88). *T. denitrificans* belongs to the *Epsilonproteobacteria* (Muyzer et al., 1995). This organism requires reclassification as a new genus. Even though *T. denitrificans*, based on phylogenetic and physiological analysis, does not belong to the genus *Thiomicrospira*, it is listed here as a species. The same description of this organism as given by Kuenen and Robertson (1989) was used. However, its characteristics are not included in the general description of the genus *Thiomicrospira* and the specific oligonucleotides do not match the 16S rRNA gene of *T. denitrificans*.

The *Thiomicrospira* group includes *Hydrogenovibrio marinus*, which differs from *Thiomicrospira* spp. only in the ability to use hydrogen as electron donor (Table BXII.γ.50) (Nishihara et al., 1991b, 1998). Since hydrogen utilization is a ubiquitous trait among many phylogenetically diverse bacteria, hydrogen utilization alone may be insufficient to separate this organism as a separate genus.

The rod-shaped *Thiomicrospira* species and strains, i.e., *T. frisia*, *T. chilensis*, *Thiomicrospira* spp. str. Art-3, and *Thiomicrospira* spp. str. Milos T-2, form a subcluster within the *Thiomicrospira* branch. This indicates a common ancestor of these organisms (Kuever, unpublished).

The reliable differentiation of *Thiomicrospira* species requires integration of physiological and genomic data. In cases of high 16S rRNA gene homology among closely related strains, DNA–

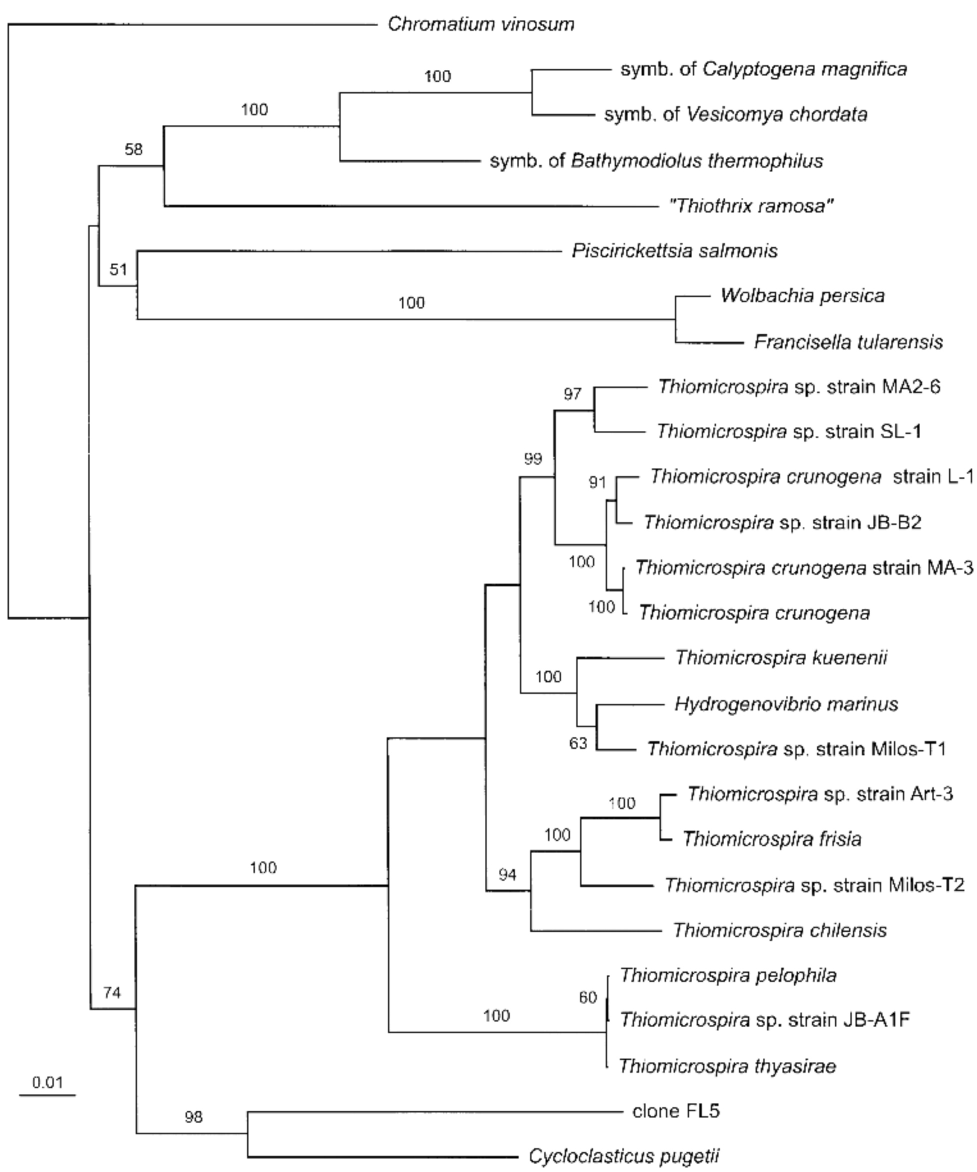

FIGURE BXII.γ.88. Neighbor joining tree based on nearly complete 16S rRNA gene sequences, showing the phylogenetic relationships between different *Thiomicrospira* spp. and closely related bacteria. The *Thiomicrospira* sequences were aligned to prealigned sequences taken from the Ribosomal Database Project (RDP; Maidak et al., 1997). *Chromatium vinosum* was taken as the outgroup. The numbers on the branches refer to bootstrap values; only values of 50% and higher are shown. Bar = 0.01 estimated nucleotide change per sequence position.

TABLE BXII.γ.50. Morphological and physiological characteristics of the species composing the genus *Thiomicrospira*, *Hydrogenovibrio marinus*, and *Thiomicrospira denitrificans*[a]

[a]Symbols: +, 90% or more strains are positive; –, 90% or more strains are negative; nd, not determined; data from Kuenen and Veldkamp, 1972, 1973; Timmer-ten Hoor, 1975; Ruby and Jannasch, 1982; Jannasch et al., 1985; Kuenen and Robertson, 1989; Wood and Kelly, 1989, 1993; Nishihara et al., 1991b, 1998; Brinkhoff et al. 1999a, 1999b; Kuever, unpublished data.

[b]The values in brackets are from the original description, determined by thermal denaturation.

[c]J. Kuever, unpublished results.

[d]In the original description Q-10 was found (Wood and Kelly, 1989); we could only detect Q-8 and traces of Q-7 (J. Kuever, unpublished results).

[e]In the original description the maximum growth rate on acetate was 0.53 (h^{-1}) (Wood and Kelly, 1989). Growth rates on thiosulfate seemed to be similar to *T. pelophila* in the range of 0.2 0.3 (Kuever, unpublished results).

[f]Brinkhoff et al., 1999a.

DNA hybridization was necessary to decide whether these strains belong to one species or not. This method revealed that *Thiomicrospira* strains, which were obtained from different hydrothermal vent systems, and which showed specific metabolic adaptations to their environments, belong to one species, *T. crunogena* (Wirsen et al., 1998). DNA–DNA hybridization also confirmed *T. pelophila*, *T. crunogena*, *T. kuenenii*, *T. frisia*, and *T. chilensis* as distinct species (Brinkhoff et al., 1999a, 1999b).

ACKNOWLEDGMENTS

The authors wish to thank Andreas Teske, Carl O. Wirsen, and Stefan Sievert for help and advice. The help of Hirofumi Nishihara and Yasuo Igarashi is greatly appreciated, because they supplied us with unpublished results and submitted manuscripts. We are grateful to Gijs Kuenen for providing the photograph of *Thiomicrospira pelophila*.

Brinkhoff, T. and G. Muyzer. 1997. Increased species diversity and extended habitat range of sulfur-oxidizing *Thiomicrospira* spp. Appl. Environ. Microbiol. *63*: 3789–3796.

Kuenen, J.G., L.A. Robertson and O.H. Tuovinen. 1992. The genera *Thiobacillus*, *Thiomicrospira*, and *Thiosphaera*. *In* Balows, Trüper, Dworkin, Harder and Schleifer (Editors), The Prokaryotes. A Handbook on the Biology of Bacteria: Ecophysiology, Isolation, Identification, Applications, 2nd Ed., Vol. III, Springer Verlag, New York. pp. 2638–2657.

List of species of the genus Thiomicrospira

1. **Thiomicrospira pelophila** Kuenen and Veldkamp 1972, 253[AL].
pe.lo′phi.la. Gr. n. *pelos* mud; Gr. adj. *phila* loving; N.L. adj. *pelophila* mud-loving.

Colonies on thiosulfate agar are small, white, and often surrounded by a halo of sulfur. On soft thiosulfate agar, colonies may be up to 1 cm in diameter and grow down into the agar as large disks. These disks are white from precipitated sulfur and only sparsely populated with bacteria. In media containing more than 0.2–0.3 mM thiosulfate, sulfur is formed. The type strain requires vitamin B_{12}; others do not. Sulfide tolerance is high in this species compared with *Thiobacillus* species (Kuenen and Veldkamp, 1972). Even though CO_2, fixed via the Calvin-Benson cycle, is the primary carbon source, small amounts of organic compounds such as acetate and succinate may serve as a

secondary source under energy-limited conditions (Kuenen and Veldkamp, 1973). See Table BXII.γ.50 for further physiological and biochemical details; Fig. BXII.γ.89 illustrates morphology and flagellation.

Isolated from a marine intertidal mud flat of the Dutch Wadden Sea.

The mol% G + C of the DNA is: 45.7 (HPLC), 44.0 (T_m).
Type strain: ATCC 27801, DSM 1534.
GenBank accession number (16S rRNA): L40809.

2. **Thiomicrospira chilensis** Brinkhoff, Muyzer, Wirsen and Kuever 1999a, 878[VP]
chi.len'sis. M.L. adj. *chilensis* from Chile, a country of South America.

Cells are rod-shaped and motile, but during late exponential growth, cells have a strong tendency to clump and to form aggregates. Strong sulfur precipitation in liquid batch cultures as *T. crunogena*. See Table BXII.γ.50 for further details. Found in sediment samples of *Thioploca* mats obtained from the Chilean coast shelf. Isolated from a sample that was filtered through a 0.45-μm pore-size filter before inoculation (Brinkhoff and Muyzer, 1997).

The mol% G + C of the DNA is: 49.9 (HPLC).
Type strain: ATCC 700858, DSM 12352.
GenBank accession number (16S rRNA): AF013975.

3. **Thiomicrospira crunogena** Jannasch, Wirsen, Nelson, and Robertson 1985, 422[VP]
cru.no.ge'na. Gr. n. *crunos* spring; Gr. v. *genomai* to be generated; Gr. part. adj. *crunogena* spring-born.

T. crunogena can withstand relatively high concentrations of sulfide, continuing to fix CO_2 at concentrations up to 800 μM. Sulfide is toxic at 2000 μM. Strong precipitation of sulfur in liquid batch cultures. Barotolerant; at 250 atm, the CO_2 fixation rate is 80% of that obtained at 1 atm. Growth does not occur at 400 atm or above. Cells are motile and vibrio shaped. For further physiological and biochemical characteristics see Table BXII.γ.50.

Isolated from a marine hydrothermal vent system (21°N, 109°W, East Pacific Rise) at a depth of 2600 m.

The mol% G + C of the DNA is: 44.2. (HPLC), 42.0 (T_m).
Type strain: ATCC 35932, DSM 12353, LMD 84.00.
GenBank accession number (16S rRNA): L40810.

Additional Remarks: Two further described *Thiomicrospira* strains belong to this species as determined by 16S rRNA gene sequence analysis and DNA–DNA hybridization (Wirsen et al., 1998): *Thiomicrospira* sp. str. L-12 (Ruby and Jannasch, 1982) and *Thiomicrospira* sp. str. MA-3 (Wirsen et al., 1993). All three strains of *T. crunogena*, but especially strain MA-3, can grow on sulfidic minerals (Eberhard et al., 1995). They also show robust growth properties compared to the other species of the genus *Thiomicrospira*. *Thiomicrospira crunogena* str. L-12 was isolated from mussel periostracum from the Galapagos Rift hydrothermal vent site and deposited under DSM 12346. The 16S rRNA gene sequence is available from GenBank under accession number L01576. *Thiomicrospira crunogena* str. MA-3 was isolated from a polymetal sulfide rock from the Mid-Atlantic Ridge TAG hydrothermal vent site and deposited under ATCC 700270 (DSM 12354). The 16S rRNA gene sequence is available from GenBank under accession number AF069959.

4. **Thiomicrospira frisia** Brinkhoff, Muyzer, Wirsen, and Kuever 1999b, 391[VP]
fri'si.a. M.L. fem. adj. *frisia* pertaining to Frisia, a coastal region in northwestern Germany and the Netherlands from where the organism was obtained.

When thiosulfate is used as the primary energy source very small amounts of sulfur and sulfite are produced. Compared to most other *Thiomicrospira* spp., sulfur precipitation in liquid medium is less obvious. Cells are rod-shaped and motile, but during late exponential growth cells have a strong tendency to clump and to form aggregates. See Table BXII.γ.50 for more details on the physiology. See Fig. BXII.γ.90A for details of the morphology.

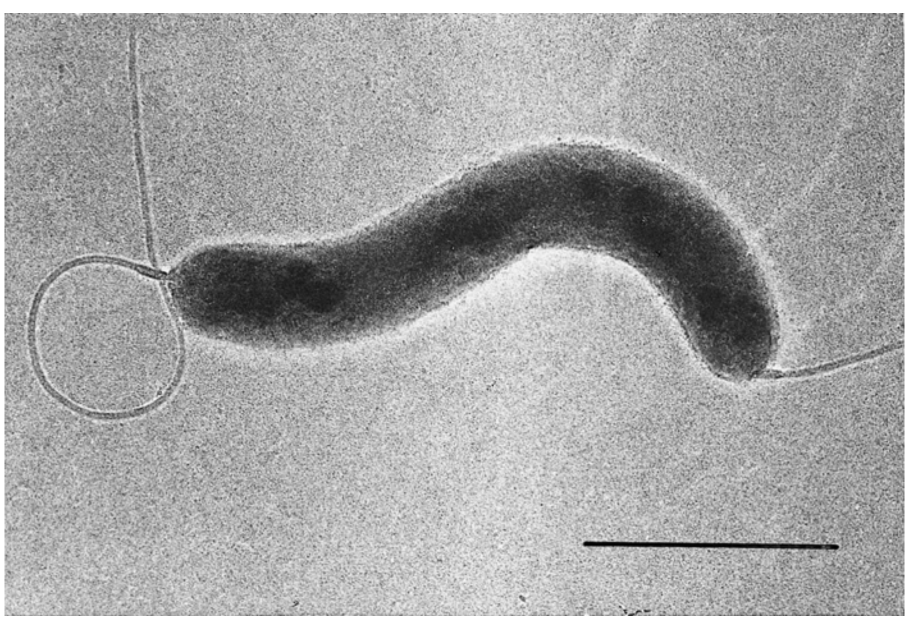

FIGURE BXII.γ.89. Electron micrograph of a *T. pelophila* cell, which was platinum-shadowed to show the shape and the flagellation. Bar = 0.5 μm.

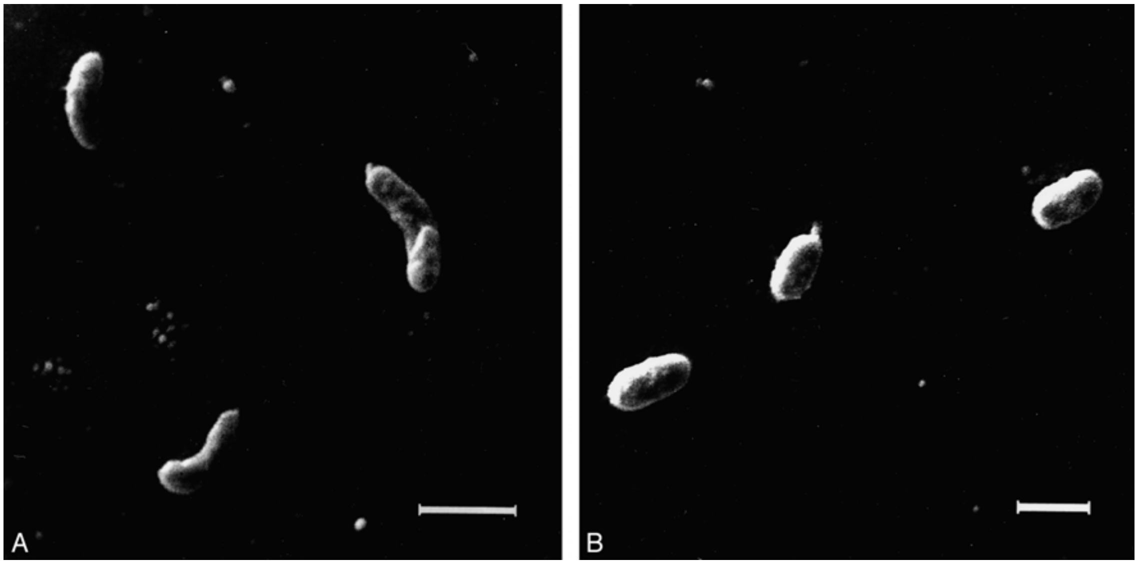

FIGURE BXII.γ.90. Electron micrographs of *T. frisia* and *T. kuenenii*to demonstrate the two morphologies found for *Thiomicrospira* spp. *A*, morphology of *T. kuenenii*, which is typical for most *Thiomicrospira* spp.; *B*, rod-like morphology of *T. frisia*. Bars = 1 μm. (Reproduced with permission from T. Brinkhoff et al., International Journal of Systematic Bacteriology *49:* 385–392, 1999, ©International Union of Microbiological Societies.)

Isolated from a marine intertidal mud flat of the German Wadden Sea.

The mol% G + C of the DNA is: 39.6 (HPLC).

Type strain: ATCC 700878, DSM 12351.

GenBank accession number (16S rRNA): AF013974.

5. **Thiomicrospira kuenenii** Brinkhoff, Muyzer, Wirsen, and Kuever 1999b, 390[VP]
kue.nen'i.i. M.L. gen. n. *kuenenii* of Kuenen; named after J.G. Kuenen, a Dutch microbiologist of the Delft School of Microbiology, who proposed the genus *Thiomicrospira*.

When thiosulfate is used as the primary energy source very small amounts of sulfur and sulfite are produced. Compared to most other *Thiomicrospira* spp., sulfur precipitation in liquid medium is less obvious. See also Table BXII.γ.50 and Fig. BXII.γ.90B. Isolated from a marine intertidal mud flat of the German Wadden Sea.

The mol% G + C of the DNA is: 42.4 (HPLC).

Type strain: ATCC 700877, JB-A1, DSM 12350.

GenBank accession number (16S rRNA): AF013978.

6. **Thiomicrospira thyasirae** (Wood and Kelly 1989) Wood and Kelly 1995, 418[VP] (Effective publication: Wood and Kelly 1993, 47) (*Thiobacillus thyasiris* Wood and Kelly 1989, 165.)
thy.a.si' rae. M.L. adj. *Thyasira* a genus of the bivalve mollusk family of the *Thyasiridae*.

Morphologically and physiologically nearly identical to *T. pelophila*. 16S rRNA gene sequences of *T. thyasirae* and *T. pelophila* are almost identical (one mismatch in 1424 bp) (Brinkhoff and Muyzer, 1997). DNA–DNA hybridization data will be required to decide whether *T. thyasirae* can be retained as a separate species. Some biochemical and physiological properties of a culture obtained from the DSMZ vary to the original description (Table BXII.γ.50). Cells exhibit pleomorphism in response to environmental conditions.

Isolated from the gills of the mussel *Thyasira flexuosa* collected from Plymouth Sound, U.K.

The mol% G + C of the DNA is: 45.6 (HPLC), 52 (T_m).

Type strain: ATCC 51452, DSM 5322.

GenBank accession number (16S rRNA): AF016046.

Other Organisms

1. *Thiomicrospira* sp. strain MA2–6 Muyzer, Teske, Wirsen and Jannasch 1995.
Vibrio-shaped isolate from a marine hydrothermal vent site at the Mid-Atlantic Ridge, (23°2′′ N, 44°57′′ W).
Deposited strain: not publicly available
GenBank accession number (16S rRNA): L40811.
Additional Remarks:

2. *Thiomicrospira* sp. strain SL-1 Brinkhoff and Muyzer 1997.
Vibrio-shaped cells isolated from a microbial mat of the hypersaline Solar Lake, Sinai, Egypt. Physiological properties similar to *T. crunogena*, but probably a different species (Kuever, unpublished). Isolated from a sample that was filtrated through a 0.45-μm pore-size filter before inoculation.
Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF013971.
Additional Remarks:

3. *Thiomicrospira* sp. strain JB-B2 Brinkhoff and Muyzer 1997.
Vibrio-shaped cells, isolated from a water sample overlying a marine intertidal mud flat of the Jadebusen Bay, Germany. High similarity (99%) of the 16S rRNA gene sequence to the sequence of *T. crunogena* and therefore probably a strain of this species (Wirsen et al., 1998).

Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF013972.
Additional Remarks:

4. *Thiomicrospira* sp. strain Milos T-1 Brinkhoff, Sievert, Kuever and Muyzer 1999c.

Vibrio-shaped isolate obtained from sediment of a marine shallow-water hydrothermal vent off the island of Milos, Greece.

Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF082327.
Additional Remarks:

5. *Thiomicrospira* sp. strain Art-3 Brinkhoff and Muyzer 1997.

Rod-shaped isolate obtained from sediment of a saline spring at the city of Artern, Germany. This organism is morphologically and physiologically similar to *T. frisia* (Kuever, unpublished).

Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF013973.
Additional Remarks:

6. *Thiomicrospira* sp. strain Milos T-2 Brinkhoff, Sievert, Kuever and Muyzer 1999c.

Rod-shaped isolate obtained from the sediment surface of a marine shallow water hydrothermal vent off the island of Milos, Greece.

Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF082328.
Additional Remarks:

7. *Thiomicrospira* sp. strain JB-AF1 Brinkhoff and Muyzer 1997.

Isolated from a sample obtained from a marine intertidal mud flat of the Jadebusen Bay, Germany. The sample was filtrated through a 0.22-μm pore-size filter before inoculation. Morphologically and by 16S rRNA gene sequence identical to *T. pelophila*.

Deposited strain: not publicly available
GenBank accession number (16S rRNA): AF013976.
Additional Remarks:

Species Incertae Sedis

1. **Thiomicrospira denitrificans** Timmer-ten Hoor 1975, 344[AL]
de.ni.tri' fi.cans. L. prep. *de* away from; L. n. *nitrum* soda; M.L. n. *nitrum* nitrate; M.L. v. *denitrifico* denitrify; M.L. part. adj. *denitrificans* denitrifying.

Colonies are brown, 1–2 mm in diameter. Sulfur is not deposited. Chemolithotrophic, obtaining energy from the oxidation of reduced sulfur compounds such as sulfide and thiosulfate. CO_2, fixed via the Calvin cycle, is the primary source of carbon. Ammonium salts serve as nitrogen source. This species is microaerophilic, only able to use oxygen as an electron acceptor when pO_2 is <0.5%. In practice, aerobic growth has been attained only in an oxygen-limited chemostat. Nitrate or nitrite can serve as electron acceptors, being reduced to molecular nitrogen. The dissimilatory nitrate reductase is constitutive. Although isolated from marine samples, this species does not have a requirement for NaCl. See Table BXII.γ.50 for further physiological details.

Found in mud of marine tidal flats where sulfide is produced.

The mol% G + C of the DNA is: 36.0 (T_m).
Type strain: ATCC 33889, DSM 1251.
GenBank accession number (16S rRNA): L40808.

Family III. **Francisellaceae** *fam. nov.*

ANDERS B. SJÖSTEDT

Fran.ci.sel.la' ce.ae. M.L. fem. n. *Francisella* type genus of the family; *-aceae* ending for the family *Francisella*.

Short, rod-shaped or coccoid cells 0.2–0.7 × 0.2–1.7 μm. Gram negative, faintly staining. Endospores are not produced. **Nonmotile. Aerobic.** Produce acid from D-glucose. **Cysteine is required for, or enhances, growth.** Weakly catalase positive. **H_2S is produced in cysteine-supplemented medium. Unique fatty acid composition**; long-chain saturated and monounsaturated C_{18} to C_{26} acids, relatively large amounts of saturated even-chain acids ($C_{10:0}$, $C_{14:0}$, and $C_{16:0}$), and two long-chain hydroxy acids ($C_{16:0\ 3OH}$ and $C_{18:0\ 3OH}$). Susceptible to tetracycline and chloramphenicol. Intracellular parasites, transmissible to a wide range of animal species, including man, and the etiological agents of the zoonotic disease tularemia. Most commonly isolated from rodents, lagomorphs, blood-sucking insects, and ticks. The family belongs to the *Gammaproteobacteria*. Signatures of *Francisella* 16S rRNA gene sequences are listed in Table BXII.γ.51. A gene encoding a 17-kDa lipoprotein of *F. tularensis* is conserved in all francisellae investigated.

The mol% G + C of the DNA is: 30–36.
Type genus: **Francisella** Dorofe'ev 1947, 176.

FURTHER DESCRIPTIVE INFORMATION

The family comprises closely related organisms within the single genus *Francisella*. The two recognized species, *F. tularensis* and *F. philomiragia*, show a 16S rRNA gene sequence similarity of ≥98.3% (Forsman et al., 1994). The family is circumscribed and readily distinguishable from other families based on a unique set of phenotypic characteristics that include a coccoidal morphology, Gram negativity, acid but no gas production from a limited number of carbohydrates, requirement for cysteine, and a unique fatty acid composition. There is no DNA relatedness between francisellae and members of other genera showing minor serological cross-reactivity (Ritter and Gerloff, 1966). This has been substantiated by phylogenetic analysis based on comparison of 16S rRNA gene sequences, demonstrating that the family is a member of the *Gammaproteobacteria* (Forsman et al., 1994). It is most closely related to, but still relatively distant from, the family *Piscirickettsiaceae*.

F. tularensis shows slow growth and usually requires cysteine

TABLE BXII.γ.51. 16S rRNA sequence signatures for the genus *Francisella*[a]

[c]Bases found in the species of *Francisella*, including *W. persica* and the symbionts isolated from *D. andersoni* and *O. moubata*.

[d]Bases found in other *Bacteria*. Letter in parentheses denote bases found in less than one-fourth of the aligned strains of *Bacteria*.

or cystine for growth. The supplements enhance, but are not required for growth of isolates of *F. tularensis* subsp. *novicida* and *F. philomiragia*. Cystine heart agar supplemented with hemoglobin, glucose cystine heart agar, or Mueller–Hinton agar supplemented with hemoglobin and IsoVitaleX are commonly used for cultivation of *F. tularensis*. Although cultivation from clinical samples of tularemia patients is often avoided due to the contagiousness of *F. tularensis*, isolation is usually possible from most types of relevant clinical specimens, e.g., wound samples, lymph node aspirates, and blood, after prolonged cultivation.

Colony-type variants of *F. tularensis*, including those associated with virulence and immunogenicity, have been described (Eigelsbach et al., 1951). Possibly, these variants can be attributed to a reversible phase variation in their lipopolysaccharide (LPS) (Cowley et al., 1996). The LPS of *F. tularensis* has been characterized and contains a unique somatic antigen (Vinogradov et al., 1991). Extracts of *F. tularensis* strains contain phosphoantigens, pyrophosphoesters bound to derivatives of uracil monophosphate or thymidine monophosphate (Poquet et al., 1998). A gene encoding a 17-kDa lipoprotein of the live vaccine strain, *F. tularensis* strain LVS, is conserved in *Francisella* species (Sjöstedt et al., 1992) and has been used both for diagnostic and taxonomic purposes (Sjöstedt et al., 1997; Niebylski et al., 1997). Francisellae are widely distributed in nature. Members of *F. tularensis* are the etiological agents of tularemia, a zoonotic disease of humans. Tularemia is transmitted by direct contact with infected animals, through contaminated water or food, or by vectors such as biting insects or ticks within endemic regions over the northern hemisphere. The disease shows epidemic outbreaks, both in humans and in animals. The bacterium is highly virulent for humans and numerous animal hosts, in particular, rodents, hares, and rabbits. Clinical manifestations in humans depend on the means of transmission. *F. tularensis* subsp. *novicida* and *F. philomiragia* have been linked to water-borne transmission and can cause disease in immunocompromised individuals.

Genus I. **Francisella** *Dorofe'ev 1947, 176*[AL]

ANDERS B. SJÖSTEDT

Fran.ci.sel'la. M.L. dim. ending *-ella*; M.L. fem. n. *Francisella* named after Edward Francis, American bacteriologist, who extensively studied the etiologic agent and pathogenesis of tularemia and is credited with naming the disease.

Short, rod-shaped or **coccoid** cells, 0.2–0.7 × 0.2 μm (*Francisella tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, and *F. tularensis* subsp. *mediasiatica*) or 0.7 × 1.7 μm (*F. philomiragia* and *F. tularensis* subsp. *novicida*) when examined during active growth, pleomorphism occurs thereafter. Gram negative, faintly staining. Endospores are not produced. **Nonmotile. Aerobic**, growth enhanced under microaerophilic conditions. Colonies are distinct, convex, pale white, and reach maximum size in 3–4 days. **Cysteine (or cystine) is required for growth (*F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, and *F. tularensis* subsp. *mediasiatica*) or enhances growth (*F. philomiragia* and *F. tularensis* subsp. *novicida*).** Weakly catalase positive. *F. tularensis* is oxidase negative and *F. philomiragia* oxidase positive (Kovacs modification). **H_2S is produced** in cysteine-supplemented medium. Strains from both species, with the exception of *F. tularensis* subsp. *mediasiatica*, produce acid but no gas from D-glucose and maltose. Urease negative and no reduction of nitrate. **Strains are characterized by a unique fatty acid composition**; long-chain saturated and monosaturated C_{18} to C_{26} acids, relatively large amounts of saturated even-chain acids ($C_{10:0}$, $C_{14:0}$, and $C_{16:0}$), and two long-chain hydroxy acids ($C_{16:0\ 3OH}$ and $C_{18:0\ 3OH}$).

Strains are susceptible to quinolones, aminoglycosides, tetracycline, and chloramphenicol. β-Lactamase positive. *F. tularensis* is a **facultative intracellular bacterium** and *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, and *F. tularensis* subsp. *mediasiatica* **cause the zoonotic disease tularemia** in humans and animals, predominantly rodents and lagomorphs. Also *F. tularensis* subsp. *novicida* may cause a tularemia-like disease. *F. philomiragia* has been associated with septicemic and pneumonic disease in humans with immunocompromised conditions.

16S rDNA sequence analysis has demonstrated that the genus belongs to the *Gammaproteobacteria*. *Francisella* strains show a high degree of 16S rRNA gene sequence similarity, ≥98.3%, and *F. tularensis* strains >99.8%. 16S rRNA gene sequence signatures of *Francisella* are shown in Table BXII.γ.51. Phylogenetically related to *Wolbachia persica* and two other endosymbionts of ticks. DNA relatedness of *F. tularensis* strains, including isolates of *F. tularensis* subsp. *novicida*, is 75–98% (65°C, hydroxyapatite method) to the type strain *F. tularensis* ATCC 6223^T. Members of *F. philomiragia* show 72–83% relatedness to the type strain *F. philomiragia* ATCC 25015^T.

Type species: **Francisella tularensis** (McCoy and Chapin 1912) Dorofe'ev 1947, 176 (*Bacterium tularense* McCoy and Chapin 1912, 61.)

FURTHER DESCRIPTIVE INFORMATION

Francisella, the only recognized genus in *"Francisellaceae"*, belongs to the *Gammaproteobacteria*. The most closely related organisms are the obligate intracellular bacterium *W. persica*, first isolated from the tick *Argas persicus* (*arboreus*), and two other endosymbionts of ticks (Fig. BXII.γ.91). *Francisella* shows the closest relationship, albeit a rather distant one, to *Piscirickettsiaceae*. The

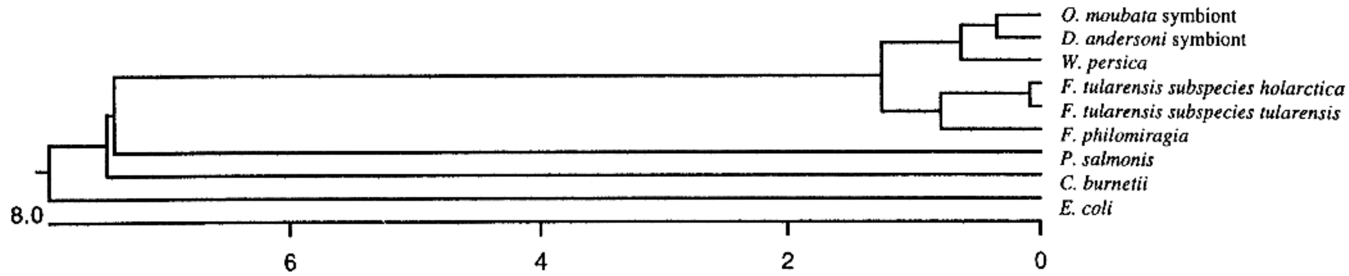

FIGURE BXII.γ.91. Evolutionary distance tree showing relationships among the recognized members of *Francisellaceae*, *Wolbachia persica*, and symbionts from the ticks *Dermacentor andersoni* and *Ornithodoros moubata*. *Escherichia coli* and *Coxiella burnetii* are included for further comparison to other members of the *Gammaproteobacteria*. The scale represents the number of nucleotide substitutions calculated against the number of compared nucleotide sites.

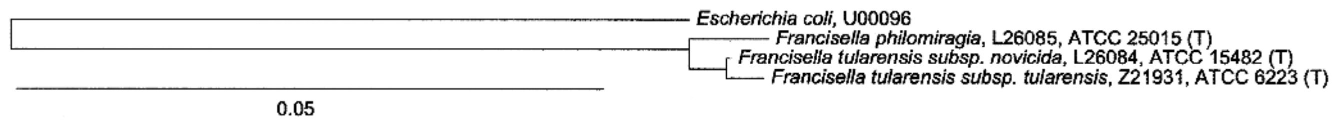

FIGURE BXII.γ.92. Phylogenetic relationships of the genus *Francisella*. The distances in the tree were calculated using 1101 positions (the least-squares method, Jukes-Cantor model). (Courtesy T. Lilburn of the Ribosomal Database Project.)

type species, *F. tularensis*, is the source of virtually all knowledge of the genus (see Fig. BXII.γ.92).

Cells of *Francisella* typically appear as short, rod-shaped or coccoid cells. They are small, singly occurring, nonmotile, and nonsporulating. Cells of *F. tularensis* are 0.2–0.7 × 0.2 μm and *F. tularensis* subsp. *novicida* and *F. philomiragia* are approximately 0.7 × 1.7 μm (Fig. BXII.γ.93). This morphology occurs typically during the logarithmic growth phase in a liquid medium. In infected tissue and during stationary growth phase, the organisms show pleomorphism. In those situations, cells often elongate, filamentous cells form, filament fragmentation occurs, and a small number of cells not larger than 300 nm are demonstrable (Ribi and Shepard, 1955). Minute forms have been shown to be infectious for mice and pass through membranes with 600 nm average pore diameter (Foshay and Hesselbrock, 1945). *Francisella* cells are faintly stained in tissue. The characteristic morphology is most readily demonstrable with a polychrome (Giemsa) stain.

Virulent strains of *F. tularensis* are surrounded by a relatively thick electron-transparent capsule that can be removed in hypertonic solutions; loss of capsule is accompanied by loss of virulence but viability is unaffected (Hood, 1977). Underlying the capsule is an outer layer surrounding the cell wall and a delicate double-layered cell wall. The lipid concentration of the capsule and cell wall is unusually high for Gram-negative bacteria. The composition is also characteristic for the genus, long-chain saturated and monosaturated C_{18} to C_{26} acids, relatively large amounts of saturated even-chain acids ($C_{10:0}$, $C_{14:0}$, and $C_{16:0}$), and two long-chain hydroxy acids ($C_{16:0\ 3OH}$ and $C_{18:0\ 3OH}$) (Jantzen et al., 1979; Hollis et al., 1989). Members of the genus also contain a ubiquinone with eight isoprene units as the major isoprenologs (Hollis et al., 1989). The live vaccine strain of *F. tularensis*, LVS, grown in a chemically defined medium, was found to have a lipid content of 21% (dry wt) and to contain phosphatidylethanolamine (76%) and phosphatidylglycerol (24%) as its two major phospholipids (Anderson and Bhatti, 1986). As opposed to other Gram-negative bacteria, all members of the genus seem to lack monounsaturated 16-carbon acid and most strains lack dodecanoic acid but possess small amounts (1–2%) of a 16-carbon aldehyde (Hollis et al., 1989).

Francisella species are strictly aerobic. *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *mediasiatica*, and *F. tularensis* subsp. *tularensis* grow more slowly and less abundantly than do isolates of *F. tularensis* subsp. *novicida* and *F. philomiragia*. *F. tularensis* is usually described as a fastidious organism since clinical isolates grow slowly and usually require cysteine or cystine for growth. These supplements enhance but are not required for growth of isolates of *F. tularensis* subsp. *novicida* and *F. philomiragia*. Cystine heart blood agar supplemented with 1% hemoglobin[1] provides excellent conditions for isolation of *F. tularensis* (Payne and Morton, 1992). Other suitable media are Mueller–Hinton agar (Baker et al., 1985)[2] supplemented with 2% IsoVitaleX and 0.025% ferric pyrophosphate, and glucose cysteine heart blood agar[3]. Glucose cysteine agar (BBL) and cystine heart agar (Difco) are two commercially produced solid media intended for cultivation of *F. tularensis*.

1. Cystine heart blood agar with hemoglobin. Suspend 102 g of cystine heart agar (Difco) in 1.0 liter of distilled water, then mix thoroughly. Heat with frequent agitation and boil for 1 min. Dispense into tubes and sterilize by autoclaving at 118–121°C for 15 min. For larger quantities, autoclave at the same temperature for 30 min. Cool to 45–48°C. Aseptically add 10 ml of hemoglobin and 50 ml of citrated bovine blood. Mix thoroughly and pour into plates. Incubate at 37°C for 24 h before use to decrease surface moisture and to test for sterility. Cystine heart agar without supplements also supports growth of *F. tularensis*.

2. Modified Mueller–Hinton II agar. Suspend 38 g of Mueller–Hinton II agar (BBL) in 1.0 liter of distilled water and mix thoroughly. Heat with frequent agitation and boil for 1 min to completely dissolve the powder. Sterilize by autoclaving at 121°C for 15 min. Aseptically add 0.1% glucose, 2% IsoVitaleX (BBL) which contains cysteine, and 0.025% ferric pyrophosphate. The pH is adjusted to 7.0 with sterile 1 N NaOH. Incubate at 37°C for 24 h before use to decrease surface moisture and to test for sterility.

3. Glucose cysteine heart blood agar. Suspend 58 g of glucose cysteine heart agar (BBL) in 1.0 liter of distilled water, then proceed as indicated in the preceding footnote. After autoclaving and cooling, aseptically add 50 ml of citrated bovine, rabbit, or sheep blood. Glucose cysteine heart agar without supplements also supports growth of *F. tularensis*.

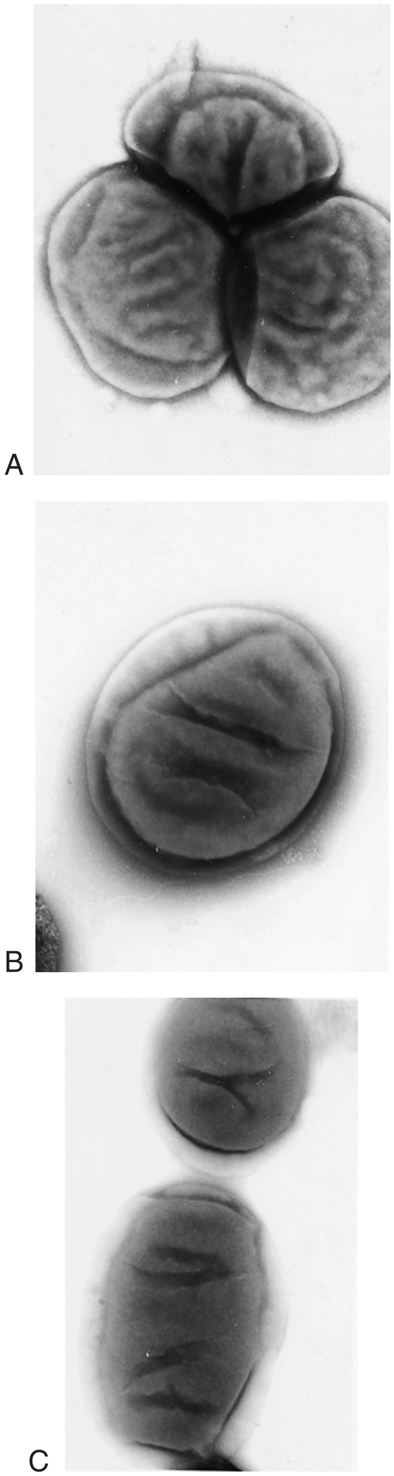

FIGURE BXII.γ.93. Electron micrographs of (*A*) the live vaccine strain (ATCC 29684) of *F. tularensis*, (*B*) the type strain of *F. tularensis* subsp. *novicida* (ATCC 15482), and (*C*) the type strain of *F. philomiragia* (ATCC 25015) (× 40,000).

There are also several reports documenting isolation of the organism on media lacking cysteine, e.g., enriched chocolate agar, Thayer–Martin agar, and Mueller–Hinton agar and in blood culture bottles (Provenza et al., 1986; Reary and Klotz, 1988; Bernard et al., 1994). In fact, cysteine enhanced, but was not critically required for, growth of a number of field isolates on agar bases supplemented with 5% blood (Payne and Morton, 1992). The low-virulence *F. tularensis* type strain, ATCC 6223, is distinctly more fastidious than virulent strains (Eigelsbach and McGann, 1984) and, in contrast to virulent strains, it may not grow on trypticase soy blood agar or brain–heart infusion blood agar (Payne and Morton, 1992). Modified Mueller–Hinton broth (Baker et al., 1985), T-medium (Tresselt and Ward, 1964), or Chamberlain's chemically defined medium (Chamberlain, 1965) can be used for liquid cultivation of *Francisella*. Provided safety precautions can be met with cultivation from samples of tularemia patients, isolation is usually possible from most types of relevant clinical specimens, e.g., wound samples, lymph node aspirates, and blood. However, the success of cultivation is dependent on rapid transportation and only some 20% of wound samples from patients with ulceroglandular tularemia yielded growth of *F. tularensis* after an average transportation time of 3–4 days (Sjöstedt et al., 1997).

Degradation of a limited number of carbohydrates occurs under suitable conditions. Acid but no gas is produced. Reactions are characteristically slow. All subspecies of *F. tularensis* except *F. tularensis* subsp. *mediasiatica* form acid from D-glucose and maltose whereas degradation of sucrose is a distinguishing feature of *F. tularensis* subsp. *novicida*. *F. tularensis* subsp. *tularensis* differs from subsp. *holarctica* by its capacity to utilize glycerol and the possession of a citrulline ureidase pathway (Marchette and Nicholes, 1961). In addition, the subsp. *mediasiatica* ferments glycerol and citrulline (Olsufjev and Meshcheryakova, 1983). *Francisella* isolates produce H_2S in media supplemented with cysteine whereas the capability to form H_2S in triple sugar iron agar is confined to *F. philomiragia*. Most isolates of *F. philomiragia* and *F. tularensis* subsp. *novicida*, but not of other subspecies of *F. tularensis*, grow in nutrient broth containing 6% NaCl. Generally, strains within each subspecies of *F. tularensis*, as well as *F. philomiragia*, show a high degree of homogeneity in their biochemical profile. However, strains of *F. tularensis* subsp. *novicida* vary in degradation of maltose and glycerol. Moreover, in contrast to an absolute majority of other strains of *F. tularensis*, *F. tularensis* subsp. *novicida* strains lack a growth requirement for cysteine. *F. philomiragia* also lacks a cysteine requirement and degrades sucrose and, in addition, is distinguished by its clearing of blood agar and by being oxidase positive (Kovacs modification). Optimal growth occurs at 37°C for *F. tularensis* and at 25°C or 37°C for *F. philomiragia* strains.

Analysis of DNA relatedness strongly indicated the presence of two species, *F. tularensis* and *F. philomiragia*, within the genus *Francisella* (Hollis et al., 1989). All data were based on relative DNA reassociation at 65°C. The type strain *F. tularensis* ATCC 6223^T showed close to 90% DNA relatedness to strains of *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *tularensis*, and *F. tularensis* subsp. *novicida*, thereby supporting the assignment of the former species *F. novicida* as a subspecies of *F. tularensis*. The calculated divergence was <2.5%. The DNA relatedness of the type strain of *F. philomiragia* ATCC 25015^T was, on average, 77% to 13 strains showing the phenotypic characteristics of the species *F. philomiragia*, with a maximum divergence of 3.5%. The type strain of *F. philomiragia* showed 39% average DNA relatedness to the *F. tularensis* type strain and seven other *F. tularensis* strains, including the reference strain of *F. tularensis* subsp. *novicida* and two *novicida*-like strains.

The 16S rDNA sequence similarities of strains within the genus *Francisella* (Forsman et al., 1994) corroborated the differ-

entiation of the genus into the species *F. tularensis* and *F. philomiragia*. In spite of clear phenotypic distinctions between the two species, the 16S rDNA sequence similarity between *F. philomiragia* and *F. tularensis* strains is high, ≥98.3%. The 16S rDNA sequence analysis strengthened the argument for assigning subsp. *novicida* as a subspecies of *F. tularensis*, the degree of 16S rDNA similarity being ≥99.8% (Forsman et al., 1994).

By PCR amplification of the rRNA gene cluster from a large number of *Francisella* strains, combined with endonuclease digestion of the resulting amplicons with *Hae*III, four patterns were demonstrable: one for *F. philomiragia*, one for *F. tularensis* subsp. *novicida*, and two for other strains of *F. tularensis* (Ibrahim et al., 1996).

A spontaneous mutant of *F. tularensis* strain LVS expressing an antigenically distinct LPS has been described (Cowley et al., 1996). This phase variation has been linked to a capacity to switch to increased induction of nitric oxide (NO) and suppression of microbial intracellular growth in rat macrophages. When the LPS returns to its original antigenic form, NO production is reduced and intracellular growth is restored (Cowley et al., 1996). A capsule-deficient mutant of *F. tularensis* strain LVS has been described. In contrast to the encapsulated vaccine strain, the capsule-deficient variant is avirulent in mice and susceptible to the bactericidal effect of nonimmune human serum (Sandström et al., 1988). A cryptic plasmid has been isolated and characterized from *F. tularensis* subsp. *novicida* (Pavlov et al., 1994) and another from *F. tularensis* subsp. *holarctica* (Zakharenko et al., 1985).

Conventional serologic procedures indicate that most *F. tularensis* strains are qualitatively similar in antigenic composition, with the exception of some strains of *F. tularensis* subsp. *novicida*. *F. tularensis* shows a minor antigenic relationship to *Brucella* (Saslaw and Carlisle, 1961) and *Yersinia pestis* (Larson et al., 1951). Immunization with the attenuated vaccine strain *F. tularensis* strain LVS protects mammals against all subspecies of *F. tularensis*. A live *F. tularensis* subsp. *novicida* vaccine protects against homologous infection and against *F. tularensis* strains of moderate virulence (Claflin and Larson, 1972). Commercial *F. tularensis* antiserum agglutinates *F. tularensis* strains of *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica*, but not all strains of *F. tularensis* subsp. *novicida* and not strains of *F. philomiragia* (Clarridge et al., 1996).

The lipopolysaccharide (LPS) of *F. tularensis* contains a unique O-antigen, though related to that of some species of *Pseudomonas aeruginosa* and *Shigella flexneri* (Vinogradov et al., 1991). It induced production of tumor necrosis factor-α, interleukin-1, and NO, but only at concentrations 100–1000 times higher than *E. coli* LPS (Sandström et al., 1992; Ancuta et al., 1996). Colony type variants of *F. tularensis*, including those associated with virulence and immunogenicity, have been described (Eigelsbach et al., 1951). Possibly, these variants can be attributed to phase variation in LPS as described above (Cowley et al., 1996).

A number of *F. tularensis* proteins have been cloned and characterized, among them a heat-labile outer membrane protein, a 17-kDa outer membrane lipoprotein, a cytoplasmic 23-kDa protein, an acid phosphatase, a triosephosphate isomerase, a putative ABC transporter protein, and the GroE and DnaK homologs (Nano, 1988; Sjöstedt et al., 1990; Mdluli et al., 1994; Zuber et al., 1995b; Reilly et al., 1996; Ericsson et al., 1997; Golovliov et al., 1997; Keeling and Doolittle, 1997). The gene encoding the 17-kDa lipoprotein of *F. tularensis* strain LVS is conserved in *Francisella* spp. although the immunoreactive proteins in *F. philomiragia* and *F. tularensis* subsp. *novicida* strains display a slightly different M_r (Sjöstedt et al., 1992). Primers specific to this gene can be used to amplify a DNA fragment from the tick endosymbiont designated DAS (Niebylski et al., 1997) and from *W. persica* (Forsman et al., 1994).

Extracts of *F. tularensis* strains have been found to contain so-called phosphoantigens, a pyrophosphoester bound to derivatives of uracil monophosphate or thymidine monophosphate, and potent inducers of Vγ9Vδ2 T cells in humans. Tularemia, but not vaccination with *F. tularensis* strain LVS, resulted in prominent expansion of Vγ9Vδ2 cells (Poquet et al., 1998).

F. tularensis shows pronounced sensitivity to aminoglycosides; streptomycin, gentamicin, and kanamycin, and also tetracyclines, chloramphenicol, and quinolones. Aminoglycosides and tetracyclines have a well-documented effect on tularemia. Notably, administration of doxycycline is recommended for at least 3 weeks (Tärnvik et al., 1997). β-Lactamase activity has been demonstrated in all *F. tularensis* isolates tested, except those from mid-Asia (Pavlovich and Mishankin, 1992). Antibiotic testing of 15 Scandinavian strains showed that all were resistant to β-lactams but had a mixed susceptibility/resistance pattern to macrolides. All strains were susceptible to gentamicin, chloramphenicol, doxycycline, and four quinolones (Scheel et al., 1993). Similar antimicrobial susceptibility was found among *F. philomiragia* strains (Hollis et al., 1989). Since quinolones show low MIC values, have good intracellular penetration, and proved to afford complete recovery in a small number of tularemia patients (Syrjälä et al., 1991; Scheel et al., 1992), they are promising agents for treatment.

F. tularensis is widely distributed in nature and is found throughout the Northern Hemisphere. Large outbreaks, especially in parts of the continental USA, the southern part of the former USSR, and northern Scandinavia, have been reported. Four subspecies, *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *mediasiatica*, and *F. tularensis* subsp. *novicida* (Olsufjev and Meshcheryakova, 1983; Hollis et al., 1989), are recognized. All have been associated with human disease, although they differ in virulence for humans and rabbits. Tularemia is transmitted by direct contact with infected animals, through contaminated water or food, or by vectors such as biting insects or ticks. Airborne transmission also occurs, especially during processing of agricultural products. The disease is often epidemic, both in humans and in animals, and clinical manifestations depend on the type of reservoir involved and the means of transmission. The bacterium has been isolated from approximately 250 wildlife species, many of which allow transmission of tularemia to man (Olsufjev, 1974).

F. tularensis subsp. *tularensis* has been isolated only in North America and is the predominant form on the continent. It is highly virulent for humans and numerous animal hosts, including domestic rabbits. Most isolates derive from ticks and rabbits. *F. tularensis* subsp. *holarctica* is spread throughout the Northern Hemisphere and causes a milder form of disease. The subspecies seems to be predominantly associated with aquatic rodents, e.g., muskrats and beaver in North America, and ground voles in the former USSR. In Europe, tularemia is most frequently observed in hares and rodents. *F. tularensis* subsp. *mediasiatica*, which has only been isolated in the Central Asian republics of the former USSR, is often found in species of *Lepus* and *Gerbillinae* and in ticks. *F. tularensis* subsp. *holarctica* and *F. tularensis* subsp. *mediasiatica* are significantly less virulent for rabbits than is *F. tularensis* subsp. *tularensis*. *F. tularensis* subsp. *tularensis* is highly infectious and even in humans, the infectious dose is 10 bacteria after

subcutaneous injection and 25 organisms when given by aerosol (McCrumb, 1961; Saslaw et al., 1961). Human-to-human transmission is extremely rare.

F. tularensis subsp. *novicida* and *F. philomiragia* are often closely linked to water-borne transmission. The reference strain of subsp. *novicida* was isolated from water in Utah (Larson et al., 1955; Owen et al., 1964) and in some cases of human disease, the suspected source has been natural water (Clarridge et al., 1996). Five isolates of *F. philomiragia*, including the type strain, were isolated from a marshy area in Utah (Jensen et al., 1969). Five out of 13 patients with a disease caused by *F. philomiragia* had a history of near-drowning (Wenger et al., 1989).

Human tularemia is an acute, febrile, zoonotic disease. The clinical picture and severity vary considerably depending on the route of infection and the virulence of the etiological organism. The incubation period is usually 3–6 days but may vary from 1 to 14 days. Before the advent of antibiotic therapy, tularemia in untreated patients in North America was associated with a mortality ranging from 5 to 30% (Dienst, 1963; Evans et al., 1985). Due to the inherently lower virulence of *F. tularensis* subsp. *holarctica* and *F. tularensis* subsp. *mediasiatica*, virtually no mortality has been recorded in Eurasia.

F. tularensis subsp. *novicida* is generally less virulent than the other subspecies and the type strain is pathogenic only for mice, guinea pigs, and hamsters, while rabbits and rats are resistant. A few cases of human disease caused by *novicida*-like strains have been reported, including one case resembling glandular tularemia, one case of typhoidal tularemia, and two cases of pneumonia in compromised patients (Hollis et al., 1989; Clarridge et al., 1996). *F. philomiragia* may cause severe disease with pneumonia and/or septicemia. A majority of cases has occurred in immunocompromised individuals with a history of granulomatous disease or near drowning (Wenger et al., 1989).

The laboratory diagnosis of tularemia relies mainly on serology. Agglutination techniques or enzyme-linked immunoassays are routinely used (Carlsson et al., 1975; Viljanen et al., 1983; Koskela and Salminen, 1984). The most common antigen is purified LPS (Carlsson et al., 1975). Seroconversion occurs normally 6–10 days after onset of disease (Koskela and Salminen, 1984). Lymphocyte stimulation tests have also been performed for diagnostic purposes (Tärnvik and Löfgren, 1975; Syrjälä et al., 1984) although not on a routine basis. In a study of 200 cases of tularemia, more than 20% of the patients showed a positive lymphocyte stimulation test during the first week of infection and virtually 100% within 2 weeks (Syrjälä et al., 1984). Cultivation can be used for identification, but due to the contagiousness of the organism, it is usually performed only at reference laboratories. Identification of *F. tularensis* in clinical specimens has been based on direct or indirect fluorescent antibody techniques (Prochazka, 1966; Karlsson and Söderlind, 1973), although not generally included as part of routine diagnostic procedures on human specimens. It is a preferred method for establishing the diagnosis on postmortem material from deceased animals (Mörner, 1981).

Antigen detection in urine and RNA hybridization on a wound specimen have been attempted as diagnostic measures (Sandström et al., 1986; Forsman et al., 1990). PCR has been applied for sensitive and specific detection of *F. tularensis* in blood from infected mice (Long et al., 1993) and for wound specimens from tularemia patients (Sjöstedt et al., 1997). The latter study showed that PCR-based detection is a promising alternative for early diagnosis of ulceroglandular tularemia. Based on the specific signatures of 16S rRNA gene sequences of *Francisella* (Table BXII.γ.51), PCR-based identification of *Francisella* strains at the genus level, and differentiation at the species level, have been developed (Forsman et al., 1994).

Enrichment and Isolation Procedures

Isolation of *F. tularensis* may be attempted from any tissue or specimen. Due to the contagiousness of the organism, all isolation procedures should be performed by trained staff working under biosafety level three conditions using efficient exhaust cabinets. Many laboratories rely only on serologic diagnosis of suspected cases of tularemia.

Detailed procedures for collection and storage of clinical specimens from patients with suspected tularemia have been described (Mollaret, 1991). Procedures for testing water samples or collection fluids from impinged air samples for the presence of *F. tularensis* have been described by Eigelsbach and McGann (1981). Successful isolation will depend on precautions taken to maintain the viability of *F. tularensis* organisms and to prevent overgrowth by normal flora. All specimens should be kept at a temperature of 10°C or lower and procedures for isolation performed as soon as possible.

Recommended media for isolation of *F. tularensis* include cystine heart blood agar supplemented with 1% hemoglobin, Mueller–Hinton agar supplemented with 2% IsoVitalex and 0.025% ferric pyrophosphate, and glucose cysteine heart blood agar. In addition, the commercially available media, glucose cysteine agar (BBL) and cystine heart agar (Difco), allow isolation of the organism from most types of clinical specimens.

Direct culture on any of the recommended media has the advantage of being more rapid and less hazardous than inoculation of susceptible laboratory animals. If specimens are from normally nonsterile sites, incorporation of antibiotics (penicillin, polymyxin B, and cycloheximide) in the medium is recommended (Berdal and Söderlund, 1977; Pavlovich and Mishankin, 1987). If adequate facilities are available for inoculating and housing infectious animals and isolation by direct culture is unsuccessful, materials can be inoculated intraperitoneally into guinea pigs or mice. Inoculation of only a few viable cells of *F. tularensis* usually results in death within 1 week. Moribund animals display gross enlargement of spleen, often 4–5 times normal size, and numerous minute, gray foci of necrosis. The presence of *F. tularensis* is readily confirmed from spleen, liver, and lung of the animals.

Maintenance Procedures

The organism can be maintained in the laboratory by transfer on the same media used for isolation. Attenuation has been observed after repeated passage and for preservation of original phenotypes of strains, plating from original isolates is recommended. Viability of isolates during long-term storage is improved by the addition of stabilizers. Recommended conditions are storage at −70°C or lyophilization in the presence of stabilizers such as 20% sucrose, 2.6% gelatin, 0.2% agar (Faibich, 1959), or 50% skim milk.

Procedures for Testing Special Characters

General characteristics Francisellae typically appear as small, coccobacillary, faintly stained Gram-negative organisms demonstrable after 2–4 days of cultivation of clinical specimens.

Media *Francisella* subspecies grow on the commercially available media, glucose cysteine agar, cystine heart agar, and

Mueller–Hinton agar, the latter with IsoVitaleX and ferric pyrophosphate as supplements. The etiological agents of tularemia, *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, and *F. tularensis* subsp. *mediasiatica*, do not grow on standard blood agar, nutrient agar, or other commonly used media lacking cysteine.

Direct identification Direct fluorescent microscopy is rarely used for diagnosis of tularemia in human specimens nowadays, but is a preferred method for establishing the diagnosis on postmortem material from deceased animals and has shown to be sensitive and specific (Mörner, 1981). A slide agglutination test based on commercial antiserum (Difco) can be used for rapid, tentative identification of *F. tularensis*.

Serology ELISA (enzyme-linked immunosorbant assay) is the standard serological test used to diagnose tularemia. Seroconversion commonly occurs within 6–10 days after onset of disease (Koskela and Salminen, 1984).

Pathology The postmortem findings of tularemia in hares and rodents are characterized by focal necrosis in liver, spleen, and bone marrow (Mörner et al., 1988). In humans, abscess necrosis of lymph nodes with or without epithelioid cell reaction is observed within one to two weeks of infection, and later caseous necrosis occurs (Sutinen and Syrjälä, 1986). These changes closely resemble those observed in tuberculosis.

Gas-liquid chromatography (GLC) GLC analysis of cellular fatty acids identifies the unique fatty acid profile characteristic of *Francisella* strains (Jantzen et al., 1979; Hollis et al., 1989). The method has been, thus far, completely specific in identifying isolates of *Francisella* at the genus level.

Molecular diagnosis Based on *Francisella*-specific 16S rRNA gene sequence signatures, PCR-based methods allowing identification of *Francisella* strains at the genus level and differentiation at the species level have been developed (Forsman et al., 1994). Another molecular target is a gene encoding a 17-kDa lipoprotein from *F. tularensis* strain LVS (Sjöstedt et al., 1990). This gene is conserved in *F. tularensis* and *F. philomiragia* isolates (Sjöstedt et al., 1992). Primer sequences are indicated in Table BXII.γ.52. Multiplex PCR-based identification of the 17-kDa lipoprotein gene and the *Francisella* 16S rRNA gene sequence has been applied on wound specimens from tularemia patients (Sjöstedt et al., 1997).

Differentiation of the genus *Francisella* from other genera

Table BXII.γ.53 indicates the characteristics useful to distinguish *Francisella* from other genera of clinically relevant, small, Gram-negative, nonsporeforming, coccobacillary bacteria pathogenic for man and other mammals. Based on DNA relatedness and 16S rRNA gene sequence analysis, no close relatives of *Francisella* are recognized (Ritter and Gerloff, 1966; Forsman et al., 1994). The requirement of *F. tularensis* strains for cysteine in growth media is a unique characteristic that distinguishes it from virtually all other clinically relevant species. It grows on media developed for isolation of legionellae. Unlike *Legionella* spp., francisellae produce acid from carbohydrates, and do not contain branched-chain fatty acids. The less fastidious species of *Francisella*, *F. philomiragia* and *F. tularensis* subsp. *novicida*, lack the requirement for cysteine and may be more difficult to differentiate from the Gram-negative genera *Pasteurella*, *Brucella*, and *Yersinia*. The latter two genera may show weak agglutination with *F. tularensis* antiserum. In contrast to the case of *Pasteurella*, *Brucella*, and *Yersinia*, a capsule is not easily demonstrable in isolates of *Francisella* and they show a weak Gram stain (Table BXII.γ.53). Other characteristic, distinguishing features of *Francisella* include weak catalase production and no production of NH_3 in liquid media. The primers indicated in Table BXII.γ.52 only give amplicons from francisellae after PCR-based amplification.

Taxonomic Comments

Circumscription As indicated in the previous edition of this *Manual*, the taxonomic position of the genus *Francisella* long remained uncertain (Eigelsbach and McGann, 1984). The highly infectious nature of these bacteria has been one of the reasons for slow development of taxonomic classification. After originally being designated *"Bacterium"*, it was subsequently placed in the genus *Pasteurella*, based on serological studies. However, DNA hybridization studies indicated that the genus was not closely related to *Pasteurella*, *Yersinia*, or the coliforms (Ritter and Gerloff, 1966). These early findings using DNA hybridization were corroborated when 16S rDNA sequence analysis demonstrated that although the genus groups within the *Gammaproteobacteria*, it shows no close relationship to other characterized genera (Forsman et al., 1994). *Francisella* is the only genus described in *"Francisellaceae"*. The closest relationship is to the intracellular bacterium *W. persica* and, outside *"Francisellaceae"*, to members of *Piscirickettsiaceae*, in particular the intracellular bacterium *Piscirickettsia salmonis*, the etiological agent of a septicemic disease in fish (Fryer et al., 1992). The cellular fatty acid composition of *Francisella* and the unusually high lipid content of the cell wall are traits distinctly different from those of other Gram-negative bacteria (Hood, 1977).

In 1959, Olsufiev et al. (1959) recognized the presence of two etiological agents of tularemia varying in virulence. The designation *F. tularensis* biovar tularensis was proposed for the organism responsible for the severe form of human illness in North America, and *F. tularensis* biovar palaearctica for the less virulent organism encountered in Europe, Asia, and North America. In 1970, Olusfiev proposed that the biovars adopt the status of subspecies and suggested the designation *F. tularensis* subsp. *holarctica* for the less virulent form (Olsufjev, 1970). Moreover, the designation *F. tularensis* subsp. *mediasiatica* for strains from the Cen-

TABLE BXII.γ.52. Nucleic acid composition of primers used in the PCR-based identification of *Francisella* isolates at the genus and species level[a]

Designation	Sequence (5′–3′)	Direction	Fragment size
F11[b]	TACCAGTTGGAAACGACTGT	Forward	1141 bp
F5	CCTTTTTGAGTTTCGCTCC	Reverse	
TUL4-435[b]	GCTGTATCATCATTTAATAAACTGCTG	Forward	428 bp
TUL4-863	TTGGGAAGCTTGTATCATGGCACT	Reverse	

[a]Adapted from Forsman et al. (1994) and Sjöstedt et al. (1997).

[b]F11 and F5 target the 16S rRNA gene. TUL4-435 and TUL4-863 target a 17-kDa lipoprotein gene. All primers anneal at 65°C.

TABLE BXII.γ.53. Differential characteristics of the genus *Francisella* and other genera of clinically relevant, small, Gram-negative, nonsporeforming coccobacillary bacteria[a]

Characteristic	*Francisella*	*Brucella*	*Pasteurella*	*Yersinia*
Mol% G + C of DNA	33–36	55–58	40–45	46–50
Cells: 0.25–0.5 μm	+[b]	−	d	−
Capsule easily demonstrated	−	−	+	+
Gram stain: weak counterstain	+	+	−	−
Strictly aerobic	+	+	−	−
CO_2 enhances growth	d	+	d	−
Optimum temperature, °C	37	37	37	25
Cysteine/cystine enhance growth	d[c]	−	−	−
Chains occur in liquid media	−	+	d	d
Carbohydrates are dissimilated	+[d]	−	+	+
Acid production from sucrose	−	−	+	d
Catalase	+[e]	+	+	+
Oxidase	d[f]	d	+	−
NH_3 produced in liquid media	−	+	+[e]	+
Sodium ricinoleate solubility	+	−	+	+
Penicillin-sensitive *in vitro*	−	−	d	d
Arthropod vectors can occur	+	−	−	+
Agglutination of *F. tularensis* antiserum	d[g]	d, weak	−	d, weak
Amplicons by use of *Francisella*-specific primers[h]	+	−	−	−

[a]Adapted from Eigelsbach and McGann (1984). For symbols see standard definitions.

[b]Cell size of tularemia-causing species in infected tissue.

[c]Absolute growth requirement for *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, and *F. tularensis* subsp. *mediasiatica* and enhance growth of *F. tularensis* subsp. *novicida* and *F. philomiragia*.

[d]Acid but no gas produced. Weak reaction and some also delayed, 3–7 d.

[e]Weak reaction.

[f]*F. tularensis* negative, *F. philomiragia* positive (Kovacs modification).

[g]No agglutination of strains of *F. philomiragia* and some of *F. tularensis* subsp. *novicida*.

[h]Primer sequences specific to 16S rDNA and a gene encoding a 17-kDa lipoprotein of *F. tularensis* are given in Table BXII.γ.52.

tral Asian republics of the former USSR was proposed. Biochemical properties, virulence, and geographical origin of strains formed the basis for this differentiation. Subdivisions of *F. tularensis* subsp. *holarctica* were also proposed (Olsufjev and Meshcheryakova, 1983). Strains were distinguished with regard to susceptibility to erythromycin and designated biovar I Ery^S and biovar II Ery^R, and Japanese strains were designated *F. tularensis* subsp. *holarctica* biovar japonica Rodionova. However, no, or very few, other phenotypic attributes support the subdivision of the subspecies. The designations type A and type B have been proposed for *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica*, respectively (Jellison, 1974).

The original strain of *F. tularensis* subsp. *novicida* was isolated from a water sample in Utah in 1951, classified in the genus *Pasteurella* in 1955 (Larson et al., 1955), and transferred to the genus *Francisella*, as *F. novicida*, in 1959 (Olsufiev et al., 1959). In 1989, it was suggested as a biogroup of *F. tularensis*, based on DNA relatedness and biochemical characteristics (Hollis et al., 1989); the 16S rDNA sequences of *F. tularensis* subsp. *novicida* and *F. tularensis* subsp. *tularensis*are also very similar (Fig. BXII.γ.92). Members of *F. tularensis* subsp. *novicida* have less fastidious metabolic requirements than members of the other three subspecies. Despite differences in growth requirements and some metabolic reactions, the placement of *F. novicida* as a subspecies of *F. tularensis* is strongly supported. Analysis of fatty acid profiles showed *F. novicida* to be similar to members of the species *F. tularensis*; the two species also shared more than 75% DNA relatedness (Hollis et al., 1989). Moreover, an almost complete identity in 16S rDNA sequences between the two species has been demonstrated (Forsman et al., 1994). Although the type strain is considered nonpathogenic for humans and shows low virulence for mice, *novicida*-like isolates have been identified as the etiological agents of severe diseases in man (Hollis et al., 1989; Clarridge et al., 1996). The relationship between *F. tularensis* subsp. *novicida* strains and other members of *F. tularensis* is also supported by the fact that *F. tularensis* subsp. *novicida* could be transformed with DNA from *F. tularensis* strain LVS (Anthony et al., 1991). In summary, *F. tularensis* subsp. *novicida* demonstrates heterogeneity with regard to virulence and metabolic characteristics but displays the characteristic fatty acid profile of *F. tularensis*, >70% DNA relatedness, and almost complete 16S rRNA gene sequence similarity to other members of the species.

F. philomiragia was originally designated *Yersinia philomiragia* (Jensen et al., 1969) but subsequent analysis showed no relationship to other members of the genus *Yersinia* (Ursing et al., 1980b) and in the latest version of the *Manual*, it was considered a species *incertae sedis* misclassified in that genus (Bercovier and Mollaret, 1984). In 1989, transfer to the genus *Francisella* based on DNA relatedness and fatty acid analysis was proposed, resulting in the designation *F. philomiragia* comb. nov. (Hollis et al., 1989). The species shows a high 16S rRNA gene sequence similarity to, and the unique fatty acid profile typical of, strains of *F. tularensis*, but is distinguished from most *F. tularensis* strains by its ability to degrade certain carbohydrates and by having no requirement of cysteine for growth.

Anticipated changes The species *W. persica* described under the section "*species incertae sedis*" and the two other symbionts of ticks described in the section "Other organisms" all show the unique 16S rRNA gene sequence signatures of *Francisella*. Thus, they should be included as members of *Francisella* in the future (Fig. BXII.γ.91). At present, insufficient data for determining their relationship at the species level exist.

ACKNOWLEDGMENTS

I thank Arne Tärnvik and Gunnar Sandström for critically reviewing this manuscript, Thomas Svensson for help with sequence analyses, Lenore Johansson for taking electron micrographs, and Stig Granström for advice on agar media. The literature search for this chapter was concluded on 30 April, 1998.

DIFFERENTIATION OF THE SPECIES OF THE GENUS *FRANCISELLA*

Differential characteristics of the species and subspecies of *Francisella* are presented in Tables BXII.γ.54 and BXII.γ.55.

List of species of the genus Francisella

1. **Francisella tularensis** (McCoy and Chapin 1912) Dorofe'ev 1947, 176[AL] (*Bacterium tularense* McCoy and Chapin 1912, 61.)

tu.la.ren' sis. M.L. adj. *tularensis* tularensis pertaining to Tulare County, California, where the disease was first described in rodents.

The characteristics of relevance for identification are as listed in Table BXII.γ.54 and other characteristics are given in Table BXII.γ.55. Four subspecies, *F. tularensis* subsp. *tularensis*, *F. tularensis* subsp. *holarctica*, *F. tularensis* subsp. *mediasiatica*, and *F. tularensis* subsp. *novicida*, are recognized; these are differentiated by the characteristics listed in Tables BXII.γ.54 and BXII.γ.55. Other differences are related to geographical origin of strains of the subspecies.

The mol% G + C of the DNA is: 34 (T_m, Bd).

Type strain: B38, ATCC 6223.

GenBank accession number (16S rRNA): Z21931, Z21932.

Additional Remarks: Strain B38 is an avirulent strain with more fastidious growth requirements and a greater tendency towards variation in colony type than is found in virulent strains.

a. **Francisella tularensis** *subsp.* **tularensis** (McCoy and Chapin 1912) Dorofe'ev 1947, 176[AL] (*Bacterium tularense* McCoy and Chapin 1912, 61.)

Characteristics distinguishing this subspecies from the other subspecies are indicated in Tables BXII.γ.54 and BXII.γ.55. Highest virulence of all subspecies, most readily demonstrable in higher mammals and man. Produce acid but no gas from maltose, D-glucose, and glycerol. No degradation of lactose and sucrose. Possession of a citrulline ureidase pathway. Isolates have been found only in North America.

TABLE BXII.γ.54. Characteristics of diagnostic value in identifying the genus *Francisella* and its species and subspecies[a,b]

Characteristics	*F. tularensis* subsp. *tularensis*	*F. tularensis* subsp. *holarctica*	*F. tularensis* subsp. *mediasiatica*	*F. tularensis* subsp. *novicida*	*F. philomiragia*

Median infectious dose for mice, $<10^3$	+	+	+	−	nt

[a]For symbols, see standard definitions; nt, not tested.

[b]Data from Eigelsbach and McGann (1984), Hollis et al., (1989), and Clarridge et al. (1996).

[c]A majority of strains reportedly grow under these conditions.

The mol% G + C of the DNA is: 34.(T_m).

Type strain: GIEM Schu, ATCC 6223.

GenBank accession number (16S rRNA): Z21931, Z21932.

Additional Remarks: Virulent strains, such as SCHU, are available only from individual investigators.

b. **Francisella tularensis** *subsp.* **holarctica** (ex Olsufiev, Emelyanova and Dunaeva 1959) Olsufjev and Meshcheryakova 1983, 872[VP]
hol.arc′ti.ca. Gr. prep. *holos* whole; Gr. n. *actos* the great and little bear constellations; M.L. adj. *holarctica* generally distributed in the arctic regions.

Characteristics distinguishing this subspecies from the other subspecies are indicated in Tables BXII.γ.54 and BXII.γ.55. Isolates show lower virulence than isolates of *F. tularensis* subsp. *tularensis.* Minimum infectious dose $<10^3$ for mice and LD_{50} $>10^6$ for rabbits. Produce acid but no gas from maltose and D-glucose. No degradation of lactose, glycerol, and sucrose. Isolates have been found on all continents throughout the Northern Hemisphere.

The mol% G + C of the DNA is: 34 (T_m).

Type strain: GIEM 503.

Additional Remarks: Strain GIEM 503 is the attenuated live vaccine strain.

c. **Francisella tularensis** *subsp.* **mediasiatica** (Aikimbaev 1966) Olsufjev and Meshcheryakova 1983, 872[VP]
med.i.as.i.a′ti.ca. Gr. adj. *media* middle; Gr. adj. *asiatica* Asian; M.L. adj. *mediasiatica* pertaining to mid-Asia.

Characteristics distinguishing this subspecies from the other subspecies are indicated in Tables BXII.γ.54 and BXII.γ.55. Isolates show lower virulence than isolates of *F. tularensis* subsp. *tularensis.* Minimum infectious dose $<10^3$ for mice and LD_{50} $>10^6$ for rabbits. Produce acid but no gas from glycerol. No degradation of lactose, sucrose, maltose, and D-glucose. Isolates have been found only in the Central Asian republics of the former USSR, in particular in the valleys and deltas of the rivers Amu-Darja, Ili, and Tshu.

The mol% G + C of the DNA is: unknown.

Type strain: 543.

Additional Remarks: Strain 543 is available from the Gamaleya Institute of Epidemiology and Microbiology, Academy of Medical Sciences, Moscow, Russia (alternative designation FSC147 is available at the Institute of Microbiology, FOA, Umeå, Sweden). It was isolated in 1965 in the Alma-Ata region, Kazakhstan.

d. **Francisella tularensis** *subsp.* **novicida** *subsp. nov.* (Larson, Wicht and Jellison 1955) (*Francisella novicida* (Larson, Wicht and Jellison 1955) Olsufiev, Emelyanova and Dunaeva 1959, 146[AL]; *Pasteurella novicida* Larson, Wicht and Jellison 1955, 253.)
no.vi′ci.da. L. adj. *novus* new; L. v. suff. *-cida* from L. v. *caedo* to cut, kill; M. L.n. *novicida* new killer.

Characteristics distinguishing this subspecies from the other subspecies are indicated in Tables BXII.γ.54 and BXII.γ.55. It was originally considered a separate species, *F. novicida* (Olsufiev et al. 1959). However, Hollis et al. (1989) showed by DNA relatedness studies that isolates of this species were indistinguishable from the type strain of *F. tularensis* and proposed that it be designated a biogroup of *F. tularensis.* It displays the characteristic fatty acid profile of *F. tularensis*, >70% DNA relatedness, and almost complete 16S rRNA gene sequence similarity to other subspecies of *F. tularensis.* The assignment of *F. novicida* as a distinct subspecies is supported by its less fastidious growth requirements, including lack of cysteine requirement, degradation of sucrose, unique morphology, and lower virulence as compared to the other subspecies of *F. tularensis.*

F. tularensis subsp. *novicida* is often closely linked to water-borne transmission. The type strain of *F. tularensis* subsp. *novicida* was isolated from water in Utah (Larson et al., 1955) and in some cases of human disease, the suspected source has been natural water (Clarridge et al., 1996). Isolates show lower virulence than those of other subspecies and there are only a few documented cases of human disease caused by isolates of the subspecies (Hollis et al., 1989; Clarridge et al., 1996). Unlike

other subspecies, growth is enhanced by, but not absolutely dependent on, the presence of cysteine in media. Another characteristic distinguishing the subspecies is growth in nutrient broth containing 6% NaCl. Produce acid but no gas from sucrose and D-glucose, but no degradation of lactose. Some isolates produce acid from glycerol and maltose. Not all isolates are agglutinated by commercially available antiserum against *F. tularensis*. Isolates have been found only in North America.

The mol% G + C of the DNA is: 34 (T_m).

Type strain: ATCC 15482 (type strain).

GenBank accession number (16S rRNA): L26084.

Additional Remarks: The type strain was isolated from a water sample from Ogden Bay, Utah in 1951 (patient died Larson et al., 1955).

2. **Francisella philomiragia** (Jensen, Owen and Jellison 1969, 1237) Hollis, Weaver, Steigerwalt, Wenger, Moss, and Brenner 1990, 105[VP] (Effective publication: Hollis, Weaver, Steigerwalt, Wenger, Moss and Brenner 1989, 1601) (*Yersinia philomiragia* Jensen, Owen and Jellison 1969, 1237.)
phi.lo.mi.ra′gi.a. Gr. adj. *philos* loving; M.L. n. *miragia* plural of Latinized English word mirage; *philomiragia* loving mirages, because of the mirages observed in the area where the first isolations of this species were made.

The characteristics are listed in Tables BXII.γ.54 and BXII.γ.55. The name *Y. philomiragia* was proposed by Jensen et al. (1969) for a small Gram-negative bacillus isolated in 1959 from a dying muskrat found in a marshy area in Utah. The species description was based on this strain and four other strains isolated from water samples in the same area in 1960. Because of morphological resemblance to *Y. pestis* and some degree of DNA relatedness to *Y. pestis* (Ritter and Gerloff, 1966), the organism was assigned to the genus *Yersinia*. Later studies indicated, however, no significant DNA relatedness between *Y. philomiragia* and other *Yersinia* species, other members of the *Enterobacteriaceae*, or *Pasteurella multocida* (Ursing et al., 1980b). Hollis et al. (1989) reviewed data on 14 *Y. philomiragia* strains isolated from human specimens. The biochemical characteristics, fatty acid composition, and DNA relatedness of these strains and the five original strains demonstrated a close relationship at the species level and supported placement of this species in the genus *Francisella*.

F. philomiragia has been isolated from water, muskrats, and humans in North America and Europe. It rarely causes human disease, but serious infections may occur. Wenger et al. (1989) reviewed case reports of 14 patients infected with *F. philomiragia*. A majority of patients belonged to two risk groups. Patients with chronic granulomatous disease and near-drowning victims. Pneumonia and fever-bacteremia were reported in most patients and one patient died.

The mol% G + C of the DNA is: 34 (T_m).

Type strain: ATCC 25015, DSM 7535.

Additional Remarks: The type strain is the original isolate from a muskrat in Utah (Jensen et al., 1969).

Other Organisms

1. *Dermacentor andersoni* symbiont Niebylski, Peacock, Fischer, Porcella, and Schwan 1997, 3933 and *Ornithodoros moubata* symbiont Noda, Munderloh, and Kurtti 1997, 3926.

By analysis of their 16S rDNA sequences, two endosymbionts of ticks have been found to be phylogenetically related to members of the genus *Francisella*. An endosymbiont (DAS) present in >90% of isolates of the wood tick *D. andersoni* from Montana (Niebylski et al., 1997) and one found in the ovaries and Malpighian tubules from the African soft tick *O. moubata* (Noda et al., 1997) show ≥97.2% 16S rRNA gene sequence similarity to *F. tularensis* and *F. philomiragia*, and ≥99.4% similarity to *W. persica*. The DAS organism has been shown to cross-react in fluorescent antibody tests with *W. persica* (Burgdorfer et al., 1973). It can be cultivated in chicken embryo cell cultures and in Vero cells (Niebylski et al., 1997), and grows well in guinea pigs and golden hamsters, killing the animals when high inocula are given (Burgdorfer et al., 1973). The data generated so far showing the immunological cross-reactivity and almost complete identity with regard to 16S rRNA gene sequence (Fig. BXII.γ.91) demonstrate that the *D. andersoni* symbiont and *W. persica* are closely related. However, due to lack of DNA relatedness data, it cannot be concluded that they belong to the same species. Moreover, the 16S rRNA gene sequences of the *D. andersoni* and *O. moubata* endosymbionts show high similarity, 99.3%, to those of *Francisella* isolates and a parsimony analysis demonstrates a close relationship (Fig. BXII.γ.91). The two endosymbionts and *W. persica* all harbor the 16S rRNA sequence signatures of *Francisella* (Table BXII.γ.51). Thus, the data available at present support their membership in *Francisella* though, due to the lack of DNA relatedness data, their exact relationship at the species level cannot be determined.

Species Incertae Sedis

1. **Wolbachia persica** Suitor and Weiss 1961, 105[AL]
per′si.ca. L. fem. adj. *persica* from the specific epithet of the reputed host tick, *Argas persicus* (later reclassified as *A. arboreus*).

The name *W. persica* was proposed by Suitor and Weiss (1961) for a coccoid, Gram-negative bacillus first isolated from the tick *Argas persicus* feeding on the buff-backed heron, *Bubulcus ibis*, in Egypt. Because of morphological resemblance, Gram-negative staining, and an arthropod association, the organism was assigned to the genus *Wolbachia*. In 1989, an analysis of 16S rRNA gene sequences of members of the *Rickettsiae* demonstrated that *W. persica* had been misclassified and instead was a member of the *Gammaproteobacteria* (Weisburg et al., 1989). Subsequent analysis indicated that it has a close relationship to members of the genus *Francisella* (Forsman et al., 1994).

W. persica can be cultivated in the yolk sac of chicken embryos, where it grows profusely and kills the embryos in 5–10 days, depending on the dose of inoculum (Burgdorfer et al., 1973). It also grows well in several types of mammalian cells or insect cell cultures. An antigenically related organism was isolated from the hard tick *Dermacentor andersoni* collected in Montana (Burgdorfer et al., 1973) and further characterized by Niebylski et al. (1997) (see Other Organisms).

W. persica has been isolated by removing and triturating

the Malpighian tubules from ticks (Suitor and Weiss, 1961). After resuspension in a salt solution, this mixture was inoculated into chicken embryos via the yolk sac. Dying embryos are examined for the presence of coccoid bodies, which are most clearly visualized by Giemsa staining following Carnoy's fixation. For the production of seed and other tests, the isolates are passaged in eggs. *W. persica* metabolizes D-glucose, as well as serine, glutamine, and other substrates, including glutamate (Weiss et al., 1962). Erythromycin, chloramphenicol, tetracycline, and *p*-aminobenzoic acid inhibit growth in chicken embryos. The viability of a suspension of *W. persica* in sucrose, phosphate buffer, glutamate solution ([Bovarnick et al., 1950]) was retained for a decade at −70°C.

W. persica displays the unique 16S rRNA sequence signatures of *Francisella* (Table BXII.γ.51), supporting its placement in the genus *Francisella*. The 16S rRNA gene sequence shows high similarity to those of two symbionts of *D. andersoni* and *Ornithodoros moubata*, and the three organisms are located on the same branch of the phylogenetic tree, showing their close relationship (Fig. BXII.γ.51). However, the lack of DNA relatedness data hinders determination of the relationship between *W. persica*, the two tick endosymbionts, and *Francisella* spp. at the species level.

The mol% G + C of the DNA is: 30 (T_m, Bd) (Kingsbury and Weiss, 1968).

Type strain: ATCC VR-331.

GenBank accession number (16S rRNA): M21292.

ATCC VR-331 was the first *Argas persicus* (*A. arboretus*) isolate (Suitor and Weiss, 1961).

Order VI. **Legionellales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Le.gi.on.el.la′ les. M.L. n. *Legionella* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Legionellales* the *Legionella* order.

The order *Legionellales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Legionellaceae* and *Coxiellaceae*.

Facultative (*Legionellaceae*) and obligate (*Coxiellaceae*) intracellular parasites infecting protozoa, invertebrates, animals, and man.

Type genus: **Legionella** Brenner, Steigerwalt and McDade 1979, 658.

Family I. **Legionellaceae** Brenner, Steigerwalt and McDade 1979, 658[AL]

Washington C. Winn, Jr.

Le.gi.on.el.la′ ce.ae. M.L. n. *Legionella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Legionellaceae* the *Legionella* family.

Rods 0.3–0.9 × 2–20 µm or more. Do not form endospores or microcysts. Not encapsulated. Not acid-fast in culture. **Gram negative.** Most species are motile by one, two, or more straight or curved polar or lateral flagella; nonmotile strains of motile species are occasionally seen and motility may be lost *in vitro*. **Aerobic. L-cysteine-HCl and iron salts are required for growth.** Catalase positive; oxidase negative or weakly positive. Nitrates are not reduced. Urease negative. Gelatin is liquefied by most species. **Chemoorganotrophic**, using amino acids as carbon and energy sources. **Carbohydrates are neither fermented nor oxidized** (Tables BXII.γ.56 and BXII.γ.57). **Branched chain fatty acids** predominate in whole cell hydrolysates (Table BXII.γ.58). All species contain ubiquinones with 9–14 isoprene units in the side chains (Table BXII.γ.59). Isolated from surface water, mud or moist soil, thermally polluted lakes and streams, and potable water systems. Associated with free-living environmental amoebae. There is no known soil or animal source. Pathogenic or potentially pathogenic for humans. Isolated from sputum, bronchoalveolar lavage washings, lung tissue, pleural fluid, pericardial fluid, blood, heart valves, abscesses, and prosthetic devices.

Growth of stock cultures obtained from humans occurs at temperatures between 25 and 43°C, but not at 50°C. The optimum temperature is 36° ± 1°C (Weaver and Feeley, 1979; Thacker et al., 1981); however, in nature, the optimum growth temperature may be 45°C or higher (Fliermans et al., 1981; Orrison et al., 1981). The optimum pH for growth of legionellae is 6.8–7.0 (Feeley et al., 1978).

The mol% G + C of the DNA is: 38–52.

Type genus: **Legionella** Brenner, Steigerwalt and McDade 1979, 658.

Further descriptive information

Analysis of highly conserved sequences of 16S RNA has established that the family *Legionellaceae* forms a subline within the *Gammaproteobacteria* (Fry et al., 1991b; Hookey et al., 1995, 1996; Birtles et al., 1996; Riffard et al., 1998); the two closest relatives are *Coxiella burnetii* and *Wolbachia persica*. The relationships among strains, as determined by 16S rRNA analysis, support the proposal that a single genus, *Legionella*, be included in the family, *Legionellaceae*. Over the succeeding years, usage among the microbiology community has established the precedence of the single genus approach.

The family contains one genus, *Legionella*, with more than 40 species. The number will undoubtedly continue to expand, because a number of unnamed species have been detected by DNA–DNA hybridization (D.J. Brenner, personal communication). All species tested grow in free-living amoebae, and at least one species has been isolated only in amoebae (Rowbotham, 1983). The family is circumscribed and readily distinguishable from other families on the basis of a unique set of phenotypic characteristics

the Malpighian tubules from ticks (Suitor and Weiss, 1961). After resuspension in a salt solution, this mixture was inoculated into chicken embryos via the yolk sac. Dying embryos are examined for the presence of coccoid bodies, which are most clearly visualized by Giemsa staining following Carnoy's fixation. For the production of seed and other tests, the isolates are passaged in eggs. *W. persica* metabolizes D-glucose, as well as serine, glutamine, and other substrates, including glutamate (Weiss et al., 1962). Erythromycin, chloramphenicol, tetracycline, and *p*-aminobenzoic acid inhibit growth in chicken embryos. The viability of a suspension of *W. persica* in sucrose, phosphate buffer, glutamate solution ([Bovarnick et al., 1950]) was retained for a decade at −70°C.

W. persica displays the unique 16S rRNA sequence signatures of *Francisella* (Table BXII.γ.51), supporting its placement in the genus *Francisella*. The 16S rRNA gene sequence shows high similarity to those of two symbionts of *D. andersoni* and *Ornithodoros moubata*, and the three organisms are located on the same branch of the phylogenetic tree, showing their close relationship (Fig. BXII.γ.51). However, the lack of DNA relatedness data hinders determination of the relationship between *W. persica*, the two tick endosymbionts, and *Francisella* spp. at the species level.

The mol% G + C of the DNA is: 30 (T_m, Bd) (Kingsbury and Weiss, 1968).

Type strain: ATCC VR-331.

GenBank accession number (16S rRNA): M21292.

ATCC VR-331 was the first *Argas persicus* (*A. arboretus*) isolate (Suitor and Weiss, 1961).

Order VI. **Legionellales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Le.gi.on.el.la' les. M.L. n. *Legionella* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Legionellales* the *Legionella* order.

The order *Legionellales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the order contains the families *Legionellaceae* and *Coxiellaceae*.

Facultative (*Legionellaceae*) and obligate (*Coxiellaceae*) intracellular parasites infecting protozoa, invertebrates, animals, and man.

Type genus: **Legionella** Brenner, Steigerwalt and McDade 1979, 658.

that include Gram negativity, nonfermentative metabolism, requirement for L-cysteine and iron salts, and predominantly branched-chain cellular fatty acids. Relatively large amounts of branched chain and hydroxy-substituted branched chain fatty acids are found in flavobacteria, but these organisms were shown by DNA–DNA hybridization to be unrelated to legionellae. DNA–DNA hybridization was also used to rule out relatedness between legionellae and members of other families that resemble *Legionellaceae* in some phenotypic characteristics (Brenner et al., 1979).

Legionellae in formalin-fixed, paraffin-embedded tissue may not be demonstrable with the staining techniques usually employed histologically. The simplest means for demonstrating legionellae in tissue is to prepare imprint smears of the fresh cut surface of the tissue, after which the smears are stained by Gram's method. If sufficient numbers of organisms are present, they may be seen in tissue sections using one of the variations of the tissue Gram stain; e.g., the Brown and Hopps stain, or even hematoxylin and eosin. One of the silver impregnation stains (Warthin-Starry, Steiner, or Dieterle), designed originally for spirochetes, provides a more sensitive means to demonstrate legionellae in paraffin-fixed tissue (Chandler et al., 1977; van Orden and Greer, 1977). The Gimenez stain, designed for rickettsiae, has been used to color *Legionella* cells in secretions and imprint smears from unfixed tissue (Greer et al., 1980). The Gimenez method employs carbol fuchsin, and the sensitivity of Gram's stain may be improved without overstaining inflammatory cells by adding 0.05% carbol fuchsin to the saffranin counterstain (W.C. Winn, Jr., personal observation). All of these histochemical stains, which have varying degrees of sensitivity for detecting bacteria, are completely nonspecific; they provide information about the morphology of the bacterial cells at the light microscopic level.

Bacterial cells have vacuoles that stain with Sudan black B and may contain poly-β-hydroxybutyrate (Chandler et al., 1979). Diaminopimelic acid has been demonstrated in the cell wall (Guerrant et al., 1979). Some species show a blue-white or red autofluorescence under long wavelength (365 nm) ultraviolet light (Tables BXII.γ.56 and BXII.γ.57), and many strains of approximately half of the recognized species produce a water-soluble, brown pigment on tyrosine-containing media (Baine et al., 1978).

The term legionellosis is used by many to indicate all infections caused by legionellae. Strains of approximately 50% of the recognized species have been implicated in human disease, usually pneumonia. All species should be considered potential pathogens if the immunologic, inflammatory, and/or nonspecific defenses of the patient are sufficiently compromised. Pneumonia caused by *L. pneumophila* is commonly referred to as Legionnaires' disease (Fraser et al., 1977) and pneumonia due to *L. micdadei* has been referred to as Pittsburgh pneumonia (Pasculle et al., 1980). Several *Legionella* species, including *L. pneumophila*, *L. micdadei*, *L. feeleii*, and *L. anisa*, can also cause a mild, nonpneumonic, febrile disease termed Pontiac fever (Glick et al., 1978; Herwaldt et al., 1984a; Goldberg et al., 1989; Fields et al., 1990).

WASHINGTON C. WINN, JR.

Le.gi.on.el′ la. M.L. n. *legio* legion or army; M.L. dim. ending *-ella*; M.L. fem. n. *Legionella* small legion or army.

As the only genus in the family, the definition of *Legionella* is identical to that of *Legionellaceae*. **Aerobic. L-cysteine-HCl and iron salts are required for growth.** Oxidase negative or weakly positive. Nitrates are not reduced. Urease negative. Gelatin is liquefied by most species. Chemoorganotrophic, using amino acids as carbon and energy sources. **Carbohydrates are neither fermented nor oxidized** (Tables BXII.γ.56 and BXII.γ.57). **Branched chain fatty acids** predominate in whole cell hydrolysate (Table BXII.γ.58). All species contain ubiquinones with 9–14 isoprene units in the side chains (Table BXII.γ.59).

The mol% G + C of the DNA is: 38–52.

Type species: **Legionella pneumophila** Brenner, Steigerwalt and McDade 1979, 658.

FURTHER DESCRIPTIVE INFORMATION

Analysis of highly conserved sequences of 16S rRNA has established that the genus *Legionella* forms a subline within the *Gammaproteobacteria* (Fry et al., 1991b; Birtles et al., 1996); the two closest relatives are *Coxiella burnetii* and *Wolbachia persica*. The relationships among strains, as determined by 16S rRNA analysis, support the proposal that a single genus, *Legionella*, be included in the family *Legionellaceae* (Fry et al., 1991a). Genetic relationships among the species of *Legionella* indicate subgroups within some species (Fry et al., 1991b; Hookey et al., 1995, 1996; Birtles et al., 1996; Riffard et al., 1998) and subspecies within *L. pneumophila* (Brenner et al., 1988c) As a generalization, the species that exhibit blue-white autofluorescence under long-wavelength ultraviolet light (Wood′s Lamp) tend to be most closely related to each other (Hookey et al., 1996), and the two species that fluoresce red are close relatives. Interestingly, *L. wadsworthii* appears in the blue-white fluorescent clade, although it does not exhibit autofluorescence. Hookey et al. (1996) suggest that *L. wadsworthii* may be descended from an autofluorescent ancestor. By analysis of 16S rRNA, Hookey et al. (1995) were able to distinguish all but seven *Legionella* species from each other. The indistinguishable species were *L. erythra* from *L. rubrilucens* (red-

fluorescing species), *L. anisa* or *L. cherrii* from *L. tucsonensis* (blue-white fluorescing species), and *L. quateirensis* from *L. shakespearei*. Riffard et al. (1998) have grouped closely related species into three phylogenetic groups, based on intergenic 16S-23S ribosomal spacer PCR analysis (Table BXII.γ.60).

Legionellae are rod shaped or filamentous, 0.3–0.9 × 2–20 μm or more in length. The filaments are found after growth on agar media, less commonly in yolk sac material, and rarely in human lung or guinea pig tissue (Chandler et al., 1979; Weaver and Feeley, 1979). Electron microscopic examination reveals filamentous nucleoids, ribosomes, and Sudan black B-staining vacuoles thought to contain poly-β-hydroxybutyrate granules (Chandler et al., 1979). Cells are enclosed by a double envelope, composed of two three-layered unit membranes; a peptidoglycan layer has been demonstrated for *L. pneumophila*, and for *L. micdadei* (Flesher et al., 1979; Pasculle et al., 1979; Gress et al., 1980). Cell division occurs by a pinching process (Chandler et al., 1979; Keel et al., 1979).

One, two, or occasionally more flagella occur per cell. The flagella are curved or straight and have a polar or lateral arrangement (Chandler et al., 1980).

Legionellae are not acid-fast by the Ziehl-Neelsen procedure for mycobacteria (Hébert et al., 1980a) after they have been isolated on agar. *L. micdadei*, however, may appear acid-fast in tissue; modified acid-fast stains that use weak acids as decolorizing agents may be required to demonstrate the acid-fastness (Pasculle et al., 1979).

Legionellae were first isolated in guinea pigs and in embryonated hens' eggs (Tatlock, 1944; Jackson et al., 1952; Bozeman et al., 1968; McDade et al., 1979). With the advent of supportive culture media, inoculation of animals and eggs has become obsolete. It has been suggested, however, that preincubation of environmental samples with protozoa increases the recovery of isolates (Rowbotham, 1983; Sanden et al., 1992). Legionellae do not grow on commonly employed media such as standard blood agar or nutrient agar. Mueller-Hinton agar, supplemented with hemoglobin and IsoVitaleX or GC base with similar supplements, was used to cultivate the first isolates of *L. pneumophila* (Centers for Disease Control, 1977). In one case, the agar was a commercially prepared chocolate agar (Dumoff, 1979). A buffered charcoal yeast extract (BCYE-α) agar supplemented with 0.1% α-ketoglutarate is now preferred for isolation of *L. pneumophila* (Feeley et al., 1979; Pasculle et al., 1980). All species grow on BCYE-α agar. The medium is buffered at pH 6.9, the optimum for growth of *Legionella* spp., by ACES buffer. The activated charcoal serves as a scavenger for toxic free radicals that are generated by the interaction of light with the medium (Hoffman et al., 1983). Yeast extract serves as a rich growth medium. Variations on BCYE-α agar have been developed (Wadowsky and Yee, 1981), and some have proven particularly useful for isolating legionellae from environmental specimens (Edelstein, 1982). Some investigators have found that addition of 1.0% bovine serum albumin enhances the growth of *L. micdadei* and some strains of *L. bozemanii* (Morrill et al., 1990). Antibiotics may be added to suppress the growth of indigenous human or environmental flora (Edelstein and Finegold, 1979; Edelstein, 1981). It is essential to include a nonselective BCYE-α agar, because both vancomycin and cefamandole, two commonly used agents for suppressing Gram-positive bacteria, will inhibit various *Legionella* species (Lee et al., 1993b). *L. pneumophila* grew better than other species. Strains of 25 of the 28 species tested were recovered on media that contained vancomycin. In contrast, cefamandole completely inhibited strains of 11 species and inhibited growth of strains from an additional 8 species. Several complex and semisynthetic broth

media are available for physiologic studies of *L. pneumophila* (Saito et al., 1981), but have not proven useful for isolation of clinical or environmental strains.

Media containing dyes that have some differential value have been described (Vickers et al., 1981), based on the appearance of isolated colonies. Data are not available for more recently isolated species.

Several species exhibit a blue-white or red autofluorescence, and many species produce a diffusible, brown pigment on tyrosine-containing agar (Tables BXII.γ.56 and BXII.γ.57).

Growth of stock cultures obtained from humans occurs at temperatures between 25°C and 43°C, but not at 50°C. The optimum temperature is 36° ± 1°C (Weaver and Feeley, 1979; Thacker et al., 1981); however, in nature, the optimum growth temperature may be 45°C or higher (Fliermans et al., 1981; Orrison et al., 1981). The optimum pH for growth of legionellae is 6.8–7.0 (Feeley et al., 1978).

CO_2 does not appear to stimulate the growth of legionellae, with the exception of *L. gormanii*. Because of this exception, and also the buffering effect of CO_2, incubation in an atmosphere of air + 2.5% CO_2, or in a candle jar, has been recommended for all legionellae; however, CO_2 may slightly inhibit growth in BCYE (Pasculle et al., 1980).

Pinpoint colonies appear on BCYE-α agar[1] in about 3 d after primary culture; the colony diameter reaches 3–4 mm after 5–7 d of incubation at 36° ± 1°C. Colonies are gray, glistening, convex, and circular with an entire edge. With a dissecting microscope one can visualize iridescence in varying colors of red, blue, and green; there is often a faceted or "cut-glass" appearance of the colonies when viewed with reflected light.

Carbohydrates are neither fermented nor oxidized by legionellae (Weaver and Feeley, 1979; Riley and Weaver, personal communication). Amino acids can presumably serve as the carbon source (Warren and Miller, 1979; George et al., 1980).

Legionellae are nutritionally fastidious. They require iron and L-cysteine for growth. As indicated previously, soluble ferric pyrophosphate, ferric nitrate, or hemoglobin can provide the iron, and IsoVitaleX (BBL) can serve as a source of the L-cysteine. The following amino acids are essential for growth: cysteine, serine, methionine, arginine, valine, leucine, isoleucine, and threonine; no vitamin or cofactor requirements have been demonstrated (George et al., 1980). Chemically defined and semisynthetic liquid media have been developed for legionellae (Pine et al., 1979; Warren and Miller, 1979; Ristroph et al., 1980).

One or more cryptic plasmids are present in many, but not all, strains of many species (Knudson and Mikesell, 1980). Neither pathogenicity nor antibiotic resistance, nor any other cell

1. BCYE agar: add 10.0 g of ACES buffer (*N*-2-acetamido-2-aminoethane-sulfonic acid; pKa = 6.9 at 20°C; available from Sigma Chemical Co., St. Louis, MO) to 500 ml of distilled water and dissolve by heating in a water bath at 45–50°C. Mix this solution with 440 ml of distilled water to which 40 ml of 1.0 N KOH has been added. Add the following ingredients: activated charcoal (Norit SG, available through Sigma Chemical Co., Cat. No. C5510 [acid-washed with phosphoric and sulfuric acids]), 2.0 g; yeast extract, 10.0 g; and agar (Difco or Oxoid), 17.0 g. Dissolve by boiling. Autoclave 15 min at 121°C. Cool to 50°C. Aseptically add L-cysteine-HCl·H_2O solution (0.4 g in 10 ml of distilled water, sterilized by filtration), followed by ferric pyrophosphate solution (0.25 g in 10 ml of distilled water, sterilized by filtration). (Soluble ferric pyrophosphate is available on request from Director, Biological Products Div., Centers for Disease Control and Prevention, Atlanta, GA 30333. It must be kept dry and stored in the dark until used. It is not usable if the color changes from green to yellow or brown. Do not heat over 60°C to dissolve the ferric pyrophosphate; a 50°C water bath is satisfactory.) The pH of the final solid medium should be 6.9 ± 0.05 at room temperature. Since reagents vary, each laboratory must determine the amount of KOH required. Do this by holding the bulk medium at 50°C while pouring one plate and checking its pH. When necessary, adjust the bulk medium with either 1.0 N KOH or 1.0 N HCl. Note the pKa of ACES buffer is influenced by temperature (0.02/°C); consequently, this must be considered with all pH determinations. Dispense 20 ml portions of the complete medium into 10- × 100-mm plastic Petri dishes; swirl the medium between pouring plates to keep charcoal particles suspended.

function was correlated with the presence of any plasmid (Mikesell et al., 1981; Aye, Wachsmuth, and Feeley, personal communication).

Motile strains of all *Legionella* species possess cross-reacting H antigens (Lewallen et al., 1979; Hébert et al., 1980d). O antigens, which define the serogroups, are primarily defined by the characteristics of cellular lipopolysaccharide (Ciesielski et al., 1986; Otten et al., 1986). They are largely unique for each species, although some cross-reactions have been demonstrated (Table BXII.γ.60). More than one O-antigen group is present in several species (Table BXII.γ.61).

Legionella species are susceptible *in vitro* to a variety of antimicrobial agents, including erythromycin, rifampin, and newer macrolides, such as azithromycin and clarithromycin, which are effective *in vivo*, as measured in experimental animals or in clinical studies (Hamedani et al., 1991; Donowitz and Earnhardt, 1993; Stamler et al., 1994). Quinolones have been used successfully to treat *Legionella* infections (Saito et al., 1986; Unertl et al., 1989), but clinical failures have also been described (Kurz et al., 1988). Tetracycline, doxycycline, and minocycline are also effective *in vitro* and possibly *in vivo*. There are no prospective, random, placebo-controlled studies of antimicrobial therapy for *Legionella* infection. Retrospective analysis of two early epidemics (Philadelphia in 1976 and Burlington, Vermont, in 1977) documented the efficacy of erythromycin and, less conclusively, tetracycline (Fraser et al., 1977; Broome et al., 1979). Other antibiotics that are not effective against *Legionella* include aminoglycosides, sulfamethoxazole-trimethoprim, chloramphenicol, and a variety of cephalosporins (Thornsberry et al., 1978).

Many species of *Legionella* produce some level of β-lactamase activity when assayed with a chromogenic cephalosporin test (Tables BXII.γ.56 and BXII.γ.57) (Hébert et al., 1980b). The β-lactamase is assumed to be chromosomal rather than of plasmid origin and is more active on cephalosporins than on penicillins (Thornsberry and Kirven, 1978). The correlation between *in vitro* susceptibility and clinical efficacy of antibiotics for legi-

onellae is poor (Kirby et al., 1978). Clinical response and survival, however, do correlate with the timely administration of effective antibiotics (Heath et al., 1996). Resistance to penicillins and cephalosporins may be partially related to β-lactamase activity, although infections caused by *L. micdadei*, which does not produce β-lactamase, do not respond to penicillins or cephalosporins. The most likely explanation for the poor correlation between *in vitro* and *in vivo* results is the accumulation of antibiotics

TABLE BXII.γ.61. Serogroups of *Legionella* species[a]

Species	Serogroup	Type strain	Source of isolate	Reference
L. pneumophila	1	Philadelphia 1	Human lung	McKinney et al., 1979a

[a]NA, not available.

within phagocytic cells. The most effective antibiotics are those that are effective *in vitro* and are also concentrated in macrophages.

Erythromycin is the drug of choice in treating human infection and should be given for a 3-week course (Kirby et al., 1978). Although there are few data, it has been suggested that rifampin should be used in combination with erythromycin when patients respond poorly to erythromycin alone or when serious disease is present (Cordes and Fraser, 1980).

All *Legionella* species are potentially pathogenic for humans. Antibodies to *Legionella* spp. are found in several species of domestic animals, but definitive evidence of active infection is lacking. Isolation of the bacterium has been accomplished only rarely and in a setting where autopsy contamination by water cannot be excluded completely (Boldur et al., 1987). Guinea pigs are easily infected by *Legionella* spp., and lethal infection often results (McDade et al., 1977; Winn et al., 1982). Rhesus monkeys and marmosets develop a fibrinopurulent pneumonia after infection with an aerosol of *L. pneumophila* (Baskerville et al., 1983). Mice and rats are variably resistant to the development of active infection, depending on the strain of rodent (Yamamoto et al., 1991b).

Disease caused by any *Legionella* species is often termed legionellosis. The two main types of legionellosis caused by *Legionella* are *Legionella* pneumonia (LP) (Fraser et al., 1977) and Pontiac fever (Glick et al., 1978). Most clinical, epidemiologic, and diagnostic data pertain to the most commonly isolated species, *L. pneumophila*; the limited data available for other species suggest that they follow the same pattern. The pneumonia has a 2- to 10-d incubation period after a presumed airborne exposure to the organism. There is no proof of person-to-person spread. The earliest symptoms include malaise, myalgia, headache, and often a nonproductive cough. Rapidly rising fever and chills usually appear within a day, at which time there are definite clinical and radiologic indications of pneumonia. Other common symptoms are chest pain, abdominal pain, vomiting, diarrhea, and mental confusion. Pathologically there is focal, lobular pneumonia, which may coalesce and even produce a lobar distribution (Winn and Myerowitz, 1981). The inflammatory response usually consists of a mixture of polymorphonuclear neutrophils and macrophages. Treatment with antibiotics is necessary; untreated, the fatality rate is 15% or higher.

Subclinical and mild cases may not be recognized unless they are a part of a larger epidemic. Smoking, preexisting respiratory illness, and conditions where the patient is immunocompromised are predisposing factors. LP occurs most often in men above the age of 50. It has been estimated that there are 8000–18,000 cases of LP in the United States each year, many not recognized and/or reported (Marston et al., 1994). The disease occurs worldwide. LP has been caused by approximately half of the recognized species, and could potentially be caused by any if the patient is sufficiently immunocompromised.

Legionella pneumonia occurs as sporadic or epidemic disease, which may be acquired in the community (Storch et al., 1979) or as a nosocomial infection (England and Fraser, 1981). Remarkable differences in the incidence of LP in similar patient populations presumably relate to the frequency and quantity of virulent strains in the local environment (Goldstein et al., 1982). Subclinical disease occurs, even in severely immunocompromised patients (Jacobs et al., 1990). Mixed infections with multiple

Legionella species (Dowling et al., 1983) occur. Differing serologic types have also been isolated from human lung (Joly and Winn, 1984), although it has been suggested that strains with differing antigenic characteristics may derive from a common parent strain (Harrison et al., 1990).

Legionella spp. also produce acute, nonpneumonic, febrile illness accompanied by chills, headache, and myalgia (Pontiac fever). It has a high attack rate and a short incubation period of hours to several days. It is, by definition, an epidemic disease. Pontiac fever is not accompanied by clinically detectable disease of the lower respiratory tract. It is self-limiting and not fatal. Pontiac fever has been caused by *L. pneumophila* (Glick et al., 1978), *L. feeleii* (Herwaldt et al., 1984a), *L. micdadei* (Goldberg et al., 1989), and *L. anisa* (Fenstersheib et al., 1990). Severe *Legionella* pneumonia and nonpneumonic disease (differing from Pontiac fever in the sporadic nature of the infection) have occurred after exposure to the same environmental source (Girod et al., 1982).

All species of *Legionella* have been isolated from the environment. Natural environmental isolates have come from streams or lakes, sometimes heated by natural or industrial thermal source. *L. pneumophila* has been identified from moist soil adjacent to a body of water (Fliermans et al., 1981), and *L. longbeachae* has been recovered from moist potting soil (Steele et al., 1990). Although a variety of environmental cofactors have been described, it is becoming increasingly clear that the association of legionellae with a variety of free-living protozoa is the most important factor (Rowbotham, 1986; Fields, 1993). Isolation of strains may be accomplished only by coculture with amoebae, both for human (Rowbotham, 1983) and environmental (Sanden et al., 1992) sources.

There have been no isolates from dry soil. Urban environmental isolates were made from water collected from air conditioning cooling towers and evaporative condensers (Orrison et al., 1981). More recently, colonization of potable water systems by *Legionella* spp. has been frequently demonstrated., with isolates being more common on the hot water than the cold water side. The sediment of hot water heaters are a particularly productive source for isolates, especially if the water temperature has been lowered to minimize scalding and reduce heating costs. Water heaters in which the heating elements are remote from the bottom of the tank where the sediment accumulates are more likely to yield isolates than units with heating elements in the bottom of the tanks (Alary and Joly, 1991). It is interesting that the portions of municipal water systems that have been colonized are all peripheral; contamination of central water distribution facilities, where chlorination is performed, has not been demonstrated. Dissipation of chlorine as water flows through the system may explain this phenomenon.

Not surprisingly, epidemic disease can usually be traced to exposure to a contaminated water source. Sporadic cases are likely related to similar exposures, but investigation is more difficult. The contaminated water may be either environmental surface water or potable water. Factors that favor production of disease include a host who is compromised by immunosuppression or chronic cardiopulmonary disease, a vehicle for generating aerosols (which may be quite local), and undoubtedly the inoculum and virulence of the bacteria. The most vulnerable patients are in health care centers, where epidemic disease has been concentrated. Epidemics have also been associated, however, with hotels, cruise ships, and even grocery stores.

The primary hazard to researchers working with *Legionella* species is exposure to aerosols, although self-inflicted wounds are a potential hazard. In the absence of large-scale aerosols, as might be produced in an experimental situation, the usual precautions for class II pathogens are sufficient. Organisms isolated on agar plates can be safely studied at the bacteriology bench. There are no documented occupational infections in standard diagnostic bacteriology laboratories.

Enrichment and Isolation Procedures

The diagnosis of *Legionella* infection can be made by three methods, which are in decreasing order of importance, isolation of the organism in culture, direct identification of antigens or nucleic acid in tissues or body fluids, and demonstration of an immune response (Zuravleff et al., 1983).

Human specimens Lung tissue, lung aspirates, pleural fluid, transtracheal aspirate or sputum, and bronchoalveolar lavage fluid are the specimens usually cultured when *Legionella* is suspected (Edelstein et al., 1980). Samples that cannot be processed within 2 h of collection can be stored on wet ice or refrigerated for 2 d. Samples that will not be cultured within a reasonable time (2–5 d) should be frozen at −70°C. Ten percent tissue suspensions in distilled water or bacteriologic broth, body fluids, or sputum should be inoculated onto media designed to grow legionellae, such as BCYE-α. If indigenous flora is likely to be present, inoculate media with and without addition of antibiotics for selective inhibition of nonlegionellae. Media with selective antibiotics should never be inoculated without an accompanying noninhibitory plate.

Inhibition of *Legionella* growth, presumably by antibiotics or toxic compounds in the specimen, may be documented as a zone of no growth where the specimen was placed on the agar, in conjunction with heavy growth in adjacent areas, where the inoculum had been spread over the surface of the agar. Homogenization and acid treatment of respiratory secretions increased the number of isolates from sputum, but not bronchoalveolar lavage fluid in one study (Buesching et al., 1983), but this finding has not been reported by other investigators. Brief heat treatment of specimens also selectively inhibits contaminating flora, but *Legionella* spp. may also be inhibited (Edelstein et al., 1982b).

Blood cultures may be positive in severely ill patients who have high-level bacteremia (Rihs et al., 1985), but the sensitivity in mild to moderate cases is not known. Continuous-reading blood culture instruments do not register growth when *Legionella* spp. are present; staining of fluid with acridine orange or blind subculture onto BCYE-α agar may be required to document the presence of bacteria. *In vitro* experiments with spiked blood samples suggest that the lysis-centrifugation method, a convenient means of culturing blood for fastidious pathogens, may be used to recover legionellae from blood efficiently, but clinical confirmation is lacking.

Each batch of media must be tested for pH and sensitivity for primary isolation of legionellae. The pH of solid media is determined with a surface electrode or by emulsifying the agar from one plate in distilled water. The quality of media from various manufacturers can vary (Lee et al., 1993b). If media are commercially prepared, the manufacturer should supply documentation of successful quality control. If the media are prepared locally or if the sensitivity of media for primary isolation is in doubt, a control should be prepared from a freshly isolated strain that has been minimally passed on BCYE-α agar. After *in vitro* passage on non-charcoal-containing agar, strains with altered growth characteristics emerge. These strains will grow well on

batches of media that do not support the growth of bacteria in fluid or tissue; a false sense of security as to the adequacy of the media may result (Keathley and Winn, 1985). Media without antibiotics, stored refrigerated in the dark, in sealed, plastic containers remain stable for at least 2 months. Users should follow manufacturers' instructions for storage and outdates of commercially prepared media.

Media for isolation of *Legionella* spp. should be incubated at 35–37°C. Incubation in an atmosphere of 2–5% CO_2 provides marginal enhancement of isolation for some *Legionella* spp., but higher concentrations of CO_2 may be inhibitory. Plates should be held for at least 5–7 d before discarding. Colonies are usually evident after incubation for 48–72 h. Use of a stereomicroscope will facilitate detection of colonies and allow assessment of fine features of colonial morphology. *Legionella* spp. produce smooth, entire colonies that exhibit a mottled, cut-glass appearance when viewed with a stereomicroscope under reflected light. Red, blue, or green iridescence may be visible early with a stereomicroscope and later with the naked eye in areas of heavy growth. *L. pneumophila* produces sticky colonies that "string" when a portion of the colony is lifted with an inoculating needle or loop.

Environmental samples A comprehensive manual for culture of environmental specimens is available from the Centers for Disease Control and Prevention (CDC) (Centers for Disease Control and Prevention, 1992). Environmental, nonpotable water samples do not require concentration. Potable water samples must be concentrated either by filtration, as recommended by CDC, or by centrifugation (Brindle et al., 1987). Collection of at least 1 l of potable water is desirable, but as many as 10 l may be required if small numbers of legionellae are present. For filtration the water should be passed through a 0.2-µm polycarbonate filter, after which the filter is folded to the outside, placed in 10 ml of water, vortexed, and subcultured onto solid media. Serial dilutions may be performed to quantify the bacterial load. Plates are incubated for 7 d in 2.5–5.0% CO_2. Samples from faucets and showers may be taken with polyester swabs that are immersed in 3–5 ml of water; the faucet aerator or shower head should be removed if possible. Samples of sediment from hot water heaters should be plated on solid agar. Detailed instructions for recovering legionellae from air samples have been provided by CDC (Centers for Disease Control and Prevention, 1992).

Environmental samples, especially those from nonpotable water, are frequently contaminated with a variety of bacterial species. A variation on BCYE agar that includes glycine has proved useful for culturing environmental specimens (Wadowsky and Yee, 1981). Addition of selective antibiotics provides an additional competitive advantage for *Legionella* spp. Antibiotic combinations have included cefamandole or vancomycin for inhibition of Gram-positive flora, polymyxin B for Gram-negative flora, and anisomycin for yeast. Cefamandole may inhibit many isolates of *Legionella*, so selective plates should not be used alone. As has been recommended for sputum, brief acidification of the sample to pH 2.0 for 5 min followed by neutralization may provide additional suppression of contaminating environmental flora (Centers for Disease Control and Prevention, 1992). Heat enrichment of environmental specimens that were negative for legionellae on primary culture may yield as many as 30% additional isolates, putatively because the bacteria multiply in free-living amoebae in the samples. Tubes of water are incubated in closed tubes at 35°C, followed by periodic subculture onto agar. If necessary, the aliquots for subculture may be treated with acid before testing.

Maintenance Procedures

Stock cultures on BCYE-α agar slants are recommended for maintenance of stock cultures. Inoculated slants are incubated for 2 d at 35°C and then stored in the dark at room temperature. Under these conditions, *L. pneumophila* cultures remain viable for 1–3 months (Hébert, 1980). Other species remain viable for variable periods from 4 months to 1 year. Lyophilization or storage at −50°C or lower is recommended for long-term maintenance (Feeley and Weaver, personal communication); a convenient and effective method for storage of isolates is to excise a piece of agar containing isolated colonies, after which the agar is frozen in a sterile container at −50°C or less (W.C. Winn, Jr., personal observation). Virulence and plasmids are often lost on lyophilization or subculture on non-charcoal-containing agar (McDade and Shepard, 1979). This conversion to avirulence is a one-way phenomenon and does not appear to occur if one of the charcoal agars, such as BCYE-α agar, is used for maintenance (Catrenich and Johnson, 1988).

Procedures for Testing Special Characters

Direct Detection of Antigen in Specimens

Human specimens The first method used to detect *Legionella* antigen in clinical specimens was direct immunofluorescence, using polyclonal antisera. Commercially available polyclonal conjugates are available for some species and serotypes. Cross-reactions have been demonstrated with *Pseudomonas aeruginosa* and *Bacteroides fragilis* (Edelstein and Edelstein, 1989), *Bordetella pertussis* (Benson et al., 1987), *Francisella tularensis* (Roy et al., 1989), and with spores of *Bacillus cereus* (Flournoy et al., 1988). A commercially available monoclonal antibody to an antigen that is specific for the species *L. pneumophila* provides cleaner staining and fewer cross-reactions than the polyclonal antisera, but monoclonal reagents are not available for other species (Edelstein et al., 1985; Tenover et al., 1985). The direct immunofluorescence test has been discontinued in many laboratories because of low sensitivity (Edelstein et al., 1980; Buesching et al., 1983). Although the specificity is high, false-positive results cause unacceptably low predictive values if the prevalence of disease is very low. In addition, legionellae in water used to make reagents may cause clusters of false-positive tests. Radioimmunoassays and enzyme immunoassays have been developed for detection of *L. pneumophila* serogroup 1 antigen in urine. A commercially available enzyme immunoassay, using polyclonal antiserum, (BINAX, Portland, Maine) has a sensitivity of 70–80% and a specificity of 90% (Kazandjian et al., 1997). *L. pneumophila* antigen may be excreted for weeks or months, so that detection of antigen does not always indicate current disease (Kohler et al., 1984).

Environmental specimens Initially direct immunofluorescence was commonly used for detection of legionellae in water samples. Many specimens that were positive by immunofluorescence could not be confirmed by culture, probably reflecting both insensitivity of early culture techniques, fastidious or nonreplicating legionellae, and/or immunologic crossreactions. The preferred method for testing environmental samples is culture.

Direct Detection of Nucleic Acid in Specimens

Human specimens A direct nucleic acid probe for *L. pneumophila* was marketed briefly, but withdrawn because of unac-

ceptably frequent false-positive reactions. There are no commercially available molecular amplification tests for clinical specimens, but amplification procedures that are approved for environmental specimens have been used successfully to detect legionellae in respiratory secretions (Kessler et al., 1993).

Environmental specimens Nucleic acid amplification, using the polymerase chain reaction, has been used successfully (Jaulhac et al., 1992), and an amplification kit is commercially available, although not approved for use with human specimens (Kessler et al., 1993; Oshiro et al., 1994).

Serologic Diagnosis

Human infections The indirect immunofluorescent antibody (IFA) test is the test of choice for serologic diagnosis of human infections. Although other methods have been used, appreciable experience has been accumulated only with the IFA test. Either heat-killed or formalin-inactivated bacterial antigen may be employed (Wilkinson and Brake, 1982). It is important to use antiglobulin conjugates that are active against both IgG and IgM (Wilkinson et al., 1979a). If the criterion for a positive test is a fourfold increase in paired sera to a titer of at least 1:128, the sensitivity of the test is 70–80% (Edelstein et al., 1980), and the specificity is approximately 99% (Wilkinson et al., 1981). The details of IFA are given by Wilkinson et al. (1979b). Sera should be examined for at least 6 weeks to demonstrate seroconversion; some patients do not seroconvert for 1 year or longer (Edelstein et al., 1980). A titer of 1:256 in a single serum has been used as presumptive evidence of *Legionella* infection during an epidemic, but the diagnosis of sporadic cases cannot be made with a single serum specimen. An elevated IgM titer suggests recent infection (Zimmerman et al., 1982), but these titers may persist for as long as a year in some patients (Zimmerman et al., 1982). Antisera are available for certain serogroups of *L. pneumophila* and for selected other species. Cross-reactions among *Legionella* serogroups and species make it impossible to assign a precise diagnosis with certainty (Wilkinson et al., 1983a). In addition, cross-reactions have been described with other bacterial species, including *Campylobacter* spp. (Boswell and Kudesia, 1992), *Pseudomonas* spp. (Edelstein et al., 1980; Klein, 1980; Collins et al., 1984), and *Bacteroides fragilis* (Edelstein et al., 1980). Under the best of circumstances, therefore, serologic diagnosis is only presumptive.

Animals Serologic studies have demonstrated anti-*Legionella* antibodies in a variety of animals (Collins et al., 1982). In the absence of bacterial isolates, it is difficult to interpret the serologic data.

Molecular Epidemiology of *Legionella* Infections It is not possible to ascribe an etiologic role to a *Legionella* isolate, simply because the same species has been recovered from human and environmental sources. An exhaustive investigation of all potential environmental sites must be undertaken. The likelihood of an etiologic association is increased by application of a variety of subtyping tools: monoclonal antibody typing (Joly and Winn, 1984; Gomez-Lus et al., 1993), ribotyping (Schoonmaker et al., 1992; Gomez-Lus et al., 1993), restriction endonuclease treatment with pulsed field electrophoresis (Saunders et al., 1991; Schoonmaker et al., 1992), polymerase chain reaction, arbitrarily primed polymerase chain reaction (Gomez-Lus et al., 1993; Ledesma et al., 1995), and alloenzyme analysis (Edelstein et al., 1986; Tompkins et al., 1987). The greatest discrimination comes from applying multiple typing tools (Barbaree, 1993; Mamolen et al., 1993). It has been suggested that certain monoclonal antibody types of *L. pneumophila* are associated with increased virulence (Dournon et al., 1988; Helbig et al., 1995).

Media Legionellae grow on BCYE agars. They do not grow on standard blood agar, nutrient agar, or other commonly employed laboratory media that do not contain both L-cysteine and iron salts. To document the nutritional pattern of a fresh isolate, parallel subcultures should be made to BCYE-α and either sheep blood agar or BCYE-α agar without L-cysteine. Growth only on BCYE-α agar with L-cysteine suggests the possibility of *Legionella* spp. Legionellae must be differentiated phenotypically from two groups of organisms that grow on some modified charcoal media that contain L-cysteine, but not on common laboratory media. The first, and most significant, for clinical diagnosis and laboratory safety is *F. tularensis* (Westerman and McDonald, 1983; K. McLeod, C.P. Patton, and J.C. Feeley, unpublished data), and possibly *F. novicida*. *Francisella* spp. are easily distinguished from *Legionella* spp. because they produce acid from carbohydrates and do not contain branched chain fatty acids (Jantzen et al., 1979). *F. tularensis* constitutes a major biohazard for unsuspecting laboratories, so this possibility must be kept in mind. A number of thermophilic, spore-forming bacilli that stain Gram-negative mimic legionellae on BCYE agars and do not grow on common laboratory media. They also have branched chain fatty acid profiles that superficially resemble those of one or more *Legionella* species (Thacker et al., 1981). These strains are distinguished from legionellae by their ability to grow at 50°C or higher, to form spores, and to grow on certain media that lack cysteine, such as tryptone broth (Thacker et al., 1981; Weaver, unpublished data). These environmental organisms rarely, if ever, produce human disease, but may cause confusion if they contaminate reagents or specimens.

Pigments Pigments are of minimal value in identification of legionellae. Brown pigment is formed on supportive clear agars that contain tyrosine (Baine et al., 1978). Yellow, blue-white, or red autofluorescence may be seen with some species if the colonies are examined in the dark with a long-wavelength ultraviolet lamp (Wood's light) (Tables BXII.γ.56 and BXII.γ.57).

Serologic identification Serologic characterization of isolates, most commonly by the direct immunofluorescent antibody (DFA) test, is the most common method of identifying isolated strains. Polyclonal antisera, probably directed primarily against a lipopolysaccharide antigen, provide a serotype-specific diagnosis. Reagents are available commercially for selected serogroups of *L. pneumophila*, *L. micdadei*, and many other species (Hookey et al., 1995). A commercially available monoclonal antibody to a species-specific antigen of *L. pneumophila* provides more consistent and easily interpreted results (Edelstein et al., 1985; Tenover et al., 1985, 1986). Although serologic identification is sufficiently accurate to use in clinical and environmental laboratories, cross-reactions among serotypes and species do occur occasionally. The only certain way to establish the nature of an isolate is by nucleic acid analysis.

A slide agglutination test can also be used for the rapid identification of legionellae (Wilkinson and Fikes, 1980), especially in laboratories that are unable to perform immunofluorescence exams. Unfortunately, the agglutination test is not commercially available in the United States.

Gas-liquid chromatography (GLC) GLC analysis of cellular fatty acids is a method used, along with DFA, to test suspect

isolates and to confirm the identification of known legionellae, new serogroups, and new species (Moss and Dees, 1979; Lambert and Moss, 1989) (Table BXII.γ.58). The procedure is, thus far, totally specific in identifying species of *Legionella* at the genus level and can identify most, but not all, legionellae to the species level. The procedure involves saponification of whole cells, methylation of the fatty acids, extraction of the resultant methyl esters with diethyl ether and then hexane, followed by GLC analysis on a nonpolar stationary-phase column. The retention time of the resultant elution peaks is recorded, and tentative identification is made by comparison to reference standards. Confirmation and quantitation of the fatty acids are obtained by subsequent procedures, including mass spectrometry, use of polar columns, hydrogenation, and acetylation.

Characterization of cellular ubiquinones is also useful in characterizing *Legionella* species (Table BXII.γ.59). The genus contains varying amounts of ubiquinones with 9-14 isoprene units in the side chains (Lambert and Moss, 1989).

DNA relatedness This is the only method whereby one can unequivocally identify legionellae to the level of species, confirm the existence of new serogroups in existing species, and identify new species. DNA relatedness, however, is not adaptable to routine laboratory use and should be used only for isolates that cannot be characterized with certainty by biochemical, antigenic, and fatty acid analysis.

Differentiation of the genus *Legionella* from other genera

Legionella pneumophila has no close relatives in other genera based on DNA relatedness (Brenner et al., 1979). The original four strains that we now know to represent three separate *Legionella* species were isolated between 1943 and 1959 (Tatlock, 1944; Jackson et al., 1952; Bozeman et al., 1968). At the time of their discovery, however, none of these strains was cultivatable on bacteriologic media. They were treated as rickettsiae and not further studied until 1978 (McDade et al., 1979; Hébert et al., 1980a,d). The "modern" study of what was to become the genus *Legionella* began in 1976 with the investigation of a large outbreak of respiratory disease at an American Legion Convention in Philadelphia, Pennsylvania (Fraser et al., 1977), resulting in the isolation of the causative agent, *L. pneumophila*, by Joseph McDade (McDade et al., 1977). Shortly thereafter, the Flint 1 strain was isolated as an unknown on bacteriologic media by Dumoff (Dumoff, 1979) and the Philadelphia strains were isolated on bacteriologic media by Weaver (Feeley et al., 1978). The first species, *L. pneumophila*, was named in 1979 (Brenner et al., 1979).

The named species of *Legionella* have similar phenotypic characteristics (Tables BXII.γ.56 and BXII.γ.57). These include growth on media designed for legionellae, optimum pH and temperature for growth, common flagellar antigens, pathogenicity for guinea pigs and embryonated hen's eggs, nonfermentative metabolism, presence of catalase, absence of urease, and *in vitro* antibiotic susceptibility patterns. The cellular fatty acid compositions of all species are characterized by relatively large amounts of branched chain acids. Approximately half of the recognized species have been directly or indirectly implicated as causative agents of human pneumonia. Available microbiological and biochemical tests are insufficient to separate all species with certainty. Once a species has been defined, it is quite simple to identify species and serogroups by DFA. As the number of recognized species has expanded, so has the number of immunological cross-reactions (Table BXII.γ.60). It is still appropriate to identify clinical isolates by DFA, particularly if the species is *L. pneumophila*, but the possibility of cross-reactions should be recognized.

Taxonomic Comments

A frequently used definition of a "genetic" species is "a group of strains whose DNAs are 70% or more related at optimal reassociation conditions and have 5% or less divergence in related sequences". Stackebrandt and Goebel (1994) consider that strains that have at least 70% relatedness will also have at least 96% sequence identity when conserved portions of 16S rRNA are analyzed. The technology of DNA hybridization is costly and time-consuming, whereas genetic sequences can now be determined quickly and relatively cheaply. Analysis of 16S rRNA, however, does not have the discriminatory ability of DNA–DNA hybridization at the species level. Stackebrandt and Goebel suggest that analysis of 16S rRNA genes be used as a screening tool to select likely candidates for hybridization studies.

Legionella species fulfill the current definition of bacterial species. DNA relatedness cannot be used to generate good genetic definitions for a genus or family. The most common method for establishing relationships at the genus level is now sequencing of 16S rDNA (Wayne et al., 1987). Some of the amoeba-associated pathogens, which are not available as isolated bacteria, are closely related to other *Legionella* species by analysis of 16S rDNA; others, representing as yet unnamed species, are more distantly related (Fry et al., 1991a, b).

New species and serogroups have been confirmed by DNA relatedness. Relatedness between strains of the same species is 75% or higher for all species except *L. bozemanii*, for which relatedness is 56–77%. The related sequences of all species, including *L. bozemanii*, exhibit 3% or less divergence (unpaired bases within heteroduplex DNA), and there is only a small decrease in relatedness when reactions are done at a supraoptimal incubation temperature. Using another approach to molecular taxonomy, Ludwig and Stackebrandt (1983) studied the phylogeny of four *Legionella* species that were closely related. Analysis of 16S rDNA from seven *Legionella* species demonstrated that they were closely related (>95%) to each other and that they fell into the *Gammaproteobacteria* (Fry et al., 1991b). Using several technical variations for detection of rDNA, several investigators have confirmed and extended these observations (Hookey et al., 1995, 1996; Birtles et al., 1996; Riffard et al., 1998).

A proposal was made to divide the family *Legionellaceae* into three genera: *Legionella*, *Tatlockia*, and *Fluoribacter* (Garrity et al., 1980; Brown et al., 1981). Other investigators have not supported the proposal and have recommended that a single genus, *Legionella*, be maintained (Brenner et al., 1985; Brenner, 1986). Analysis of 16S ribosomal RNA supported existence of a single genus (Fry et al., 1991b). Most importantly, the single-genus concept has been uniformly accepted within the community of microbiologists.

Differentiation of the species of the genus *Legionella*

Selected characteristics useful for differentiating legionellae from other organisms and from one another are presented in Tables BXII.γ.56 and BXII.γ.57. Cellular fatty acids of *Legionella* species are shown in Table BXII.γ.58, ubiquinone content in Table BXII.γ.59, and DNA relatedness data in Table BXII.γ.62. Immunologic cross-reactions are detailed in Table BXII.γ.60, and the serogroups of Legionella species are described in Table BXII.γ.61. Morphology is shown in Figs. BXII.γ.94, BXII.γ.95, and BXII.γ.96.

List of species of the genus Legionella

1. **Legionella pneumophila** Brenner, Steigerwalt and McDade 1979, 658.[AL]
pneu.mo'phi.la. Gr. n. *pneumo* lung; Gr. adj. *philos* loving; M.L. adj. *pneumophila* lung-loving.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Hydrolysis of hippurate is not positive for all strains of *L. pneumophila* (Hébert, 1981). Serologic cross-reactions are detailed in Table BXII.γ.60. The species contains 15 serogroups (Table BXII.γ.61). Causative agent of legionellosis, presenting either as a pneumonia with a high fatality rate in untreated patients (Legionnaires' disease) or as an acute, self-limited, febrile illness (Pontiac fever). Isolated from human lung, bronchoalveolar lavage fluid, sputum, blood, intravascular devices, peritoneal fluid, abscess fluids, and potable and surface water. DNA relatedness between strains of *L. pneumophila* is 75–100%. *L. pneumophila* is 4–21% related to other *Legionella* species (Table BXII.γ.62). The fatty acid composition of *L. pneumophila* closely resembles that of *L. longbeachae*, and the two species cannot be distinguished by this technique (Bibb et al., 1981). The phenotype of strains, derived by serogrouping, does not always match their genotype. Strains within the same serogroup may be genetically disparate, whereas strains in different serogroups may be closely related genetically. *L. pneumophila* was divided into three DNA groups, based on a study of 60 strains (Brenner et al., 1988c). Subspecies designations were proposed for these nucleic acid groups.

The mol% G + C of the DNA is: 39 (T_m, Bd).
Type strain: Philadelphia 1, ATCC 33152, DSM 7513.
GenBank accession number (16S rRNA): M59157, M36023.
Additional Remarks: The type strain was isolated from human lung tissue by McDade and Weaver in 1977. The oldest isolate is strain OLDA isolated by E. Jackson in 1947 (Jackson et al., 1952).

a. **Legionella pneumophila** *subsp.* **pneumophila** (Brenner, Steigerwalt and McDade 1979) Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1989, 205[VP] (Effective publication: Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1988c, 1701) (*Legionella pneumophila* Brenner, Steigerwalt and McDade 1979, 658.)
pneu.mo'phi.la. Gr. n. *pneumo* lung; Gr. adj. *philos* loving; M.L. adj. *pneumophila* lung-loving.

This subspecies represents DNA group I and contains strains in serogroups 1–10. All strains hydrolyze sodium hippurate. Strains of *L. pneumophila* subsp. *pneumophila* are >70% related to each other under optimal conditions (60°C) with ≤3.0% divergence in related sequences; they are >60% related under stringent conditions (75°C). DNA relatedness of these strains to other subspecies is below the species level in at least one and usually two of these hybridization parameters. Isolated from human lung tissue.

The mol% G + C of the DNA is: 39–41 (T_m); type strain: 39 (T_m).
Type strain: Philadelphia 1, ATCC 33152, DSM 7513.
GenBank accession number (16S rRNA): M59157, M36023.

b. **Legionella pneumophila** *subsp.* **fraseri** Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1989, 205[VP] (Effective publication: Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1988c, 1702.)
fra'ser.i. M.L. gen. n. *fraseri* in honor of D.W. Fraser, who headed the investigation of the Legionnaires' disease outbreak in Philadelphia that led to the recognition of legionellosis and isolation of *L. pneumophila*.

This subspecies represents DNA group II and contains strains from serogroups 1, 4, 5, and Lansing 3. Strains from serogroups 1 and 5 hydrolyze sodium hippurate; strains from serogroups 4 and Lansing 3 do not hydrolyze hippurate. Strains of *L. pneumophila* subsp. *fraseri* are >65% related to each other under optimal conditions with <3% divergence and >60% related under stringent conditions. DNA relatedness of these strains to other subspecies is below the species level in at least one and usually two of these hybridization parameters. Isolated from human lung tissue.

The mol% G + C of the DNA is: 38–39 (T_m); type strain: 39 (T_m).
Type strain: Los Angeles 2, ATCC 33156, DSM 7514.
GenBank accession number (16S rRNA): M36025.

c. **Legionella pneumophila** *subsp.* **pascullei** Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1989, 205[VP] (Effective publication: Brenner, Steigerwalt, Epple, Bibb, McKinney, Starns, Colville, Selander, Edelstein and Moss 1988c, 1702.)
pas.cul'le.i. M.L. gen. n. *pascullei* in honor of A.W. Pasculle for his pioneering studies on media, isolation, and nosocomial spread of *L. pneumophila* and *L. micdadei*.

This subspecies represents DNA group III that hydrolyze sodium hippurate. Strains of subsp. *pascullei* are

[c]The DNA relatedness among the three subspecies of *L. pneumophila* is below the species level in at least one and usually two hybridization parameters.

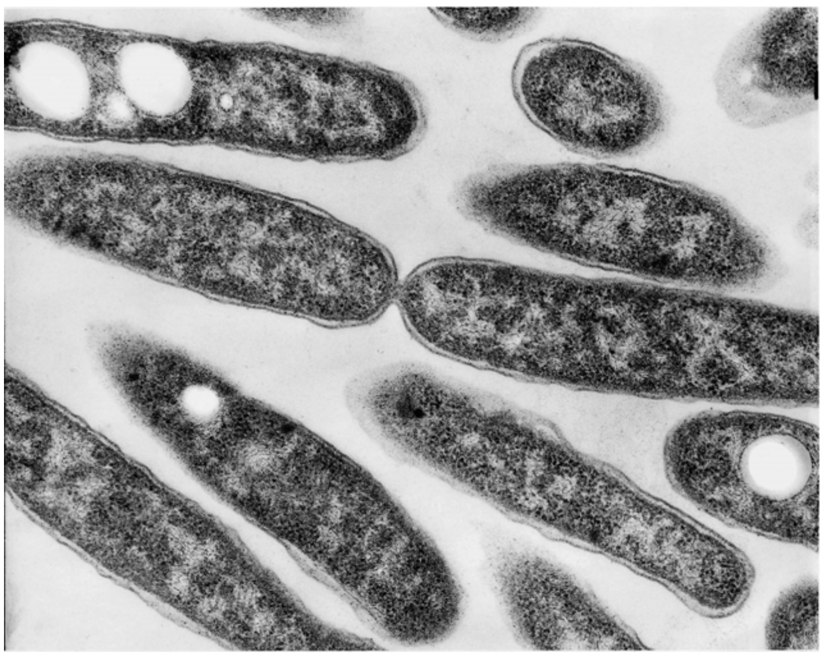

FIGURE BXII.γ.94. Electron micrograph of *Legionella pneumophila* grown in broth (× 90,000).

>95% related to each other at optimal conditions with a divergence of 1% and >95% related at stringent conditions. DNA relatedness of these strains to other subspecies is below the species level in at least one and usually two of these hybridization parameters.

The type strain was isolated from a hospital water supply, but has not been isolated from humans.

The mol% G + C of the DNA is: 39 (T_m).

Type strain: U8W, ATCC 33737, DSM 7515.

2. **Legionella adelaidensis** Benson, Thacker, Lanser, Sangster, Mayberry and Brenner 1991b, 580[VP] (Effective publication: Benson, Thacker, Lanser, Sangster, Mayberry and Brenner 1991a, 1005.)

a.del.aid.en′ sis. M.L. fem. adj. *adelaidensis* coming from Adelaide, Australia.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from surface water. *L. adelaidensis* was >31% related to 28 other *Legionella* species tested.

The mol% G + C of the DNA is: 40 (T_m).

Type strain: 1762-AUS-E, ATCC 49625.

Additional Remarks: The type strain was isolated from cooling tower water in Adelaide, Australia in 1987.

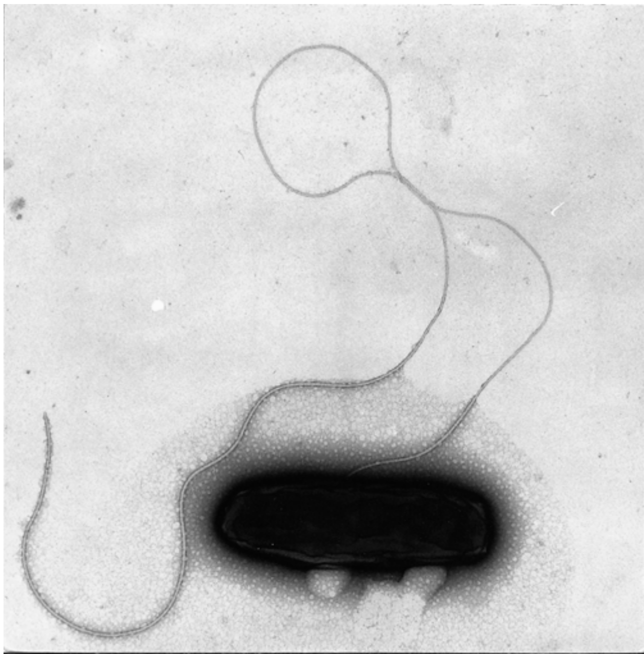

FIGURE BXII.γ.95. Transmission electron micrograph of *Legionella pneumophila* grown on CYE agar, showing a single, probably lateral, flagellum (× 61,700).

3. **Legionella anisa** Gorman, Feeley, Steigerwalt, Edelstein, Moss and Brenner 1985b, 375[VP] (Effective publication: Gorman, Feeley, Steigerwalt, Edelstein, Moss and Brenner 1985a, 308.)
a'ni.sa. M.L. gen. n. *anisa* from Gr. adj. *anisos* unequal, referring to the fact that blue-white autofluorescence is exhibited by most, but not all, strains.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. One of the original five strains did not exhibit autofluorescence (Gorman et al., 1985a). Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia and empyema and of acute, non-pneumonic, febrile illness (Pontiac fever) (Gorman et al., 1985a; Bornstein et al., 1989b; Fenstersheib et al., 1990; Thacker et al., 1990a). Isolated from human bronchial lavage and pleural fluid and from surface and potable water. The strain that was associated with acute, nonpneumonic, febrile illness was isolated from a public fountain (Fenstersheib et al., 1990). The DNA relatedness among strains of *L. anisa* is 84–99% with divergence of 0.5–1.0% at 60°C ; relatedness at 75°C is 84–92%. *L. anisa* is 5–57% related to other *Legionella* species with divergence of 7.0–14% at 60°C and 1–27% at 75°C. It is most closely related to other species that exhibit blue-white autofluorescence (Table BXII.γ.62).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: WA-316-C3, ATCC 35292.

GenBank accession number (16S rRNA): X73394, Z32635.

Additional Remarks: The type strain was isolated in Los Angeles, California, from hot water in a sink by George W. Gorman in 1981.

4. **Legionella birminghamensis** Wilkinson, Thacker, Benson, Polt, Brookings, Mayberry, Brenner, Gilley and Kirklin 1988b, 220[VP] (Effective publication: Wilkinson, Thacker, Benson, Polt, Brookings, Mayberry, Brenner, Gilley and Kirklin 1987, 2121.)
bir.ming.ham.en'sis. N.L. fem. adj. *birminghamensis* from Birmingham, Alabama, where the original isolate was made.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Causative agent of human pneumonia (Wilkinson et al., 1987). Isolated from human lung biopsy. *L. birminghamensis* was 1–3% related to 18 other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 42.9 (T_m).

Type strain: 1407-AL-H, ATCC 43702.

Additional Remarks: The type strain was isolated from a human lung biopsy in Birmingham, Alabama in 1986.

5. **Legionella bozemanii** (sic) Brenner, Steigerwalt, Gorman, Weaver, Feeley, Cordes, Wilkinson, Patton, Thomason and Lewallen Sasserville 1980d, 676[VP] (Effective publication: Brenner, Steigerwalt, Gorman, Weaver, Feeley, Cordes, Wilkinson, Patton, Thomason and Lewallen Sasserville 1980c, 114.)
boze.ma'ni.i. M.L. gen. n. *bozemanii* named after F. Marilyn Bozeman, the microbiologist who isolated and first studied the organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. *L. bozemanii* cannot be distinguished reliably from *L. micdadei*, *L. dumoffii*, or *L. gormanii* by analysis of cellular fatty acids (Karr et al., 1982). There are two serogroups of *L. bozemanii* (Table BXII.γ.61) (Tang et al., 1984). Causative agent of human pneumonia and empyema. Isolated from human lung, pleural fluid, and potable water. DNA relatedness between strains of *L. bozemanii* is 56–77%. *L. bozemanii* is 3–65% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 43 (T_m).

Type strain: WIGA, ATCC 33217.

GenBank accession number (16S rRNA): M36031.

Additional Remarks: The type strain was isolated in 1959 by Bozeman from human lung tissue.

6. **Legionella brunensis** Wilkinson, Drasar, Thacker, Benson, Schindler, Potuznkiova, Mayberry and Brenner 1989, 205[VP] (Effective publication: Wilkinson, Drasar, Thacker, Benson, Schindler, Potuznkiova, Mayberry and Brenner 1988a, 399.)
bru.nen'sis. N.L. gen. n. *brunensis* coming from Brno, Czechoslovakia.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from surface water. *L. brunensis* is 1–8% related to 32 other described *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 41.5 (T_m).

Type strain: 441-1, ATCC 43878, CDC 1635-CZK-E.

GenBank accession number (16S rRNA): Z32636.

Additional Remarks: The type strain was isolated from cooling tower water in Brno, Czechoslovakia; first reported in 1986.

7. **Legionella cherrii** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Ska-

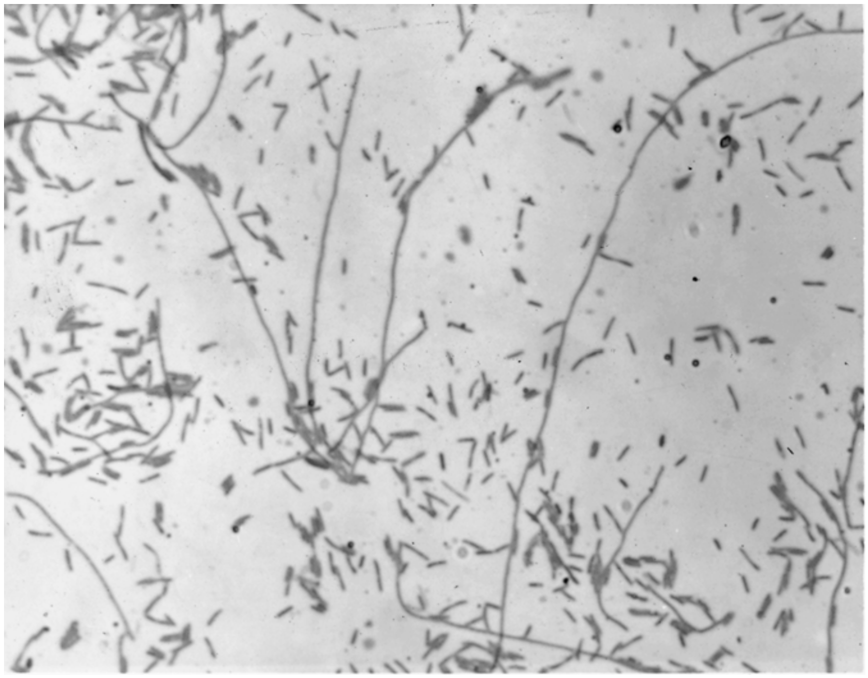

FIGURE BXII.γ.96. Carbol fuchsin-stained *Legionella pneumophila* grown on CYE agar, showing both short rods and filaments (× 1000).

liy, Martin, Brake, Fields, McEachern and Corcoran 1985, 57[VP]
cher′ri.i. N.L. gen. n. *cherrii* in honor of William B. Cherry for his many pioneering contributions to our knowledge of legionellae.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from surface water. *L. cherrii* strains are ≥94% related to each other at both 60°C and 75°C with 0.0–0.5% divergence. It is highly related to the following species that also exhibit blue-white autofluorescence: *L. steigerwaltii* (67%), *L. dumoffii* (57%), *L. bozemanii* (51%), and *L. gormanii* (47%). It is 24% related to another species that produces blue-white autofluorescence, *L. parisiensis*, and is 6–35% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 39–40 (T_m).

Type strain: ORW, ATCC 35252.

GenBank accession number (16S rRNA): X73404.

Additional Remarks: The type strain was isolated from thermally polluted water in Minnesota by R.L. Tyndall and C.B. Duncan in 1982.

8. **Legionella cincinnatiensis** Thacker, Benson, Staneck, Vincent, Mayberry, Brenner and Wilkinson 1989b, 205[VP] (Effective publication: Thacker, Benson, Staneck, Vincent, Mayberry, Brenner and Wilkinson 1988a, 419.)
cin.cin.na.ti.en′sis. N.L. fem. adj. *cincinnatiensis* from Cincinnati, Ohio, where the species was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Isolates from two clinical cases of *L. cincinnatiensis* cross-reacted with *L. longbeachae*, serogroup 1, and *L. dumoffii* in the direct immunofluorescence test and were initially misidentified (Thacker et al., 1988a; Jernigan et al., 1994). Causative agent of human pneumonia. Isolated from an open lung biopsy. At 60°C *L. cincinnatiensis* was 44% related to *L. longbeachae*, 39% related to *L. santicrucis*, and 36% related to *L. sainthelensi*. At 75°C it is 5–10% related to these species (Table BXII.γ.62).

The mol% G + C of the DNA is: 36 (T_m).

Type strain: 72-OH-H, ATCC 43753.

GenBank accession number (16S rRNA): X73407.

Additional Remarks: The type strain was isolated from a human open lung biopsy in Cincinnati, Ohio in 1982.

9. **Legionella dumoffii** Brenner, Steigerwalt, Gorman, Weaver, Feeley, Cordes, Wilkinson, Patton, Thomason and Lewallen Sasseville 1980d, 676[VP] (Effective publication: Brenner, Steigerwalt, Gorman, Weaver, Feeley, Cordes, Wilkinson, Patton, Thomason and Lewallen Sasseville 1980c, 115.)
du.mof′fi.i. M.L. gen. n. *dumoffii* of Dumoff, named after Morris Dumoff, who first isolated *L. pneumophila* directly on bacteriologic media.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. One strain of *L. dumoffii* failed to produce brown pigment on tyrosine-containing media (Edelstein and Pryor, 1985). Serologic cross-reactions are detailed in Table BXII.γ.60. *L. dumoffii* cannot be distinguished reliably from *L. bozemanii*, *L. micdadei*, or *L. gormanii* by analysis of cellular fatty acids (Karr et al., 1982). Causative agent of human pneumonia (Dumoff, 1979). Isolated from human lung tissue, prosthetic heart valves (Tompkins et al., 1988), and from water. DNA relatedness between strains of *L. dumoffii* is 90%. *L. dumoffii* is 3–57% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 41–42 (T_m).

Type strain: NY-23, ATCC 33279.

GenBank accession number (16S rRNA): Z32637, X73405.

Additional Remarks: The type strain was isolated from water by G. W. Gorman in 1978.

10. **Legionella erythra** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.VP

e.ryth′ra. Gr. fem. adj. *erythra* red after the red autofluorescence exhibited by the species.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. A second serogroup of *L. erythra* cannot be distinguished serologically from *L. rubrilucens* (Table BXII.γ.60) (Saunders et al., 1992). The species contains two serogroups (Table BXII.γ.61) (Saunders et al., 1992). Not yet demonstrated to cause human disease. Isolated from surface water. *L. rubrilucens* and *L. erythra* are 59–62% interrelated, with 9.0–9.5% divergence in related sequences. Relatedness to other *Legionella* species ranges from 5–59%. The closest other species was *L. spiritensis* with 20% relatedness. At 75°C *L. rubrilucens* and *L. erythra* are 27–34% related (Table BXII.γ.62).

The mol% G + C of the DNA is: 51 (T_m).

Type strain: SE-32A-C8, ATCC 35303.

GenBank accession number (16S rRNA): Z32638.

Additional Remarks: The type strain was isolated from cooling tower water in Seattle, Washington, by George W. Gorman in 1981.

11. **Legionella fairfieldensis** Thacker, Benson, Hawes, Gidding, Dwyer, Mayberry and Brenner 1991b, 580VP (Effective publication: Thacker, Benson, Hawes, Gidding, Dwyer, Mayberry and Brenner 1991a, 477.)

fair.field.en′sis. N.L. fem. adj. *fairfieldensis* coming from Fairfield, Victoria, Australia.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from surface water. Strains of *L. fairfieldensis* are 87–94% related at 60°C, with 0.0–0.5% divergence. *L. fairfieldensis* was ≤17% related to 30 other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: 1725-AUS-E, ATCC 49588.

Additional Remarks: The type strain was isolated from cooling tower water in Fairfield, Victoria, Australia, in 1987.

12. **Legionella feeleii** Herwaldt, Gorman, McGrath, Toma, Brake, Hightower, Jones, Reingold, Boxer, Tang, Moss, Wilkinson, Brenner, Steigerwalt and Broome 1984b, 355VP (Effective publication: Herwaldt, Gorman, McGrath, Toma, Brake, Hightower, Jones, Reingold, Boxer, Tang, Moss, Wilkinson, Brenner, Steigerwalt and Broome 1984a, 338.)

fee.le′i.i. M.L. gen. n. *feeleii* of the late James Feeley, who contributed greatly to early work on *Legionella* and developed effective agar media for primary isolation.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Hydrolysis of hippurate by *L. feeleii* has been reported by some investigators, but not others (Brenner et al., 1985). Serologic cross-reactions are detailed in Table BXII.γ.60. The species contains two serogroups (Thacker et al., 1985). Causative agent of human pneumonia (Thacker et al., 1985) and acute, nonpneumonic, febrile illness (Pontiac fever) (Herwaldt et al., 1984a). Isolated from human sputum and lung tissue and from surface water. The DNA relatedness among strains of *L. feeleii* is 78–100% at 75°C; *L. feeleii* is 1–15% related to other *Legionella* species (Table BXII.γ.60).

The mol% G + C of the DNA is: 46 (T_m).

Type strain: WO-44C, ATCC 35072.

GenBank accession number (16S rRNA): X73395.

Additional Remarks: The type strain was isolated from industrial coolant by George W. Gorman in 1981.

13. **Legionella geestiana** Dennis, Brenner, Thacker, Wait, Vesey, Steigerwalt and Benson 1993, 335.VP

gees.ti.a′na. M.L. gen. n. *geestiana* pertaining to the Geest office building.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from potable water. *L. geestiana* is 0–10% related to other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 52 (T_m).

Type strain: 1308ATCC 49504.

Additional Remarks: The type strain was isolated from a domestic hot water tap in the Geest Office Building in London, United Kingdom, between 1982 and 1984.

14. **Legionella gormanii** Morris, Steigerwalt, Feeley, Wong, Martin, Patton and Brenner 1980b, 676VP (Effective publication: Morris, Steigerwalt, Feeley, Wong, Martin, Patton and Brenner 1980a, 720.)

gor.man′i.i. M.L. gen. n. *gormanii* of Gorman; named after G.W. Gorman, who isolated and first studied the organism and pioneered in the isolation of legionellae from environmental and clinical sources.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. *L. gormanii* cannot be distinguished reliably from *L. bozemanii*, *L. micdadei*, or *L. dumoffii* by analysis of cellular fatty acids (Karr et al., 1982). Causative agent of human pneumonia (Griffith et al., 1988). Isolated from bronchial lavage fluid and from water. *L. gormanii* is 1–47% related to other *Legionella* species. The relationship of strains within the species is >90%.

The mol% G + C of the DNA is: 41 (T_m).

Type strain: LS-13, ATCC 33297.

GenBank accession number (16S rRNA): Z32639.

Additional Remarks: The type strain was isolated by G.W. Gorman from creek bank soil in 1978.

15. **Legionella gratiana** Bornstein, Marmet, Surgot, Nowicki, Meugnier, Fleurette, Ageron, Grimont, Grimont, Thacker, Benson and Brenner 1991, 580VP (Effective publication: Bornstein, Marmet, Surgot, Nowicki, Meugnier, Fleurette, Ageron, Grimont, Grimont, Thacker, Benson and Brenner 1989a, 550.)

gra′ti.an.a. M.L. fem. adj. *gratiana* of Gratianus, the Roman emperor who bathed in the hot springs where the species was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from surface and potable water. Using the hydroxyapatite method at 60°C, *L. gratiana* was most closely related to *L. longbeachae* (46%), *L. cincinnatiensis* (41%), *L. sainthelensi* (38%), and *L. parisiensis* (32%). The relationship to 23 other species was <16% (Table BXII.γ.62).

The mol% G + C of the DNA is: 38 (T_m).

Type strain: Lyon 8420412, ATCC 49413, CDC 1242.

Additional Remarks: The type species was isolated from spring water at a spa in the Savoy region of France, first reported in 1989.

16. **Legionella hackeliae** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.[VP]
hack.el′i.ae. M.L. gen. n. *hackeliae* after Meredith Hackel, who first isolated the organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Causative agent of human pneumonia (Brenner et al., 1985; Wilkinson et al., 1985b). Isolated from human bronchial biopsy tissue (Brenner et al., 1985; Wilkinson et al., 1985b). *L. hackeliae* is 3–22% related to other *Legionella* species under optimal conditions; it is 14–17% related to *L. jamestowniensis* in reciprocal studies and is 22% related to *L. cherrii* (Table BXII.γ.62).

The mol% G + C of the DNA is: 40 (T_m).

Type strain: Lansing 2, ATCC 35250.

GenBank accession number (16S rRNA): M36028.

Additional Remarks: The type strain was isolated from a bronchial biopsy specimen by Meredith Hackel in 1981.

17. **Legionella israelensis** Bercovier, Steigerwalt, Derhi-Cochin, Moss, Wilkinson, Benson and Brenner 1986, 369.[VP]
is.ra.el.en′sis. M.L. fem. adj. *israelensis* coming from Israel.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from surface water. Strains of *L. israelensis* are 95–100% related to each other under optimal conditions. The relationship to other species tested was 3–12% (Table BXII.γ.62).

The mol% G + C of the DNA is: 40 (T_m).

Type strain: Bercovier 4, ATCC 43119.

GenBank accession number (16S rRNA): X73408, Z32640.

Additional Remarks: The type strain was isolated from an oxidation pond in Gaash, Israel, by Hervé Bercovier.

18. **Legionella jamestowniensis** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.[VP]
james′town.i.en.sis. M.L. gen. n. *jamestowniensis* named after Jamestown, New York, where the organism was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not yet demonstrated to cause human disease. Isolated from wet soil. When tested under stringent conditions at 75°C *L. jamestowniensis* is 1–17% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: JA-26-G1-E2, ATCC 35298.

GenBank accession number (16S rRNA): X73409.

Additional Remarks: The type strain was isolated by G.W. Gorman from wet soil in 1979.

19. **Legionella jordanis** Cherry, Gorman, Orrison, Moss, Steigerwalt, Wilkinson, Johnson, McKinnery and Brenner 1982b, 384[VP] (Effective publication: Cherry, Gorman, Orrison, Moss, Steigerwalt, Wilkinson, Johnson, McKinnery and Brenner 1982a, 294.)
jor.da′nis. M.L. gen. n. *jordanis* named after the Jordan River in Bloomington, Indiana, source of the first isolate.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Thacker et al., 1988b). Isolated from human lung tissue and from water and sewage. DNA relatedness among strains of *L. jordanis* is >90%. *L. jordanis* is 2–20% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 45 (T_m).

Type strain: BL-540, ATCC 33623.

GenBank accession number (16S rRNA): Z32667, X73396.

Additional Remarks: The type strain was isolated from surface water by G.W. Gorman in 1978.

20. **Legionella lansingensis** Thacker, Dyke, Benson, Havlichek, Robinson-Dunn, Stiefel, Schneider, Moss, Mayberry and Brenner 1994, 595[VP] (Effective publication: Thacker, Dyke, Benson, Havlichek, Robinson-Dunn, Stiefel, Schneider, Moss, Mayberry and Brenner 1992, 2400.)
lan.sing.en′sis. M.L. fem. adj. *lansingensis* from Lansing, Michigan, where the species was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Thacker et al., 1992). Isolated from human bronchoscopic washings. *L. lansingensis* was 1–12% related to the 28 other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 42.6 (T_m).

Type strain: 1677-MI-H, ATCC 49751.

Additional Remarks: The type strain was isolated from human bronchoscopic washings in Lansing, Michigan, in 1986.

21. **Legionella londiniensis** Dennis, Brenner, Thacker, Wait, Vesey, Steigerwalt and Benson 1993, 335.[VP]
lon.din.i.en′sis. M.L. gen. n. *londiniensis* coming from London where the first isolate was made.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Weak hydrolysis of hippurate may be observed. Not demonstrated to cause human disease. Isolated from surface water. Strains of *L. londiniensis* are >90% related to each other. They are 0–36% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 43 (T_m).

Type strain: 1477, ATCC 49505.

Additional Remarks: The type strain was isolated between 1982 and 1984 from cooling tower pond water in London, England.

22. **Legionella longbeachae** McKinney, Porschen, Edelstein, Bissett, Harris, Bondell, Steigerwalt, Weaver, Ein, Lindquist, Kops and Brenner 1982, 266^{VP} (Effective publication: McKinney, Porschen, Edelstein, Bissett, Harris, Bondell, Steigerwalt, Weaver, Ein, Lindquist, Kops and Brenner 1981, 743.)
long.beach' ae. M.L. gen. n. *longbeachae* of Long Beach (California) where the organism was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. *L. longbeachae* cannot be distinguished from *L. pneumophila* by analysis of fatty acid composition (Table BXII.γ.58) (Bibb et al., 1981). The species contains two serogroups (Table BXII.γ.61) (Bibb et al., 1981). Causative agent of human pneumonia. Isolated from human lung tissue and transtracheal aspirates and from surface water and moist potting soils. The DNA relatedness among strains of *L. longbeachae* is 97–100% *L. longbeachae* is 2–22% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 40 (T_m).

Type strain: Long Beach 4, ATCC 33462, DSM 10572, NCTC 11477.

GenBank accession number (16S rRNA): M36029.

Additional Remarks: The type strain was isolated from a transtracheal aspirate by R. Porschen in 1980.

23. **Legionella lytica** (Drozanski 1991) Hookey, Saunders, Fry, Birtles and Harrison 1996, 529^{VP} (*Sarcobium lyticum* Drozanski 1991, 86.)
ly' ti.ca. M.L. neut. adj. *lyticum* that which causes lysis.

Identity was established between an amoebal pathogen, *Legionella lytica*, and a previously described amoebal pathogen, *Sarcobium lyticum* (Drozanski, 1991). The new nomenclature is proposed, because the genus *Legionella* has priority over *Sarcobium.* This species is an obligate intracellular parasite of amoebae with limited ability to grow on agar. The few known characteristics are listed in Table BXII.γ.56. Etiologic agent of human disease (Fry et al., 1991a). Isolated from human sputum and lung with amoebae. Isolated bacteria are not available for DNA hybridization experiments. The genetic sequence of *L. lytica* is <97% related to other *Legionella* spp. and thus likely to represent a new species (Fry et al., 1991aM).

The mol% G + C of the DNA is: 43 (T_m).

Type strain: L2, PCM 2298.

GenBank accession number (16S rRNA): X97364.

24. **Legionella maceachernii** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.^{VP}
mac.kath' er.ni.i. M.L. gen. n. *maceachernii* named after Harold V. McEachern, who first isolated the organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Wilkinson et al., 1985a). Isolated from human bronchial biopsy tissue, water from a home evaporative condenser, and a potable water cistern. When tested under stringent conditions at 75°C *L. maceachernii* is 3–23% related to other *Legionella* species; it is 14–17% related to *L. jamestowniensis* in reciprocal studies and is 22% related to *L. cherrii* (Table BXII.γ.62).

The mol% G + C of the DNA is: 41 (T_m).

Type strain: PX-1-G2-E2, ATCC 35300.

GenBank accession number (16S rRNA): Z32641.

Additional Remarks: The type species was isolated by George W. Gorman from water from a home evaporative condenser in 1979.

25. **Legionella micdadei** Hébert, Steigerwalt and Brenner 1980c, 676^{VP} (Effective publication: Hébert, Steigerwalt and Brenner 1980b, 257) (*Legionella pittsburghensis* Pasculle, Feeley, Gibson, Cordes, Myerowitz, Patton, Gorman, Carmack, Ezzell and Dowling 1980, 731.)
mic.da' de.i. M.L. gen. n. *micdadei* of McDade, named after Joseph E. McDade, who isolated the etiologic agent of the 1976 Legionnaires' disease outbreak in Philadelphia.

Selected characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of pneumonia. Originally referred to as the Pittsburgh pneumonia agent. Not acid-fast by the Ziehl-Neelsen method (Hébert et al., 1980d), but may appear acid-fast in tissue preparations stained by other methods (Pasculle et al., 1979). Browning was demonstrated on F-G agar only after some strains were well adapted to and growing well on this medium. This took 12 or more subcultures (Hébert et al., 1980d). Without adaptation or in the absence of heavy growth, no browning occurs on F-G agar (Morris et al., 1980a). Isolated from human lung, blood, soft tissue, and from potable water. DNA relatedness between strains of *L. micdadei* is 90–100%. *L. micdadei* is 1–23% related to other *Legionella* species (Table BXII.γ.62). *L. micdadei* cannot be distinguished reliably from *L. bozemanii*, *L. dumoffii*, or *L. gormanii* by analysis of cellular fatty acids (Karr et al., 1982).

The mol% G + C of the DNA is: 41–44 (T_m).

Type strain: TATLOCK, ATCC 33218.

GenBank accession number (16S rRNA): M36032.

Additional Remarks: The type strain was isolated by H. Tatlock from a guinea pig inoculated with human blood in 1943.

26. **Legionella moravica** Wilkinson, Drasar, Thacker, Benson, Schindler, Potuznkiova, Mayberry and Brenner 1989, 205^{VP} (Effective publication: Wilkinson, Drasar, Thacker, Benson, Schindler, Potuznkiova, Mayberry and Brenner 1988a, 399.)
mo.ra' vi.ca. M.L. gen. n. *moravica* coming from Moravia, Czechoslovakia.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from surface water. *L. moravica* was 1–9% related to 31 other named or described *Legionella* species and 24–36% related to two undescribed species (Table BXII.γ.62).

The mol% G + C of the DNA is: 41.5 (T_m).

Type strain: 316-36, ATCC 43877, CDC 1634-CZK-E.

Additional Remarks: The type strain was isolated from cooling tower water in Moravia, where the species was first isolated; first reported in 1987.

27. **Legionella nautarum** Dennis, Brenner, Thacker, Wait, Vesey, Steigerwalt and Benson 1993, 335.[VP]
nau.ta'rum. M.L. gen. n. *nautarum* of sailors.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from potable water. Two strains of *L. nautarum* were 70% related to each other at 60°C and 78% at 75°C. Relatedness with other *Legionella* species ranges from 2–24% at 60°C (Table BXII.γ.62).
The mol% G + C of the DNA is: 41 (T_m).
Type strain: 1224, ATCC 49506.
Additional Remarks: The type strain was isolated from a domestic water system in London, England.

28. **Legionella oakridgensis** Orrison, Cherry, Tyndall, Fliermans, Gough, Lambert, McDougal, Bibb and Brenner 1983b, 672[VP] (Effective publication: Orrison, Cherry, Tyndall, Fliermans, Gough, Lambert, McDougal, Bibb and Brenner 1983a, 544.)
oak.ridg.en'sis. M.L. gen. n. *oakridgensis* named after Oak Ridge, Tennessee, where the species was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Tang et al., 1985). Isolated from human lung (Tang et al., 1985) and from cooling tower water (Orrison et al., 1983a). The DNA relatedness among strains of *L. oakridgensis* is 90–100%; *L. oakridgensis* is 2–22% related to other *Legionella* species (Table BXII.γ.62).
The mol% G + C of the DNA is: 43–45 (T_m).
Type strain: Oak Ridge 10, ATCC 33761.
GenBank accession number (16S rRNA): X73397, Z32642.
Additional Remarks: The type strain was isolated from cooling tower water by R.L. Tyndall, C.B. Duncan, and E.L. Domingue in 1981.

29. **Legionella parisiensis** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.[VP]
pa.ri.si.en'sis. M.L. fem. adj. *parisiensis* coming from Paris, France.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Lo Presti et al., 1997). Isolated from surface water and human tracheal aspirate. *L. parisiensis* is substantially related to the other *Legionella* species that exhibit blue-white autofluorescence: *L. bozemanii*, *L. dumoffii*, *L. gormanii*, *L. cherrii*, and *L. steigerwaltii*. Of the species that do not exhibit blue-white autofluorescence, *L. parisiensis* is most closely related to *L. wadsworthii* (37%) (Table BXII.γ.62).
The mol% G + C of the DNA is: 42 (T_m).
Type strain: PF-209C-C2, ATCC 35299.
Additional Remarks: The type strain was isolated from cooling tower water by George W. Gorman in 1981.

30. **Legionella quateirensis** Dennis, Brenner, Thacker, Wait, Vesey, Steigerwalt and Benson 1993, 336.[VP]
qua.teir.en'sis. M.L. gen. n. *quateirensis* coming from Quateira.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. *L. quateirensis* cannot be distinguished serologically from *L. worsleiensis* or *L. pneumophila* serogroup 4. Not demonstrated to cause human disease. Isolated from potable water. *L. quateirensis* is 2–36% related at 60°C to other *Legionella* species tested. It is most closely related to *L. moravica* (36%) (Table BXII.γ.62).
The mol% G + C of the DNA is: 39 (T_m).
Type strain: 1335, ATCC 49507.
Additional Remarks: The type strain was isolated from a shower in a bathroom of a hotel in Quateira, Portugal, between 1982 and 1984.

31. **Legionella quinlivanii** Benson, Thacker, Waters, Quinlivan, Mayberry, Brenner and Wilkinson 1990b, 105[VP] (Effective publication: Benson, Thacker, Waters, Quinlivan, Mayberry, Brenner and Wilkinson 1989, 196.)
quin.li.va'ni.i. N.L. gen. n. *quinlivanii* named after P.A. Quinlivan.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. There are two serogroups of *L. quinlivanii* (Birtles et al., 1991). Isolated from surface water. The relationship among strains of *L. quinlivanii* is 92–100%. *L. quinlivanii* is 1–30% related to other *Legionella* species; under optimum conditions the most closely related *Legionella* sp. was *L. birminghamensis* (23–30%) (Table BXII.γ.62).
The mol% G + C of the DNA is: 43 (T_m).
Type strain: 14442-AUS-E, ATCC 43830, NCTC 12433.
Additional Remarks: The type strain was isolated from water in Australia in 1986.

32. **Legionella rubrilucens** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.[VP]
ru.bri.lu'sens. M.L. gen. n. *rubrilucens* "red shining" after the red autofluorescence exhibited by the species.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. A second serogroup of *L. erythra* cannot be distinguished serologically from *L. rubrilucens* (Table BXII.γ.60) (Saunders et al., 1992) Not yet demonstrated to cause human disease. Isolated from tap water. *L. rubrilucens* and *L. erythra* are 59–62% interrelated, with 9.0–9.5% divergence in related sequences. Relatedness to other *Legionella* species ranges from 3–59%. The most closely related other species was *L. spiritensis* at 34%. At 75°C *L. rubrilucens* and *L. erythra* are 27–34% related (Table BXII.γ.62).
The mol% G + C of the DNA is: 52 (T_m).
Type strain: WA-270A-C2, ATCC 35304, DSMZ 11884.
GenBank accession number (16S rRNA): X73398, Z32643.

Additional Remarks: The type strain was isolated from tap water in Los Angeles, California, by Giorge W. Gorman in 1980.

33. **Legionella sainthelensi** Campbell, Bibb, Lambert, Eng, Steigerwalt, Allard, Moss and Brenner 1984b, 355[VP] (Effective publication: Campbell, Bibb, Lambert, Eng, Steigerwalt, Allard, Moss and Brenner 1984a, 372.)
saint.he' len.si. M.L. gen. n. *sainthelensi* from Mount St. Helens, where the original isolate was made from surface water in the devastated area after a volcanic eruption.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. The species contains two serogroups (Benson et al., 1990a). Causative agent of human pneumonia (Benson et al., 1990a). Isolated from human respiratory secretions (Benson et al., 1990a) and from surface water (Campbell et al., 1984a). The DNA relatedness among strains of *L. sainthelensi* is 91–100%; the two species most closely related to *L. sainthelensi* are *L. santicrucis* (58% related with a divergence of 9% at 60°C and 11% related at 75°C) and *L. longbeachae* (37% related with 8.5% divergence at 60°C and 4% related at 75°C). *L. spiritensis* was 3–14% related to the other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 41 (T_m).

Type strain: Mt. St. Helens 4, ATCC 35248.

GenBank accession number (16S rRNA): X73399.

Additional Remarks: The type strain was isolated from spring water by J. Campbell and S. Eng in 1981.

34. **Legionella santicrucis** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 58.[VP]
san.ti.cru' cis. M.L. gen. n. *santicrucis* named after Santa Crux, the Latin name for St. Croix, Virgin Islands.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from potable water. *L. santicrucis* is 7–64% related to other *Legionella* species. It is closely related to *L. sainthelensi* (64% related at 60°C and 23% at 75°C) and is 38% related to *L. longbeachae* (Table BXII.γ.62).

The mol% G + C of the DNA is: 38 (T_m).

Type strain: SC-63-C7, ATCC 35301.

Additional Remarks: The type strain was isolated from tap water in St. Croix, Virgin Islands, by George W. Gorman in 1982.

35. **Legionella shakespearei** Verma, Brenner, Thacker, Benson, Vesey, Kurtz, Dennis, Steigerwalt, Robinson and Moss 1992, 406.[VP]
shakes.pea.re' i. N.L. gen. n. *shakespearei* named after the playwright William Shakespeare, because the organism was isolated in Stratford-upon-Avon.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. The species is distinctive in production of uniformly pink colonies on BCYE agar. Not demonstrated to cause human disease. Isolated from surface water. *L. shakespearei* was 25% related to *L. jordanis* at 60°C. It was <10% related to 26 other *Legionella* species tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 45.5 (T_m).

Type strain: 214, ATCC 49655.

Additional Remarks: The type strain was isolated from cooling tower water in Stratford-upon-Avon, United Kingdom, reported in 1992.

36. **Legionella spiritensis** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 55.[VP]
spi.ri.ten' sis. M.L. fem. adj. *spiritensis* coming from Spirit Lake near Mount St. Helens in Oregon.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not yet associated with human disease. There are two serogroups of *L. spiritensis* (Harrison et al., 1988). Isolated from surface water. *L. spiritensis* is most closely related (34%) to *L. rubrilucens*, a red fluorescing species. It is 4–34% related to a number of species, including *L. erythra*, another red fluorescing species (Table BXII.γ.62).

The mol% G + C of the DNA is: 46 (T_m).

Type strain: Mt. St. Helens 9, ATCC 35249.

GenBank accession number (16S rRNA): M36030.

Additional Remarks: The type strain was isolated from lake water by J. Campbell in 1981.

37. **Legionella steigerwaltii** Brenner, Steigerwalt, Gorman, Wilkinson, Bibb, Hackel, Tyndall, Campbell, Feeley, Thacker, Skaliy, Martin, Brake, Fields, McEachern and Corcoran 1985, 57.[VP]
stei.ger.wal' ti.i. M.L. gen. n. *steigerwaltii* named in honor of Arnold G. Steigerwalt, who did the definitive experiments to classify the first 22 *Legionella* species.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from potable water. *L. steigerwaltii* is 32–54% related to other species that exhibit blue-white autofluorescence. It is 31–34% related to three species that do not autofluoresce: *L. santicrucis*, *L. wadsworthii*, and *L. sainthelensi*. The relationship with other species is 6–33% (Table BXII.γ.62).

The mol% G + C of the DNA is: 40 (T_m).

Type strain: SC-18-C9, ATCC 35302.

GenBank accession number (16S rRNA): X73400.

Additional Remarks: The type strain was isolated from tap water in St. Croix, Virgin Islands, by George W. Gorman in 1982.

38. **Legionella taurinensis** Lo Presti, Riffard, Meugnier, Reyrolle, Lasne, Grimont, Grimont, Vandenesch, Etienne, Fleurette and Freney 1999, 401.[VP]
tau.ri.nen' sis. M.L. adj. *taurinensis* pertaining to Turin, Italy, whose classical Latin name was Augusta Taurinorum.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from potable and surface water. Strains of *L. taurinensis* were 78–100% related to each other. *L. taurinensis* was >20% related to *L. rubrilucens*, *L. erythra*, and *L. spiritensis*. Its closest relative was *L. rubrilucens*, which was 54% related. In reciprocal reactions *L. taurinensis* was 64% re-

lated to *L. rubrilucens* with 7.5% divergence under optimal conditions tested (Table BXII.γ.62).

The mol% G + C of the DNA is: 46 (T_m, HPLC).

Type strain: Turin 1, ATCC 700508.

GenBank accession number (16S rRNA): AF037597.

Additional Remarks: The type strain was isolated from a humidifier in Turin, Italy.

39. **Legionella tucsonensis** Thacker, Benson, Schifman, Pugh, Steigerwalt, Mayberry, Brenner and Wilkinson 1990b, 105[VP] (Effective publication: Thacker, Benson, Schifman, Pugh, Steigerwalt, Mayberry, Brenner and Wilkinson 1989a, 1833.)
tuc.so.nen′ sis. M.L. fem. adj. *tucsonensis* from Tucson, Arizona, where the species was first isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Thacker et al., 1989a). Isolated from pleural fluid. Of the species tested, *L. tucsonensis* was most closely related to the following species that show blue-white autofluorescence: *L. bozemanii*, *L. gormanii*, and *L. parisiensis*. It is only 1–11% related to *L. birminghamensis*, *L. cincinnatiensis*, *L. brunensis*, *L. moravica*, and *L. quinlivanii* (Table BXII.γ.62).

The mol% G + C of the DNA is: 44 (T_m).

Type strain: 1087-AZ-H, ATCC 49180.

GenBank accession number (16S rRNA): Z32644.

Additional Remarks: The type strain was isolated from human pleural fluid in Tucson, Arizona in 1984.

40. **Legionella wadsworthii** Edelstein, Brenner, Moss, Steigerwalt, Francis and George 1983, 672[VP] (Effective publication: Edelstein, Brenner, Moss, Steigerwalt, Francis and George 1982a, 812.)
wads′ wor.thi.i. M.L. gen. n. *wadsworthii* of V.A. Wadsworth Medical Center after James Wadsworth, and the location where the patient was hospitalized and the bacterium isolated.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Causative agent of human pneumonia (Edelstein et al., 1982a). Isolated from human sputum. *L. wadsworthii* is 3–36% related to other *Legionella* species with a divergence of 9.5–16% at 60°C. When tested under stringent conditions at 75°C *L. wadsworthii* is 2–15% related to other *Legionella* species (Table BXII.γ.62).

The mol% G + C of the DNA is: 42 (T_m).

Type strain: Wadsworth 81-716A, ATCC 33877.

GenBank accession number (16S rRNA): X73401.

Additional Remarks: The type strain was isolated from sputum by Paul H. Edelstein in 1981.

41. **Legionella waltersii** Benson, Thacker, Daneshvar and Brenner 1996, 633.[VP]
wal′ ters.i.i. M.L. gen. n. *waltersii* of Walters, to honor R.P. Walters, who isolated the organism.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Not demonstrated to cause human disease. Isolated from potable and surface water. It was <10% related to other *Legionella* spp. tested.

The mol% G + C of the DNA is: unknown.

Type strain: 2074-AUS-E, ATCC 51914.

Additional Remarks: The type strain was isolated from a drinking water distribution system in South Australia by R.P. Waters in 1987–88.

42. **Legionella worsleiensis** Dennis, Brenner, Thacker, Wait, Vesey, Steigerwalt and Benson 1993, 336.[VP]
wors.lei.en′ sis. M.L. gen. n. *worsleiensis* coming from Worsley.

The characteristics are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. It cannot be distinguished serologically from *L. pneumophila* serogroup 4 or from *L. quateirensis*. Not demonstrated to cause human disease. Isolated from surface water. *L. worsleiensis* is 1–24% related to other *Legionella* species tested at 60°C (Table BXII.γ.62).

The mol% G + C of the DNA is: 41 (T_m).

Type strain: 1347, ATCC 49508.

Additional Remarks: The type strain was isolated from cooling tower return flow at an industrial site in Worsley, United Kingdom, between 1982 and 1984.

Other Organisms

1. *Legionella* genomospecies 1 Benson, Thacker, Daneshvar, and Brenner 1996.

This genetically distinct organism was reported as a genomospecies, because it could not be distinguished biochemically or serologically from *L. quinlivanii*, serogroup 2. The characteristics of the genomospecies are as described for the genus and as listed in Tables BXII.γ.56, BXII.γ.57, BXII.γ.58, and BXII.γ.59. Serologic cross-reactions are detailed in Table BXII.γ.60. Not demonstrated to cause human disease. Isolated from surface water. The relationship between *Legionella* genomospecies 1 and *L. quinlivanii* in reciprocal reactions was 53–69% with 4.5–6.5% under optimal conditions and 31–51% under stringent conditions. In the same laboratory the relationship between strains of *L. quinlivanii* was 79–99% with 0.5–3.0% under optimal conditions and 85–100% under stringent conditions is unknown. It was <10% related to other *Legionella* spp. tested (Table BXII.γ.62).

The mol% G + C of the DNA is: unknown.

Deposited strain: 2055-AUS-E, ATCC 51913.

Additional Remarks: The type strain was isolated from cooling tower water in South Australia, Australia.

Bacterial isolates recovered by conventional techniques may represent additional, as yet unnamed *Legionella* species (Wilkinson et al., 1990; Benson et al., 1996). Strains that have been described as probably new species include LC878, *"L. donaldsonii"* (Riffard et al., 1998i) and strain "glasgow" (Hookey et al., 1996). At least six genomospecies distinct from all named species except *L. taurinensis* have been characterized (D.J. Brenner, personal communication).

Family II. **Coxiellaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Co.xi.el.la′ ce.ae. M.L. fem. n. *Coxiella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Coxiellaceae* the *Coxiella* family.

The family *Coxiellaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Coxiella* (type genus) and *Rickettsiella*.

Found only in vacuoles in cells of invertebrate or vertebrate hosts. Serial passage in cell-free medium has not been achieved.

Type genus: **Coxiella** (Philip 1943) Philip 1948, 58[AL] (**Rickettsia (Coxiella) burnetii** Philip 1943, 306.)

Genus I. **Coxiella** *(Philip 1943) Philip 1948, 58[AL] (Rickettsia (Coxiella) burnetii Philip 1943, 306)*

Michel Drancourt and Didier Raoult

Co.xi.el′ la. M.L. fem. dim. *-ella* ending; M.L. fem. n. *Coxiella* named after Harold R. Cox, who in collaboration with G.E. Davis, first isolated this organism in the United States shortly after its discovery in Australia and who introduced the technique of yolk sac inoculation of the chick embryo, which greatly facilitated the study of this and other genera.

Strictly intracellular bacteria, usually 0.2–0.4 μm × 0.4–1.0 μm. Best stained by **Gimenez staining**. They have no flagella or capsule. They live in close natural association with **arthropod and vertebrate hosts**. The genus includes *Coxiella burnetii*—the **agent of Q fever**—and endosymbionts of ticks and aquatic invertebrates. *C. burnetii* grows well in cultured cell lines and in the yolk sac of chicken embryos, where it undergoes a cycle of development with formation of an endospore-like body. *Coxiella burnetii* possesses **two antigenic phases**: natural virulent phase I and attenuated phase II, which is obtained after passage in cultured cell lines and yolk sac. The organism **grows in vacuoles of the host cell** rather than in the cytoplasm or the nucleus. *C. burnetii* phase I vacuoles share characteristics of late-stage, immature phagosomes whereas *C. burnetii* phase II vacuoles are bactericidal phagolysosomes. Highly resistant to chemical agents and elevated temperature. Coxiellae occur worldwide in ticks and various vertebrates, including humans. Infection is particularly prevalent in cattle, sheep and goats. Extremely infectious; a single aerosol-borne organism can cause the human disease Q fever. *C. burnetii* is one of the ten most feared potential **bioterrorism agents**.

The mol% G + C of the DNA is: 42.7.

Type species: **Coxiella burnetii** (Derrick 1939) Philip 1948, 58[AL] (*Rickettsia burnetii* (sic) Derrick 1939, 14.)

Further descriptive information

Coxiellae are generally regarded as Gram-negative rods, but they are best stained by Gimenez staining (Gimenez, 1964) (Fig.BXII.γ.97). They have no flagella or capsule and are not always retained by ordinary bacteriological filters. Coxiellae have never been cultured axenically in laboratory media, although outside the host, the organisms metabolize glutamate, glucose and other substrates if the pH is low. Electron microscopy of bacteria separated from host cell components reveals great variation in morphology.

Cell morphology Two forms of *C. burnetii* cells are found in infected eucaryotic cells: a metabolically inactive sporelike "small-cell variant" (SCV; 204–450 nm) and a "large-cell variant" (LCV;

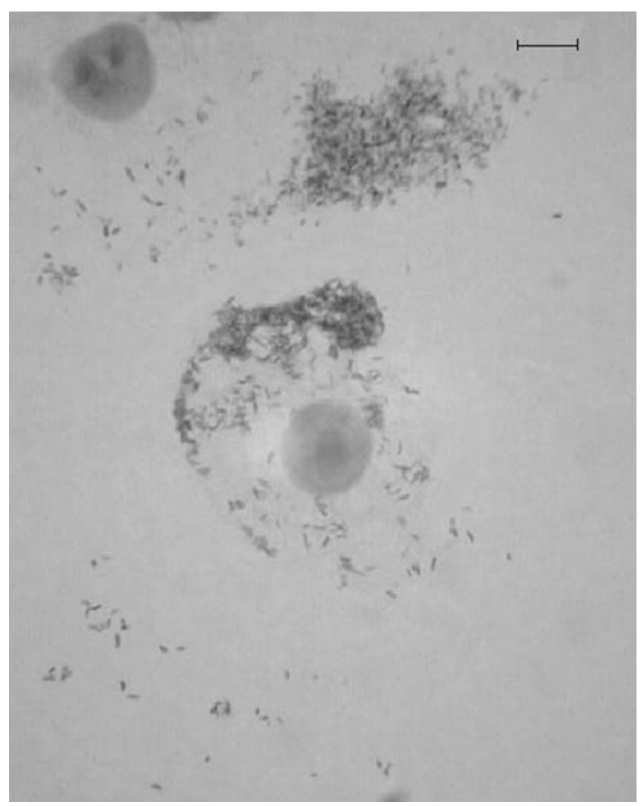

FIGURE BXII.γ.97. Gimenez-stained *Coxiella burnetii* inside a large vacuole of a L 929 cell. Bar = 5 μm.

up to 2 μm in length). SCVs develop from LCVs following an asymmetric cell division (McCaul, 1991) and are distinguished from LCVs by having a regular rod shape, a dense layer of peptidoglycan and protein between the two layers of the cell envelope, and condensed nucleoids. The more pleomorphic LCVs possess dispersed nucleoids and granules or sometimes fibrils in their cytoplasm. Condensation or dispersal of the nucleoid may be associated with the presence in SCVs of a 20-kDa protein—Hq1—that binds DNA; Hq1 is a homolog of histone H1 (Heinzen and Hackstadt, 1996).

SCVs also possess greater resistance than LCVs to drying, UV irradiation, acid or alkaline pH, disinfectants, and other chemicals (Ranson and Huebner, 1951; Babudieri, 1959; Maurin and Raoult, 1999). At 4°C, viability of SCVs is retained for 1 year or more in dried fomites such as tick feces and wool, as well as in sterile skim milk or unchlorinated water. Meats remain infected for at least 1 month. Complete inactivation is not always accomplished by exposure to 63°C for 30 min or 85–90°C for a few seconds. *C. burnetii* is rapidly inactivated by diethyl ether but not by ethanol (Ranson and Huebner, 1951; Babudieri, 1959).

Thus, the morphogenesis and properties of SCVs are comparable, although not identical, to cycles of cell differentiation and formation of resistant, inactive cell forms in other bacteria (McCaul and Williams, 1991). SCVs are released from host cells and bind to the membranes of phagocytic cells; hence, SCVs appear to be a resistant stage adapted to survive transmission between individual hosts. In addition, *C. burnetii* is highly infectious: a single organism can cause aerosol-borne disease. It has therefore been considered a potential weapon for biological warfare (Lederberg, 2000) and has been classified as a category B biological weapon by the Centers for Disease Control and Prevention, Atlanta, GA.

Antigenic structure Repeated serial passage (10–100 times) in cultured eucaryotic cells or in embryonated eggs produces attenuated "rough" or Phase II variants of naturally-occurring virulent "smooth" or Phase I *C. burnetii*. This phenomenon resembles the production of rough variants of smooth strains of enterobacteria (Stoker and Fiset, 1956; Brezina, 1978) and involves mutation in the genes encoding enzymes that synthesize the lipopolysaccharide (LPS) (Hackstadt et al., 1985; Hackstadt, 1988). Phase II *C. burnetii* strains exhibit changes in both the sugar composition and the length of the LPS (Amano and Williams, 1984). The sugars dihydrohydroxystreptose, galactosamine uronyl-α-(1,6)-glucosamine and L-virenose are present in Phase I but not Phase II LPS (Schramek and Mayer, 1982; Schramek et al., 1985; Amano et al., 1987; Hackstadt, 1990). The protein complement of the outer membrane also changes during the transition from Phase I to Phase II (Amano and Williams, 1984). Vodkin and Williams (1986) demonstrated large deletions in the genome of the Phase II Nine Mile strain.

Genetics The genome of *C. burnetii* consists of a chromosome plus a facultative 36–42-Kb plasmid whose function remains undetermined. The genome of the Nine Mile strain of *C. burnetii* is 1.99 Mb based on the complete genome sequence (GenBank accession number NC002971), but the genome size varies from 1.5 to 2.4 Mb among different *C. burnetii* strains (Willems et al., 1998). In addition, complete genome sequencing confirmed that the chromosome is circular, contrary to previous speculations of a linear geometry (Willems et al., 1996; 1998; Dr. J.E. Samuel, personal communication). The *C. burnetii* Nine Mile strain genome comprises 6653 open reading frames (ORFs) that code for peptides of ≥50 residues. A physical macrorestriction map of *C. burnetii* Nine Mile phase I was constructed by Willems et al. (1996; 1998); 25 DNA fragments were distinguished by pulsed field gel electrophoresis (PFGE) after digestion of total DNA with *Not*I. Vodkin and Williams (1988) and Hoover and Williams (1990) have elucidated operon structures in *C. burnetii*.

Fifteen *C. burnetii* genes have been cloned to date in *Escherichia coli*, including genes involved in metabolism (*gltA* (Heinzen and Mallavia, 1987), *pyrB* (Hoover and Williams, 1990), and *icd* (Nguyen and Hirai, 1999)), transcription and translation (*rpoD* and *rpoS* (Seshadri and Samuel, 2001) and *serS* (Willems et al., 1996)); stress responses, (*sodB* (Heinzen et al., 1992), *htpA* and *htpB* (Vodkin and Williams, 1988), and *dnaJ* (Zuber et al., 1995a)), production of surface antigens (*omp* (Hendrix et al., 1990), *mucZ* (Zuber et al., 1995b), and *algC* (Willems et al., 1996)), and environmental sensing (*qrsA* (Mo and Mallavia, 1994)). In addition, a possible chromosomal origin of replication (*oriC*) has been cloned (Chen et al., 1990a), but Suhan et al. (1996) were unable to demonstrate the ability of this DNA fragment to initiate DNA replication in *C. burnetii*.

Plasmid DNA can be introduced into *C. burnetii* by electroporation; plasmids bearing both antibiotic resistance determinants (Suhan et al., 1994; 1996) and a green fluorescent protein gene (Lukacova et al., 1999) have been introduced and the genes expressed.

Four plasmids native to *C. burnetii* have been characterized: QpH1 (Samuel et al., 1983), QpRS (Samuel et al., 1985), QpDG (Mallavia, 1991), and QpDV (Valkova and Kazar, 1995). These plasmids are 33–42 Kb in size and share 30 kb of homology with each other (Minnick et al., 1990; Mallavia, 1991). The chromosomal DNAs of some plasmid-free genomic group V *C. burnetii* strains contain a region of homology to the DNA of plasmid QpRS (Savinelli and Mallavia, 1990); this region is derived from plasmid sequences (Lautenschlager et al., 2000). The entire DNA sequences of plasmids QpH1 and QpDV have been obtained (Thiele et al., 1994, GenBank accession number NC002118; and Valkova and Kazar (1995), GenBank accession number NC002131; respectively).

DNA–DNA hybridization studies showed that *C. burnetii* strains are homogenous (Vodkin and Williams, 1986). Early studies of genetic differences among strains revealed by RFLP analysis (Hendrix et al., 1991), plasmid analysis (Samuel et al., 1983, 1985; Mallavia, 1991), and immunoblotting of LPS (Hackstadt, 1986) suggested that six RFLP-defined groups differed in their association with "acute" or "chronic" cases of Q fever. However, recent studies on larger numbers of strains from a variety of locations and sources using improved techniques—genomic RFLP (Thiele and Willems, 1994; Jäger et al., 1998), PCR-based plasmid analysis (Stein and Raoult, 1993), immunoblotting of LPS with specific monoclonal antibodies (Yu and Raoult, 1994), and gene sequence analysis (Nguyen and Hirai, 1999; Sekeyova et al., 1999)—have shown that genetic variation in this pathogen is geographic in origin. (See also Thiele et al. (1993) and Willems et al. (1996).) Moreover, variation in host factors is more likely to explain whether individual cases of Q fever are "acute" or "chronic" than is genetic variation in the pathogen (La Scola et al., 1998b; Maurin and Raoult, 1999; Raoult et al., 2000; Fenollar et al., 2001).

Epidemiology In humans, contact between *C. burnetii* and a nonimmune individual results in a primary infection which can be either asymptomatic or symptomatic. The symptomatic primary infection is acute Q fever, which is usually followed by complete recovery of a normal host. In some hosts, *C. burnetii* can multiply despite an antibody response following primary infection, symptomatic or not. In these cases, chronic infection develops because the immune system is unable to control the infection. This distinction between acute and chronic infection is based on clinical expression, temporal course, and the serological profile of the patient, and is mainly determined by host factors. This hypothesis is supported by all available data from humans as well as from animal models.

The aerosol route is the principal mode of acquisition of *C. burnetii* infection (Babudieri, 1959; Dupuis et al., 1987; Tissot-Dupont et al., 1999). *C. burnetii* is highly infectious, and a single organism can cause the aerosol-borne Q fever. This fact and the great resistance of *C. burnetii* to environmental stresses have led to the classification of *C. burnetii* as a group B bioterrorism agent. Indeed, due to its sporelike form, *C. burnetii* may remain viable in soil and milk for several months following contamination. Cattle, sheep, and goats are the main reservoirs of *C. burnetii* infection for humans. High densities of *C. burnetii* are found in the placenta of infected parturient animals and are shed in the environment following labor. In Europe, most cases occur between January and June because of the heavily contaminated environment following lambing season. Cases among students following visits to farms as part of school activities and outbreaks following exposure to birth products of cats, dogs, and rabbits, have been reported. *C. burnetii* can also be transmitted by ingestion of unpasteurized dairy products (Fishbein and Raoult, 1992). Recently, cases were linked to ingestion of pasteurized milk in Canada (Hatchette et al., 2001). Human cases have been reported following contact with parturient products of an infected woman (in an obstetrician) and through transplacental, blood, and sexual transmission (Maurin and Raoult, 1999). Based on the results of animal experimentation (La Scola et al., 1997), it has been hypothesized that the route of acquisition of *C. burnetii* infection may influence the clinical presentation of the disease; i.e., infection via an aerosol results in pneumonia, whereas infection via intraperitoneal injection results in hepatitis.

Q fever has been described worldwide except in New Zealand. Estimates of the incidence of Q fever are complicated by the lack of systematic investigation of this illness worldwide. In regions of France where Q fever is endemic, the annual incidence of acute Q fever is estimated at 50/100,000 persons (Maurin and Raoult, 1999). The incidence of hospital admission for acute and chronic Q fever is estimated at 1.7 and 0.5/1,000,000 persons, respectively. Comparable figures have been reported from England.

Pathogenicity in humans In Q fever outbreaks, there is a high ratio of males to females in infected patients and a low ratio of children to adults (Maltezou and Raoult, 2002). Because the levels of exposure and seroprevalence are not different in these groups, it is suspected that host factors determine different clinical expression of acute disease. The incubation period for acute Q fever is 1–3 weeks. Data from the National Reference Center for Rickettsial Diseases, Marseille, France, and from large outbreaks show that up to 60% of infected patients remain asymptomatic. Among symptomatic patients, most (95%) develop a mild, non-specific flu-like illness, whereas the remaining 5% require hospitalization. Chronic Q fever accounts for about 10% of hospital cases and 0.2% of all cases (Dupuis et al., 1987; Maurin and Raoult, 1999). Acute Q fever has two primary clinical presentations: atypical pneumonia and hepatitis. Most infected patients experience a transient bacteremia with *C. burnetii*, usually late in the incubation period. The spread of the organisms to other organs can result in severe complications; endocarditis is the primary manifestation of chronic Q fever. Other aspects of the pathogenicity of *C. burnetii* in humans, the clinical aspects of Q fever, and current recommendations for treatment of Q fever have been reviewed in detail by Maurin and Raoult, 1999.

Animal infection and reservoirs Livestock—including cattle, sheep and goats—and pets are major reservoirs of *C. burnetii* (Langley et al., 1988; Laughlin et al., 1991; Buhariwalla et al., 1996). The pathogen can be found in urine, feces, milk, and birth products of these animals and transmitted to humans by these substances as well as by aerosols. Animals are usually not harmed by *C. burnetii*, although association of the organisms with infertility (Ho et al., 1995), abortion (Waldhalm et al., 1978), low birth weight (Ho et al., 1995), and death of newborns (Buhariwalla et al., 1996) in animal hosts has been reported. Serological studies of cattle herds have shown that large proportions of seronegative animals brought into a region where *C. burnetii* is endemic are exposed to *C. burnetii* (Huebner and Bell, 1951) and that the incidence of exposure may be increasing (Krauss, 1989). Some animals, including cattle and goats, may become chronically infected (Babudieri, 1959; Baca and Paretsky, 1983; Lang, 1990). There is a lack of current data on *C. burnetii* infection in livestock.

The pathogenicity of *C. burnetii* in various laboratory animals has been reviewed by Maurin and Raoult, 1999. Rats, mice, guinea pigs, rabbits, and monkeys have been used in laboratory studies; infection can produce no symptoms, can produce fever and granulomas, or can lead to death.

Interactions with host cells *C. burnetii* infects mammalian monocytes and macrophages *in vivo* (Dellacasagrande et al., 2000); the organism can be grown in embryonated eggs and in Vero, fibroblast, and mouse macrophagelike cells *in vitro*. *In vitro* cultures of *C. burnetii*-infected cells can be maintained for long periods (Burton et al., 1978; Baca et al., 1981, 1985; Akporiaye et al., 1983; Roman et al., 1986). Both the mechanisms of entry of Phase I and Phase II *C. burnetii* cells into mammalian cells and the adaptations that promote long-term survival and reproduction of *C. burnetii* cells inside mammalian cells specialized to kill them have been investigated extensively (Hackstadt and Williams, 1981; Akporiaye et al., 1983; Zuerner and Thompson, 1983; Hendrix and Mallavia, 1984; Roman et al., 1986; Chen et al., 1990b; Raoult et al., 1990; Maurin et al., 1992; Ghigo et al., 2002).

Antibiotic susceptibility Antibiotic susceptibility testing of *C. burnetii* has been carried out in cell cultures, in animals, and in embryonated eggs. These methods and the results obtained have been reviewed in detail by Maurin and Raoult (1999).

Vaccination Vaccination is a logical strategy for the prevention of Q fever both among humans at high risk for this infection and among animals. A killed Q fever vaccine was approved for use in Australia (O-Vax; Commonwealth Serum Laboratories). Further information about the effectiveness of this vaccine can be found in Ormsbee and Marmion (1990). In areas where Q fever is endemic, the following groups should be offered vacci-

nation: dairy workers, abattoir workers; and others who work with cattle, sheep, or goats. Vaccination of cattle, sheep, and goats in these areas is also indicated, although few data are available to indicate the effectiveness and cost benefit of such a strategy in eliminating Q fever.

Enrichment and Isolation Procedures

Isolation of *C. burnetii* requires a Biosafety Level 3 facility and poses a substantial risk to laboratory personnel. In the past, isolation was achieved by injecting potentially infected specimens into guinea pigs, mice, or embryonated eggs (Ormsbee, 1952; Perrin and Bengtson, 1942; Williams et al., 1986a); organisms are most readily recovered from the spleens of guinea pigs 5–8 days after infection. Tissue culture cells can be substituted for animals (Maurin and Raoult, 1999).

Maintenance Procedures

C. burnetii is maintained in liquid nitrogen but can be more conveniently maintained at −80°C. Phase I organisms are obtained by experimental passage in laboratory animals (guinea pig). Phase II organisms are obtained by passage in cultured cell systems or embryonated eggs.

Differentiation of the genus *Coxiella* from other genera

Coxiella can be differentiated from *Rickettsiella* by its relatively high heat resistance and by its formation of an endospore-like structure. Although electron-dense forms have been observed in the developmental cycles of both *Rickettsiella* and *Coxiella burnetii* (Avakyan et al., 1983; Popov et al., 1991), *Rickettsiella* species do not develop intracellularly into larger particles that multiply and then condense to reform the smaller forms in a cycle that resembles that of *Chlamydia*.

Taxonomic Comments

Phylogenetic analysis, chiefly based on 16S rRNA gene sequences, has shown that *Coxiella* belongs to the *Gammaproteobacteria* (Weisburg et al., 1985, 1989; Wilson et al., 1989b; Stein et al., 1993), with *Legionella*, *Francisella*, and *Rickettsiella* as its closest relatives (Fig. BXII.γ.98). Bacteria of the genus *Rickettsia* and of the family *Bartonellaceae* belong to the *Alphaproteobacteria* (Fig. BXII.γ.99). In addition, uncultured endosymbionts of ticks as diverse as *Rhipicephalus sanguineus*, *Haemaphysalis longicornis*, *Haemophysalis concinnae*, and *Ornithodoros moubata* are closely related to *C. burnetii* by 16S rRNA gene sequence analysis (Noda et al., 1997). The 16S rDNA sequence of one rickettsia-like organism isolated in the yolk sac of chicken embryos using material from farm-reared *Cherax quadricarinatus* crayfish possessed 95.6% similarity to the *C. burnetii* 16S rRNA gene sequence; this organism has been proposed as *Coxiella cheraxi* sp. nov. (Tan and Owens, 2000) (Fig.BXII.γ.100), but the new name has not yet been validated.

List of species of the genus Coxiella

1. **Coxiella burnetii** (Derrick 1939) Philip 1948, 58[AL] (*Rickettsia burneti* (sic) Derrick 1939, 14.)
bur.ne′ ti.i. M.L. gen. n. *burnetii* of Burnet, named after Frank MacFarlane Burnet, who first studied the properties of this organism.

The characteristics are as described for the genus. The complete genome sequence of strain RSA 493 is available (GenBank accession number NC002971).

The mol% G + C of the DNA is: 42.6 (by sequencing).

Type strain: ATCC VR 615 strain (Nine Mile Phase I).

Reference strains include: (1) ATCC V5-145 [strain Henzerling; essentially in phase II]; (2) VR 616 [strain Nine Mile Q (Davis and Cox, 1938), essentially Phase II]; (3) VR 147 Strain Dyer, from blood from patient, USPHS Rocky Mountain Laboratory, 1938; (4) VR 542 Strain Ohio 314, from milk from cow; collected by Ohio Dept. Hlth., 1955; (5) VR 614 Strain California 76, from a dairy cow in California; and (6) VR 730 Strain Bangui, from a human in Central Africa.

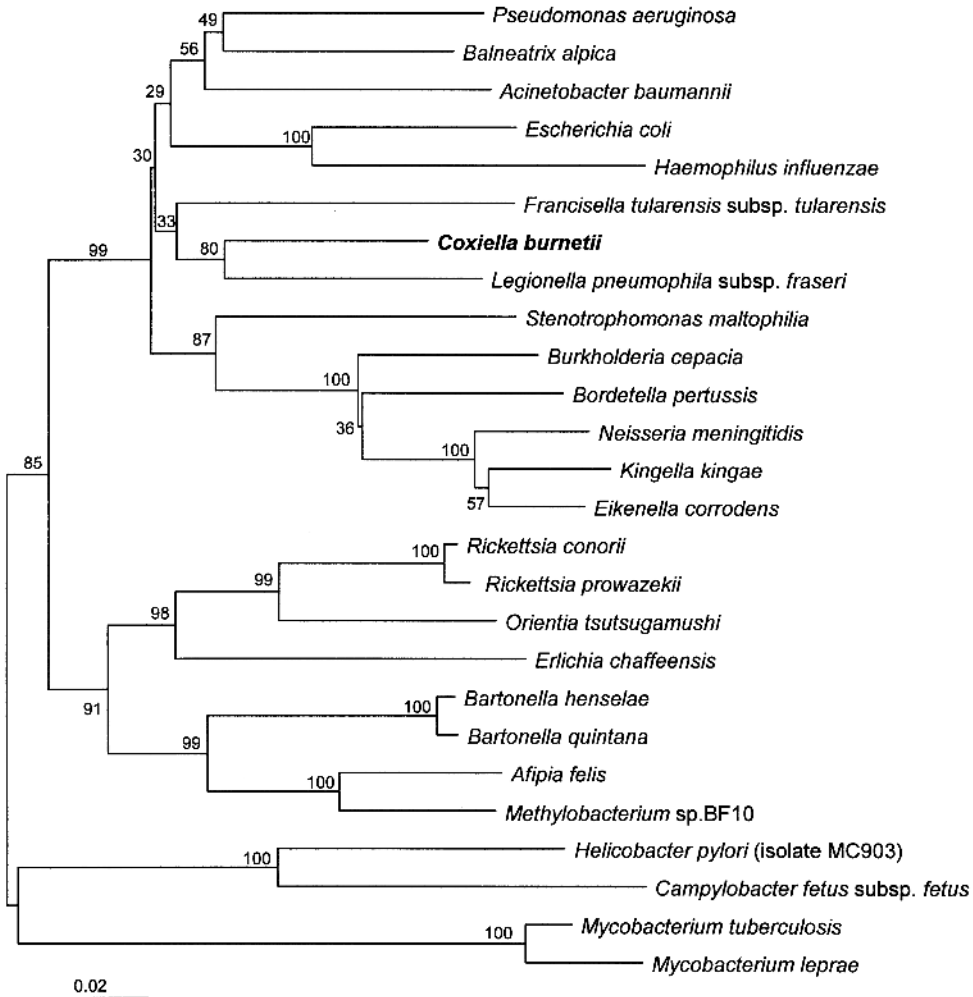

FIGURE BXII.γ.99. Dendogram based on 16S rRNA gene sequence comparison of *Coxiella burnetii* with other *Proteobacteria*. This dendogram includes *Coxiella* sequences derived from: *Coxiella burnetii* (strain 607, taxon 777), GenBank accession number D89792; *Francisella tularensis* (strain SCHU, isolate FSC 043, taxon:263), GenBank accession number Z21932; *Rickettsia conorii* (taxon 781), GenBank accession number L36107; *Rickettsia prowazekii* (taxon 782), GenBank accession number M21789; *Bartonella henselae* (strain BA-TF, taxon:38323, clone PL 84-1), GenBank accession number Z11684; *Bartonella quintana* (taxon 803), GenBank accession number AJ250247; *Mycobacterium tuberculosis* (taxon 1773), GenBank accession number X52917; *Mycobacterium leprae* (taxon 1769), GenBank accession number X55022; *Pseudomonas aeruginosa* (taxon 287), GenBank accession number M34133; *Haemophilus influenzae* (strain NCTC 11146, taxon:67859), GenBank accession number AF024530; *Orientia tsutsugamushi* (taxon 784), GenBank accession number AF062074; *Ehrlichia chaffeensis* (taxon 945), GenBank accession number AF147752; *Afipia felis* (taxon 1035), GenBank accession number M65248; *Methylobacterium* sp.BF10 (taxon 194432), GenBank accession number Z23156; *Bordetella pertussis* (ATCC 9797, taxon 520), GenBank accession number U094950; *Burkholderia cepacia* (taxon 292), GenBank accession number AB091761; *Kingella kingae* (ATCC 23330, taxon 504), GenBank accession number M22517; *Neisseria meningitidis* (strain NCTC 10025 ^{T}, taxon 487), GenBank accession number X74900; *Helicobacter pylori* (isolate MC903, taxon 210), GenBank accession number U01332; *Campylobacter fetus* (taxon 196), GenBank accession number M65012; *Stenotrophomonas maltophilia* (strain N4-15, taxon:40324), GenBank accession number AF017749; *Legionella pneumophila* (strain Los Angeles 1, taxon:44), GenBank accession number M36025; *Balneatrix alpica* (taxon:75684), GenBank accession number Y17112; *Acinetobacter baumannii* (isolate DSM 30008, taxon 470), GenBank accession number X81667; *Escherichia coli* (taxon 562), GenBank accession number J01859; *Eikenella corrodens* (taxon 539), GenBank accession number M22513.

Genus II. **Rickettsiella** *Philip 1956, 267*[AL]

Pierre-Edouard Fournier and Didier Raoult

Rick.ett.si.el′la. M.L. dim. *-ella* ending; M.L. fem. n. *Rickettsia* genus of parasitic bacteria; M.L. fem. n. *Rickettsiella* small *Rickettsia*.

Rod- or disk-shaped organisms, developing intracellularly into larger particles that multiply and then condense to reform the smaller forms in a cycle that resembles that of *Chlamydia*. Sometimes produce or induce the formation of large crystalline bodies. Gram negative. **Grow in cell vacuoles of the fat body, hepatopancreas, and other organs of insects and other invertebrate hosts.** In some instances the organisms have been cultivated in invertebrates other than the host of origin, but such cultivation has occurred rarely and only for a few passages in vertebrate and invertebrate cell cultures and in a cell-free medium. **Pathogenic**

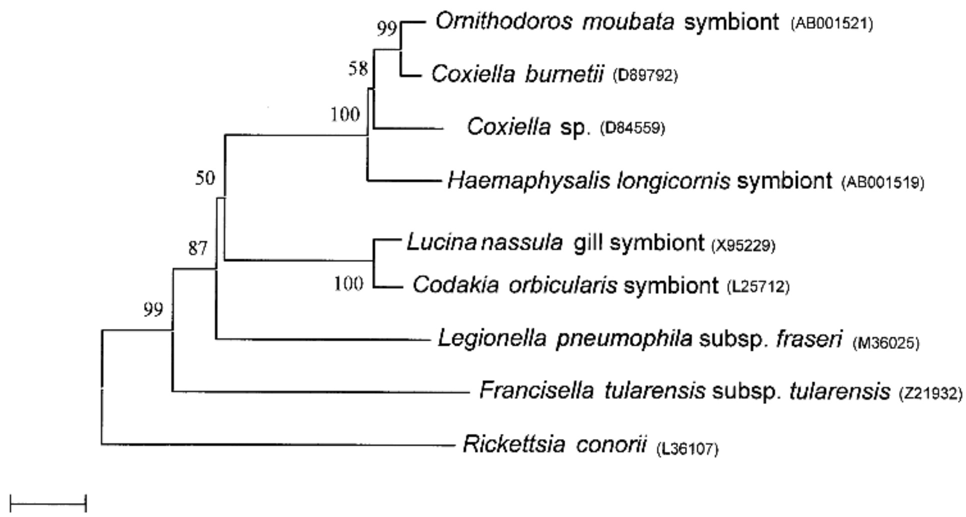

FIGURE BXII.γ.100. Dendrogram based on 16S rRNA gene sequence comparison of *Coxiella burnetii* to its close relatives. *Rickettsia conorii* (part of the *Alphaproteobacteria*) was used as an outgroup to root the tree. Bootstrap values are indicated for each node. Bar = 2 inferred nucleotide substitutions per 100 nucleotides.

for the larvae of the host species and for young and mature stages of other invertebrate hosts. Pathogenicity for vertebrate hosts demonstrated only in a mouse experimental model. Natural hosts include insects, crustaceans, and arachnids.

The mol% G + C of the DNA is: 36–41.

Type species: **Rickettsiella popilliae** (Dutky and Gooden 1952) Philip 1956, 267 (*Coxiella popilliae* Dutky and Gooden 1952, 749)

Further descriptive information

Most of the knowledge of this genus is based on light and electron microscopic observations. Bacteria were classified in the genus *Rickettsiella* mainly based on morphologic criteria, including their intracellular location, their oval, rod-like, or pleomorphic forms, the occurrence of a complex intravacuolar cycle, and the occurrence of crystals. Studies of host specificity, attempts at cultivation in cells or axenic media, or antigenic analyses have not been extensive and only minimally successful. Table BXII.γ.63 lists the species that, to the best of our limited knowledge, appear to belong to this genus.

Phylogenetic classification In the previous edition of the *Manual*, the genus *Rickettsiella* was classified in the order *Rickettsiales* based on a very few morphological data, including a close association with arthropods and intravacuolar location during multiplication. Recently, analysis of the 16S rDNA sequence of *Rickettsiella grylli* has revealed that this bacterium is most closely related to *Coxiella burnetii* (Philip, 1943) in the *Gammaproteobacteria*; therefore, it has been provisionally removed from the order *Rickettsiales* (Roux et al., 1997). An analysis of the 16S rDNA sequences from another two rickettsiellae—isolates from the psyllid *Cecidotrioza sozanica* (*Insecta*, *Psylloidea*) (Spaulding and Hennessy, 1960) and from the tick *Ixodes woodii* (*Arachnida*, *Acarina*) (Kurtti et al., 2002)—has demonstrated that these organisms cluster with *R. grylli* with a high statistical probability (Fig. BXII.γ.101). The 16S rDNA sequence of *R. grylli* has 98.2% and 94.3% similarity to that of the psyllid and the tick isolates, respectively, and 88.3% similarity to that of *Coxiella burnetii.* However, the 16S rDNA sequences of *Rickettsiella popilliae* and *Rickettsiella chironomi* are not available, and thus their phylogenetic position is not clear.

Cell structure All strains studied in some detail have been shown to undergo a cycle of development. The infectious form is a small, dense particle (elementary body) that gains entrance into a vacuole of its host cell by phagocytosis. There it enlarges into intermediate and large forms of much lower electron density and which are capable of multiplication (reticulate body). As the host-cell vacuole becomes crowded with multiplying bacteria, the large forms condense to reform the small dense particles, which eventually escape from the vacuole to start another cycle.

There are striking differences between the cycles of *R. popilliae* and *R. chironomi.* The cycle of *R. grylli* resembles that of *R. popilliae. R. popilliae* cells, although displaying some plasticity, retain typical outer membranes and a rod-shaped appearance through most of their cycle (Devauchelle et al., 1972). Some large forms become giant round cells from which bipyramidal crystalline bodies (0.8–1.8 × 3.8 μm in size) arise. The roles of the bacteria and of the host cell in the production of the crystalline bodies are not entirely clear. Except for the absence of tyrosine, these bodies have approximately the same amino acid composition as the albuminoid spheres that are found in greatest numbers in late larval and pupal stages in normal insects. It has been postulated that the crystalline bodies are derived from the albuminoid reserve as the result of a disturbance of host cell metabolism (Huger, 1959; Krieg, 1959). Other evidence suggests a close association of the crystalline bodies with the bacterial cycle (Huger, 1962; Devauchelle et al., 1972) and host dependence. A *Cetonia* strain (Table BXII.γ.63) produces crystalline bodies in *Coleoptera* but not in *Orthoptera* or *Lepidoptera* (Meynadier and Monsarrat, 1969), and a *Melolontha* strain does not produce crystalline bodies in mammalian cell cultures (Pourquier et al., 1963).

In *R. chironomi*, the infectious particle is a disk-shaped elementary body 0.06 × 0.6 μm in size. This body enlarges in a newly infected cell into a spherical initial body 1 μm in diameter,

TABLE BXII.γ.63. Ecology of the species of the genus *Rickettsiella* and proposed nomenclature

Nomenclature used in the present edition of the *Manual*	Host zoological class	Host zoological order	Host common name (scientific name)	Location	Subjective synonyms	References
R. popilliae	*Insecta*	*Coleoptera*	Japanese beetle (*Popillia japonica*)	USA	"*Rickettsiella popilliae*"	Dutky and Gooden, 1952; Philip, 1956

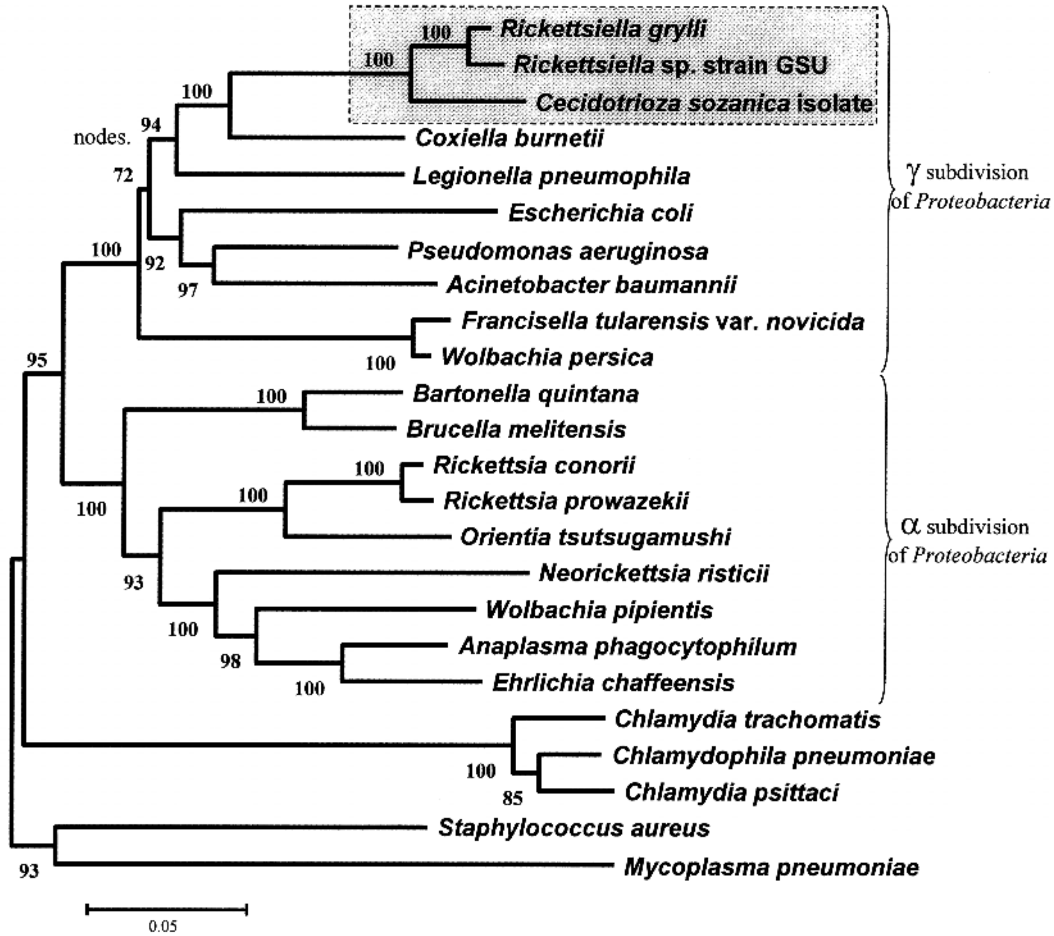

FIGURE BXII.γ.101. Unrooted 16S rDNA-based phylogenetic tree showing the position of *Rickettsiella grylli*. The tree was constructed using the neighbor-joining method, and the bootstrap values are indicated at the nodes. This tree includes *Rickettsiella* sequences derived from: *Rickettsiella grylli*, GenBank accession number U97547; *Rickettsiella* sp. (strain GSU), GenBank accession number AF383621; isolate from *Cecidotrioza sozanica*, GenBank accession number AF286124; *Coxiella burnetii* (strain Q177), GenBank accession number M21291; *Legionella pneumophila* (strain ATCC 33152), GenBank accession number M59157; *Escherichia coli*, GenBank accession number Z83204; *Pseudomonas aeruginosa*, GenBank accession number AB073312; *Acinetobacter baumannii* (ATCC 19606T), GenBank accession number Z93435; *Francisella tularensis* subsp. *novicida*,* GenBank accession number L26084; *"Francisella persica"* (= *Wolbachia persica*), GenBank accession number M21292; *Bartonella quintana* (strain Fuller), GenBank accession number M11927; *Brucella melitensis* biovar abortus, GenBank accession number X13695; *Rickettsia conorii* (strain Moroccan), GenBank accession number L36105; *Rickettsia prowazekii* (strain Breinl), GenBank accession number M21789; *Orientia tsutsugamushi* (strain Karp), GenBank accession number D38623; *Neorickettsia risticii* (strain SHSN-1), GenBank accession number AF037210; *Wolbachia pipientis*, GenBank accession number U23709; *Anaplasma phagocytophilum*, GenBank accession number U02521; *Ehrlichia chaffeensis*, GenBank accession number AF147752; *Chlamydia trachomatis* (strain:B/TW-5/OT), GenBank accession number D85719; *Chlamydia pneumoniae* (strain TW183), GenBank accession number L06108; *Chlamydia psittaci* (strain 6BC, ATCC VR-125T), GenBank accession number AB001778; *Staphylococcus aureus* (strain M2), GenBank accession number Y1585; *Mycoplasma pneumoniae* (strain FH, ATCC 15531), GenBank accession number M29061.

**Editorial Note:* In this volume Sjöstedt proposes that *Francisella tularensis* var. *novidica* be regarded as a subspecies of *Francisella tularensis* (see page 208).

which divides by binary fission. The initial bodies are eventually reduced to intermediate forms that subsequently condense to reform the elementary bodies. Occasionally the initial bodies continue to grow to become particles 1.5 × 2.0 μm in diameter, which divide equally or unequally (Federici, 1980), or which may undergo multiple divisions that result in the formation of as many as 30 elementary bodies (Götz, 1972). Unlike those of *R. popilliae*, the giant cells in *R. chironomi* do not evolve into typical crystalline bodies (Weiser and Zizka, 1968).

Cultivation Most strains of *R. popilliae* have been grown in the larvae of *Melolontha*, the common cockchafer. The *R. popilliae* and *R. grylli* strains from the cetonid beetle have been grown in *Orthoptera*, *Coleoptera*, and *Lepidoptera* (Meynadier and Monsarrat, 1969). Intracoelomically inoculated female *Dermacentor reticulatus* ticks (*Arachnida*, *Acarina*) have been used to isolate and maintain *"Rickettsiella phytoseiuli"*, a *Rickettsiella* sp. isolated from the mite *Phytoseiulus persimilis* (*Arachnida*, *Acarina*) (Sutakova and Ruttgen, 1978).

Limited growth of *R. popilliae* has been obtained in chicken embryo endodermal cell cultures and in McCoy cells incubated at 28 or 32°C. Typical organisms were first detected after 1 week and their numbers increased during the following 2 weeks. Infectivity was reduced progressively during serial passage. No growth occurred after 4–5 passages (Suitor, 1964). *R. popilliae* has also been passed three times in other mammalian cell lines (Pourquier et al., 1963). *R. grylli* was grown in cricket cardiac cell cultures (Meynadier et al., 1967).

The only cultivation of a *Rickettsiella* in a cell-free medium has been reported for *"R. phytoseiuli"* in SM IMV-72 medium, which is used for cultivation of phytopathogenic mycoplasmas (Sutakova et al., 1991). The bacteria were maintained until day 66 in primary culture and until day 16 after the first passage. Further passages failed.

Drugs and antibiotic susceptibility Currently, there are no data on the antimicrobial susceptibility of rickettsiellae available.

Pathogenicity The chief interest in rickettsiellae stems from the effect of these organisms on laboratory insectaries and other animal collections as well as from the possible use of these organisms as biological control agents for agricultural pests. Rickettsiellae are not as virulent and persistent as some of the viral and mycotic pathogens of agricultural pest insects; however, rickettsiellae stay alive in the soil for years. Infection of offspring is effected through contamination of soil, rather than by transovarian passage (Hurpin and Robert, 1972, 1976, 1977). The wide distribution of rickettsiellae geographically and in arthropod taxa suggests an early appearance in the course of evolution.

R. popilliae causes blue disease of insect larvae, a deadly disease characterized by the discoloration of the infected larvae. In the cricket and locust, *R. grylli* causes swelling of the abdomen and, at later stages, turgidity of the intersegmentary membranes and ventral inclination of the head, leading to death. *R. grylli* induces a "behavioral fever" in experimentally infected crickets *Acheta domesticus* and *Gryllus bimaculatus* (Louis et al., 1986; Adamo, 1998). These infected invertebrates, when exposed to a temperature gradient, are more likely to survive at 32–33°C than at 26°C—their optimal temperature when uninfected. Infected insects move to areas that are at the higher temperature. This behavior is thought to be used by the insects to create a fever and protect them from infection.

Rickettsiella species have never been reported to be human pathogens. Virulence for vertebrate hosts has not extensively been studied. *R. popilliae* (*Melolontha* strain) is virulent for mice only when massive doses are inoculated intraperitoneally (Krieg, 1955b). Successful infection by the intranasal route has also been demonstrated (Giroud et al., 1958). When inoculated intraperitoneally or by inhalation, *R. grylli* multiplies in the mouse, but the severity of the infection depends on the inoculum size. With a low inoculum, the bacterium has either no effect or causes local inflammation; the mouse overcomes the infection and the microorganism disappears within 45 d (Croizier and Meynadier, 1972; Delmas and Timon-David, 1985).When injected with a high inoculum, mice develop a cirrhotic hepatitis and malignant tumors, including hematosarcomas.

Enrichment and Isolation Procedures

Successful propagation of *Rickettsiella* has been achieved by the inoculation of healthy larvae of the same or compatible insect species with infected blood or other infectious material. Japanese beetles or cockchafers inoculated with *R. popilliae* are incubated under appropriate conditions of temperature, food and moisture for about 35 d. Following surface sterilization, the organisms are obtained from the surviving larvae by grinding. The bacteria can be separated from tissue components by cycles of adsorption and dilution from Celite and filtration through diatomaceous filters of medium porosity (Dutky, 1959) or by comparable more recently developed methods such as differential centrifugation (Morel, 1980).

Isolation in cell culture is useful for the study of antigenic cross-reactions by fluorescent antibody techniques or for other comparative investigations. However, unlimited growth in cell culture has not been demonstrated.

Maintenance Procedures

If *R. popilliae* suspensions are not contaminated with other bacteria, viability can be retained for 1 year at 4°C but not for 3 years. Viability is retained for least 3 years at −70°C.

Differentiation of the genus *Rickettsiella* from other genera

These intracellular bacteria are pathogenic for, or symbiotic with, invertebrates and exhibit a developmental cycle similar to that of *Chlamydia* species. Rickettsiellae are phylogenetically related to *Coxiella burnetii* within the *Gammaproteobacteria*.

Taxonomic Comments

Little of the sort of information that is generally used for bacterial classification is available for the classification of *Rickettsiella*.

Historically, based on the similarity in the ultrastructure and developmental cycles, many investigators suggested that rickettsiellae more closely resembled *Chlamydia* than *Rickettsia* and that they should be transferred to the order *Chlamydiales* (Yousfi et al., 1979; Morel, 1980; Avakyan and Popov, 1984). Points of similarity with *Chlamydia* are: (1) both *Chlamydia* and rickettsiellae multiply in the vacuoles of their host cells, and (2) both undergo a developmental cycle consisting of up to six stages that involve the formation of a small dense particle whose function is to infect and a much larger particle of lower density whose function is to multiply. Points of difference between *Chlamydia* and rickettsiellae are (1) the rod or disk shape of the infectious particles of rickettsiellae, (2) the formation of large crystalline bodies, and (3) the absence of relatedness between *Rickettsiella* and *Chlamydia* based on serological analyses (Croizier et al., 1975). Resemblances to other members of the *Rickettsiales* include a close association with arthropods and the intravacuolar location during multiplication—characters that are found in *Ehrlichia* and other genera in the order *Rickettsiales*. By pulsed field gel electrophoresis, the genome sizes of members of the genus *Rickettsiella* range from 1.55 Mb to 2.65 Mb (Frutos et al., 1989) (Table BXII.γ.64). On the basis of DNA–DNA hybridization, DNA restriction site polymorphism, DNA melting profiles, and mol% G + C data (Table BXII.γ.64), Frutos et al. (1994) concluded that the classification of members of the genus *Rickettsiella* was valid at the generic level but not at the species level. Three distinct groups were identified: (1) the *R. grylli* complex containing *R. grylli* and *R. popilliae*, with *"Rickettsiella armadillidii"* being recognized as a strain of *R. popilliae* rather than a synonym of *R. grylli*; (2) *R. chironomi*; and (3) *"R. buthi"*, a strain previously considered to

belong to the species *R. chironomi*, from the scorpion *Buthus occitanus* (*Arachnida*, *Scorpionida*) (Frutos et al., 1994). According to Frutos et al., *Rickettsiella*, *Coxiella*, *Chlamydia*, and *Rickettsia* are taxonomically distinct genera, and the classification of the genus *Rickettsiella* into a separate order might be justifiable (Frutos et al., 1994). However, based on 16S rDNA sequence analysis, *R. grylli* is most closely related to *Coxiella burnetii* and *Legionella* species in the *Gammaproteobacteria*, whereas members of the order *Rickettsiales* belong to the *Alphaproteobacteria* (Roux et al., 1997) (Fig. BXII.γ.101). This finding is supported by the observation of electron-dense forms in the developmental cycles of both *Rickettsiella* and *Coxiella burnetii* (Avakyan et al., 1983; Popov et al., 1991). Based on 16S rDNA analysis, *Rickettsiella* strain GSU—which is present in the ovarian tissues and Malpighian tubules of female *Ixodes woodii* ticks (*Acarina*: *Ixodidae*)—has also been classified in the *Gammaproteobacteria* (Kurtti et al., 2002) as has a *Rickettsiella*-like endosymbiont of the psyllid *Cecidotrioza sozanica* (*Insecta*) (Spaulding and von Dohlen, 2001). Both bacteria were closely related phylogenetically to *R. grylli*. However, because the 16S rDNA sequences of *R. popilliae* and *R. chironomi* have not yet been determined, it is not known whether all species of the genus *Rickettsiella* are misplaced in the order *Rickettsiales* and whether all current members of the genus are phylogenetically homologous (Roux et al., 1997).

The differential characteristics of the species of the genus *Rickettsiella* are presented in Table BXII.γ.64. Six specific names previously proposed (Table BXII.γ.63) are treated as synonyms of the first described species, *R. popilliae*, since no major differences have been encountered among them. The *Popillia*, *Melolontha*, *Tipula*, and *Cetonia* pathogens have common antigens (Krieg, 1958) (Croizier and Meynadier, 1971). The pathogens of *Tenebrio* and *Blatta* have not been extensively studied.

The separation of *R. popilliae* from *R. grylli* was initially based primarily on serological cross-reactions between the cricket and isopod pathogens and lack of reaction with *R. popilliae* antisera (Croizier and Meynadier, 1971). The developmental cycles of the cricket and isopod pathogens appear to be quite similar (Louis et al., 1977a, b), but the results of DNA hybridization studies indicate that *R. grylli* and *R. popilliae* are separate species, with *"R. armadillidii"*—the isopod isolate—showing greater DNA relatedness to *R. popilliae* than to *R. grylli* (Frutos et al., 1994). The hosts from which *R. grylli* have been isolated—*Orthoptera* and Crustacea—may not constitute a valid criterion for classification, but they might serve as a guide for the provisional placement of the less well-studied pathogens of the desert locust and amphipod (Table BXII.γ.63). *R. popilliae* and *R. grylli* have different genome sizes, but their DNAs have similar mol% G + C contents and DNA melting temperatures (Table BXII.γ.64).

The third species, *R. chironomi*, can be clearly separated from the other two by its unusual life cycle, in which flat disks are formed instead of rods. There is a remarkable similarity between the cycle of the midge pathogen and the cycles of the arachnid pathogens (Morel, 1977; Federici, 1980), although differences have been described (Louis et al., 1979). In 1976, the creation of the genus *"Porochlamydia"* was proposed to accommodate the phenotypically different isolates from the midge and the scorpion, with *"P. chironomi"* being present in the midge larvae and *"P. buthi"* infecting the scorpion *Buthus occitanus* (*Arachnida*, *Scorpionida*). This genus was not included in the Approved Lists or the 1984 issue of the *Manual*. The midge and scorpion isolates were later shown to have chromosomal DNAs markedly different in size (Frutos et al., 1989), to exhibit no DNA relatedness as demonstrated by the absence of cross-hybridization, and to have distinct DNA melting profiles. However, the differentiation of the scorpion isolate as a different species has not been officially proposed.

The stethorus beetle pathogen, for which the name *R. stethorae* has been assigned (Table BXII.γ.63), is clearly different in morphology from the above listed species of *Rickettsiella* (Hall and Badgley, 1957), but further studies are necessary to allow proper classification. The other isolates listed in Table BXII.γ.63 appear to be typical rickettsiellae, but additional information is required for appropriate placement in a species.

It should be noted that four of the species recognized in the present edition of the *Manual*, *R. popilliae*, *R. grylli*, *R. chironomi*, and *R. stethorae* were included on the Approved Lists of Bacterial Names. However, as indicated above, sufficient evidence is not available at present to warrant considering *R. stethorae* as a distinct species.

Differentiation of the species of the genus *Rickettsiella*

Characteristics useful for the differentiation of *Rickettsiella* species are listed in Table BXII.γ.64.

List of species of the genus Rickettsiella

1. **Rickettsiella popilliae** (Dutky and Gooden 1952) Philip 1956, 267[AL] (*Coxiella popilliae* Dutky and Gooden 1952, 749.)
pop.il′ li.ae. M.L. gen. n. *popilliae* of *Popillia*, the generic name of the Japanese beetle, one of its hosts.

This species includes the subjective synonyms *"Rickettsiella melolonthae"*, *"Rickettsiella tenebrionis"*, *"Rickettsiella cetonidarum"*, *"Rickettsiella tipulae"*, *"Rickettsiella blattae"*, *"Rickettsiella armadillidii"*, and an unnamed isolate from various scarabaeid and carabid beetles (Table BXII.γ.63). The form usually obtained from infected host tissues by the separation procedures described above is a rod 0.2 × 0.6 μm or slightly larger; the rods may be oval, curved or kidney-shaped, with rounded edges. Satisfactorily stained by the Giemsa or Macchiavello methods (Macchiavello, 1937) and presumably by the Gimenez (1964) method. The developmental cycle, the formation of crystalline bodies, and attempts at cultivation outside the host have been discussed above in the section on Further Descriptive Information.

R. popilliae is the etiological agent of blue disease of insect larvae, a name reflecting the discoloration of the infected larvae. Other names reflecting either the locality where the disease was discovered or the host have also been used. Infection is most commonly encountered among larvae but is not confined to this stage. The infection starts in the fat body but ultimately spreads to the blood and the other organs. Larvae have been infected experimentally by injection, by feeding, or by holding them in soil inoculated with suspensions of the organism. By injection, fewer than six organisms are sufficient to infect a Japanese beetle larva with its naturally occurring pathogen. The time required for appearance of symptoms is dependent on dosage and on the temperature of incubation of the larvae (optimum 27°C). With an injection of 10^4 organisms per larva, the symptoms appear after 19 d and death occurs in 19–26 d after the first appearance of symptoms. Larvae can be protected by injection of streptomycin (20 μg/larva) or sulfadiazine (200 μg/larva) but not penicillin or chlortetracycline (Dutky, 1959).

There is considerable variation in the time of appearance of symptoms and death of the larvae infected by the various strains of *R. popilliae*. It is not known to what extent this variation reflects strain virulence or host susceptibility. The organisms can be inactivated by incubation at 60°C for 10 min. The genome size is 1.72 Mb (Frutos et al., 1989, 1994).

The mol% G + C of the DNA is: 36.9 (T_m).

Type strain: no culture has been isolated.

2. **Rickettsiella chironomi** (ex Weiser 1963) Weiss, Dasch and Chang 1984b, 356[VP] (Effective publication: Weiss, Dasch and Chang 1984a, 716.)
chi.ro.no′ mi. M.L. gen. n. *chironomi* of *Chironomus*, the generic name of the midge, one of its hosts.

This species includes unnamed isolates from the midge *Chironomus tentans* and the spider *Argyrodes gibbosus* (Table BXII.γ.63). The infectious stage has an unusual disk-shaped morphology, 0.06 × 0.6 μm, as indicated above in the section on Further Descriptive Information. There is probably a greater diversity among the strains previously included in this species than among the strains of the other two species of *Rickettsiella*. *"R. buthi"*, which infects the scorpion *Buthus occitanus* (*Arachnida*, *Scorpionida*) has a markedly different chromosomal DNA size (Frutos et al., 1989), exhibits no DNA relatedness to *R. chironomi*, and has a DNA melting profile distinct from that of *R. chironomi* (Frutos et al., 1994) (Table BXII.γ.63). However, the differentiation of the scorpion isolate as a different species has not been officially proposed.

In the midge, the disease affects primarily the last two instars and the pupal stages. The infection starts in the fat body and progresses to lobes around the intestine, which eventually rupture and fill the whole body with white fluid. Experimental infection results in death in 7–14 d (Weiser and Zizka, 1968). In arachnids, the hepatopancreas and intestinal diverticula are the organs primarily affected. The genome size of *R. chironomi* is 2.65 Mb, whereas the genome size of *"R. buthi"* is 1.55 Mb and its mol % G + C of the DNA is 41 (T_m) (Frutos et al., 1989, 1994).

The mol% G + C of the DNA is: 36.7 (T_m).

Type strain: no culture has been isolated.

3. **Rickettsiella grylli** (ex Vago and Martoja 1963) Weiss, Dasch and Chang 1984b, 356[VP] (Effective publication: Weiss, Dasch and Chang 1984a, 716.)
gryl′ li. M.L. gen. n. *grylli* of *Gryllus*, the generic name of the cricket, one of its hosts.

This species includes the subjective synonym *"Rickettsiella schistocercae"* and an unnamed isolate from the amphipod *Crangonyx floridanus* (Table BXII.γ.63). The organism resembles *R. popilliae* in the morphology of its infectious particle and subsequent developmental stages and crystalline body production. It can be differentiated from *R. popilliae* by serological tests and, to a certain extent, by the natural hosts infected, although it does not have a high degree of host specificity (Table BXII.γ.63).

The disease in naturally infected hosts affects both larvae and adults and develops very slowly. In the cricket and locust, it is characterized by swelling of the abdomen and, at later stages, by turgidity of the intersegmentary membranes and by ventral inclination of the head. The time of death following first appearance of symptoms is quite variable. In the isopod, death is preceded by loss of weight and a whitish coloration of the intersegmentary membranes due to the accumulation of iridescent fluid in the body cavities. Diseased amphipods are also recognized by their opaque pale green iridescence. Most patently diseased amphipods die within six weeks.

The genome size is 2.1 Mb (Frutos et al., 1989, 1994). Based on the 16S rDNA sequence, *R. grylli* is most closely related to *Coxiella burnetii* within the *Gammaproteobacteria* (Roux et al., 1997).

The mol% G + C of the DNA is: 36.3–38.4 (T_m).

Type strain: no culture has been isolated.

Order VII. **Methylococcales** *ord. nov.*

JOHN P. BOWMAN

Me.thy.lo.coc.ca' les. M.L. fem. pl. n. *Methylococcus* type genus of the order; *-ales* ending to denote an order; M.L. fem. pl. n. *Methylococcus* order.

Morphology varies from **rods to cocci**. Cells are usually single or diploid, occasionally forming chains and tetrads. Do not form rosettes. If motile, possess single polar flagellum. **Gram negative.** The majority of species produce a polysaccharide **cyst-like resting stage**. Cysts may be desiccation resistant or sensitive. Dissimilatory methane oxidation is associated with **type I intracytoplasmic membranes,** which appear as stacks of vesicular disks derived from convolutions of the cytoplasmic membrane. Catalase and oxidase are usually produced. **Strictly aerobic respiratory metabolism** with oxygen as the electron acceptor. **Obligate utilizers of methane and other C_1 compounds for carbon and energy. Compounds with carbon–carbon bonds are not utilized.** High levels of organic solutes and ammonia ions inhibit growth. C_1 compounds are incorporated by the **ribulose monophosphate pathway**. The **tricarboxylic acid cycle is incomplete,** with 2-oxoglutarate dehydrogenase activity absent. Nitrogenase activity may be present. Contain mainly **C_{16} fatty acids,** which are predominantly monounsaturated with several different $C_{16:1}$ isomers present. **Ubiquinone-8 or 18-methyleneubiquinone-8** are the predominant lipoquinones. Habitat: isolated from aerobic and microaerobic habitats that have an influx of methane (from methanogenesis or hydrocarbon seeps), including benthic sediments of fresh water and marine bodies of water; oxyclines and thermoclines of lakes and oceans; wetland muds; coal mine drainage waters and coal surfaces; sewage sludge and wastewater; most soils; subsurface sediment; groundwater; and natural gas reserves. Some members form endosymbiotic relationships with invertebrates, including mytilid mollusks and pogonophora. Genome sizes range from 2.5–5.5 Mb. Member of the *Gammaproteobacteria.*

The mol% G + C of the DNA is: 43–65.

Type genus: **Methylococcus** Foster and Davis 1966, 1929, emend. Bowman, Sly, Nichols and Hayward 1993b, 748.

FURTHER DESCRIPTIVE INFORMATION

Bacteria that have the capability to oxidize and utilize methane as a sole carbon and energy source are referred to as methanotrophic bacteria or methanotrophs (Whittenbury et al., 1970b). The original description of the family *Methylococcaceae* (Whittenbury and Krieg 1984a) included two distinct groups of methanotrophs referred to in the literature as "type I" and "type II" methanotrophs. In addition, there is a third group called the "type X" methanotrophs (Hanson and Hanson, 1996) that essentially represents a subgroup of type I methanotrophs. Type I and II methanotrophs possess extensive biological differences that are morphological, biochemical, chemotaxonomic, and phylogenetic in nature. As type II methanotrophs belong to the *Alphaproteobacteria*, they are dealt with in a separate section of this volume. Currently, the family *Methylococcaceae* includes all type I methanotrophs (Bowman et al., 1995) in five genera: *Methylococcus*, *Methylosphaera*, *Methylobacter*, *Methylomicrobium*, and *Methylomonas*. Phenotypic properties and fatty acid components differentiating these genera are shown in Tables BXII.γ.65 and BXII.γ.66, respectively.

Methane oxidation The major characteristic that separates methanotrophs from other procaryotes is their ability to utilize methane as a sole carbon and energy source. Methanotrophs oxidize methane to CO_2 in a dissimilatory pathway that generates energy and allows access to metabolizable carbon units in the form of formaldehyde. The critical first step of this pathway is the oxidation of methane to methanol, which is performed by methane monooxygenase (MMO). Methanol is then oxidized to formaldehyde by a pyrrolquinol quinone-containing methanol dehydrogenase. The formaldehyde is then either used for cell carbon (see below) or oxidized to formate and then CO_2; the

$C_{16:0\ cyc}$	0–1	–	–	–	–
$C_{17:0\ cyc}$	0–15	–	–	0–2	–
$C_{19:0\ cyc}$	0–3	–	–	0–tr	–

[a]For symbols, see standard definitions; tr, trace (fatty acid present at a level of less than 0.5%).

[b]Data from Bowman et al. (1991a), Bowman et al. (1993b), and Bowman et al. (1997c).

[c]Fatty acids are designated as follows: the number of carbon atoms:number of double bonds. The number (n) of carbon atoms of the closest double bond from the methyl end (ω) of the molecule is given by ωn. The suffixes iso, ante, and cyc indicate iso-branched, anteiso-branched, and cyclopropane fatty acids, respectively. The suffixes c and t indicate *cis* and *trans* geometry, respectively

final steps form reducing equivalents needed to drive methane oxidation.

In all type I methanotrophs, MMO is present in a membrane-bound form and is referred to as particulate MMO (pMMO). This enzyme consists of three polypeptides (sizes 45, 35, and 26 kDa) and contains copper (Semrau et al., 1995). Synthesis of a cytoplasmic version of MMO, referred to as soluble MMO (sMMO) (Dalton, 1992; Murrell, 1992; Lipscomb, 1994), appears to be a strain-specific trait (Koh et al., 1993; Miguez et al., 1997; Shen et al., 1997) that is relatively rare in type I methanotrophs. This enzyme is copper-repressible and contains three components. The first includes a 245 kDa hydroxylase that contains an unusual non-heme iron–oxygen linked active site. The second component is a 15 kDa regulatory protein, and the third is a ferredoxin-based reductase. Particulate MMO has a high affinity for methane, allowing for more efficient growth yields compared to sMMO, which appears to be an adaptation to copper-limiting growth conditions (Hanson and Hanson, 1996). However, the substrate specificity of sMMO is exceptionally broad, and it can oxidize an extraordinarily wide range of aliphatic, aromatic, and heterocyclic compounds (Haber et al., 1984). This property has been exploited biotechnologically, with methanotrophs proposed for organic transformations in industrial applications (Lidstrom and Stirling, 1990) and as a bioremediation agent (Hanson and Hanson, 1996).

The amino acid sequence of the *pmo*A gene, which encodes a pMMO protein component in type I methanotrophs, has been used in phylogenetic analyses. This gene is very similar to that encoding the ammonia monooxygenase (*amo*A) in *Nitrosococcus oceani*, suggesting a common evolutionary link (Holmes et al., 1995a; Bodrossy et al., 1997). Several physiological comparisons, in fact, have been drawn between methanotrophs and ammonia-oxidizing bacteria, because both groups are capable of oxidizing methane and ammonia by similar means (Hanson and Hanson, 1996). The sequences of *pmo*A in type II methanotrophs are quite different from those of type I methanotrophs. The amino acid sequences of sMMO polypeptides (*mmo*A, *mmo*B, *mmo*C, and *mmo*X) show a high degree of conservation, however, and are similar between type I and II methanotrophs (Stainthorpe et al., 1991; Murrell, 1992). These genes have been used to develop oligonucleotide probes to specifically target methanotrophs (Holmes et al. 1995b; McDonald and Murrell, 1997; Miguez et al., 1997).

C_1 carbon assimilation Methanotrophs are specialized to utilize the C_1 compounds methane, methanol, and formaldehyde. Occasionally, other C_1 compounds can also be utilized, but this is the exception rather than the rule. Compounds with carbon–carbon bonds (acetate, D-glucose, etc.) are not utilized as energy sources by methanotrophs; however, they may be used as supplementary carbon sources when cells are grown in the presence of methane or other utilizable C_1 compounds (Hanson et al., 1992). So far, no evidence exists for the presence of facultative methanotrophic bacteria that are otherwise similar to the type I methanotrophs.

Formaldehyde is toxic to methanotrophic cells at relatively low concentrations and so is often not tested as a carbon source. In addition, freshly isolated methanotrophs often prove sensitive to methanol (due to accumulation of formaldehyde). Consequently, methanol utilization should be tested with only low methanol concentrations (10–30 mM) or with methanol provided as a vapor in a sealed container. Methanotrophs may be "trained" to tolerate higher concentrations of methanol (Lidstrom, 1988). Type I methanotrophs use the ribulose monophosphate (RuMP) pathway to incorporate formaldehyde into anabolic pathways. Type II methanotrophs, on the other hand, use the serine transhydroxymethylase (Serine) pathway to fix carbon (Strom et al., 1974). In the RuMP pathway, formaldehyde

is combined with ribulose-5-phosphate to form D-erythro-L-glycero-3-hexulose-6-phosphate through the action of the enzyme hexulose-6-phosphate synthase. Subsequently, 1-glyceraldehyde-3-phosphate is formed via 1-fructose-6-phosphate and 3-fructose-6-phosphate. Ribulose-5-phosphate is regenerated via rearrangement reactions from 3-fructose-5-phosphate. Hexulose-6-phosphate synthase is often used as an indicator of the RuMP pathway and thus can be used as a direct way to distinguish type I and II methanotrophs. Some type I methanotrophs, mostly *Methylococcus* strains, possess a low level of activity for α-hydroxypyruvate reductase, a key enzyme for the Serine pathway. The tricarboxylic acid cycle is incomplete and lacks the enzyme 2-oxoglutarate dehydrogenase. The cofactor for isocitrate dehydrogenase differs among type I methanotrophs: in some strains the enzyme activity is dependent on either NAD or NADP; in others it is dependent only on NAD and is unresponsive to NADP, and in still others it is NADP-dependent and unresponsive to NAD (Davey et al., 1972).

Intracytoplasmic membranes When cells are grown in the presence of methane (and sometimes methanol), characteristic intracytoplasmic membranes (ICMs) are formed from convolutions of the cytoplasmic membrane. ICMs are about 80–90 nm thick, appear as typical lipid bilayers, and in type I methanotrophs, are arranged as layered bundles of vesicular disks (Proctor et al., 1969; Davies and Whittenbury, 1970; De Boer and Hazeu, 1972; Hyder et al., 1979) (Fig. BXII.γ.102). Type II methanotrophs, on the other hand, have ICMs that extend peripherally throughout the cell and are arranged parallel to the cell wall. The relative ICM content in cells is enhanced in conditions of limiting oxygen and methane tensions or elevated copper ion concentrations and when a stable and rapid rate of methane transfer is available (Scott et al., 1981; Stanley et al., 1983).

FIGURE BXII.γ.102. Electron micrograph of a ruthenium red-stained thin section of *Methylomonas fodinarum*, showing typical type I methanotrophic intracytoplasmic membrane ultrastructure.

Resting stages Type I methanotrophs often produce single- or multiple-bodied cyst-like inclusions often regarded as being similar to the cysts observed in the genus *Azotobacter*. Encystment usually increases in the stationary growth phase and when cells are grown at low methane tensions (Whittenbury et al., 1970a). Cyst formation depends on cell density, calcium ion concentration, pH, and the rate of cell autolysis (Mulyukin et al., 1997). Cysts may be readily observed by the *Azotobacter* cyst-staining procedure developed by Vela and Wyss (1964). Cysts appear to be made up of a glucan-like polysaccharide, unlike those of the type II methanotroph *Methylocystis*, which are composed mostly of lipid (Sutherland and MacKenzie, 1977). Cyst production appears to allow some methanotrophs to resist methane starvation. In other species, it can also confer desiccation resistance. Heat resistance, however, is not present; it requires more specialized structures such as the exospore formed by the type II methanotroph *Methylosinus*. Excellent photographic descriptions of both multi- and single-bodied cysts have been published by Hazeu et al. (1980a).

Fatty acid composition Members of the *Methylococcaceae* contain mainly C_{16} fatty acids. Although this is not unusual among Gram-negative bacteria, type I methanotrophs species contain abundant levels of several $C_{16:1}$ fatty acid isomers that are rarely encountered in other prokaryotes, including $C_{16:1\ \omega8c}$, $C_{16:1\ \omega6c}$, $C_{16:1\ \omega5c}$, and $C_{16:1\ \omega5t}$ (Makula, 1978; Nichols et al., 1985; Bowman et al., 1991a). The combinations of these fatty acids are diagnostic for the identification of type I methanotrophic genera (Andreev and Gal'chenko, 1978; Bowman et al., 1991a; Bowman et al., 1993b, 1997c) (Table BXII.γ.66). By comparison, type II methanotrophs contain mostly $C_{18:1}$ fatty acids; however, as in the type I methanotrophs, the double bond in most is an unusual position ($C_{18:1\ \omega8c}$) (Nichols et al., 1985). These unusual fatty acids are very useful as signatures for detection and quantitation of methanotroph populations in environmental samples (Nichols et al., 1987; Guckert et al., 1991; Jahnke et al., 1995; Sundh et al., 1997; Guezennec and Fiala-Medioni, 1996).

Lipopolysaccharide composition Studies of the carbohydrate moieties of the lipopolysaccharide of various type I methanotrophs have revealed a pattern typical of Gram-negative bacteria (i.e., D-glucose, L-fucose, and D-heptose) (Sutherland and Kennedy, 1986). The lipid moieties of lipopolysaccharide are composed mostly of $C_{16:0\ 3OH}$, with smaller quantities of β-hydroxylated and saturated components with carbon chain lengths of 10–15. The phospholipids found in type I methanotrophs are generally quite similar to one another and are composed mainly of phosphatidylethanolamine and phosphatidylglycerol, with lower levels of phosphatidylcholine and diphosphatidylglycerol (cardiolipin) (Makula, 1978; Andreev and Gal'chenko, 1983).

Quinones The isoprenoid lipoquinone (coenzyme Q) content of many type I methanotrophs consists mainly of ubiquinone (Q)-8 (94–99%), with small amounts of Q-7 also present. In several species, coenzyme Q is substituted with a methylene group identified as 18-methylene-Q-8 or MQ-8 (Collins and Green, 1985). The MQ-8 is accompanied by minor amounts of MQ-7.

Habitats Methane is an important greenhouse gas and the most abundant organic gas in the atmosphere (Crutzen, 1991). Methanotrophs are the largest global methane sink and, as a result, are ubiquitous in nature. They produce the highest and most active populations in environments where oxygen and methane are readily available (Reeburgh et al., 1993). Recent evidence suggests that methanotrophs make up a high propor-

tion of the total bacterial biomass (up to 40%) in many aquatic environments and surface sediments (Ross et al., 1997; P. I. Boon, personal communication). Methane is highly ^{13}C-depleted, and stable isotopic analyses indicate that a considerable proportion of carbon found in aquatic life at different trophic levels has its origin from methanotrophic bacteria (Boschker et al., 1998). Habitats from which methanotrophs have been successfully isolated include marshes and swamps, rivers and streams, rice paddies, oceans, ponds, lakes, soils of meadows and forests, groundwater, sewage sludge, and coal mines (Hanson and Hanson, 1996). Psychrophilic methanotrophs have been isolated from tundra soils and Antarctic lakes (Omel'chenko et al., 1996; Bowman et al., 1997c). Methanotrophs may be halophilic, although so far, only a few have been described with this property (Lidstrom, 1988; Lees et al., 1991; Sieburth et al., 1993; Bowman et al., 1997c). Methanotrophs have also been isolated from the effluent of an underground hot spring found within a natural gas field (Bodrossy et al., 1995). Methanotrophs have been detected and/or isolated from acidic peat bog soils (Dedysh et al., 1998) and deep sea sediments (Guezennec and Fiala-Medioni, 1996). Methanotrophs can be endosymbiotic in invertebrates associated with marine hydrocarbon seeps (see below). There is also good evidence that methanotrophs are closely associated with aquatic macrophytes (King, 1994; Calhoun and King, 1998).

Endosymbionts Methanotrophic endosymbionts, in coexistence with sulfur-oxidizing chemoautotrophic endosymbionts (Childress et al., 1986; Cavanaugh et al., 1987; Fisher et al., 1993), are the metabolic basis of unusual invertebrate communities associated with hydrocarbon seeps in the Pacific and Atlantic Oceans. The invertebrate hosts include deep-sea mytilid mussels (family *Mytlidae*) (Childress et al., 1986), and the pogonophoran tubeworm *Siboglinum poseidoni* (Dando et al., 1994). Cold-water reefs of algae-free coral found in waters north of Norway, associated with hydrocarbon seeps, are also believed to use methane

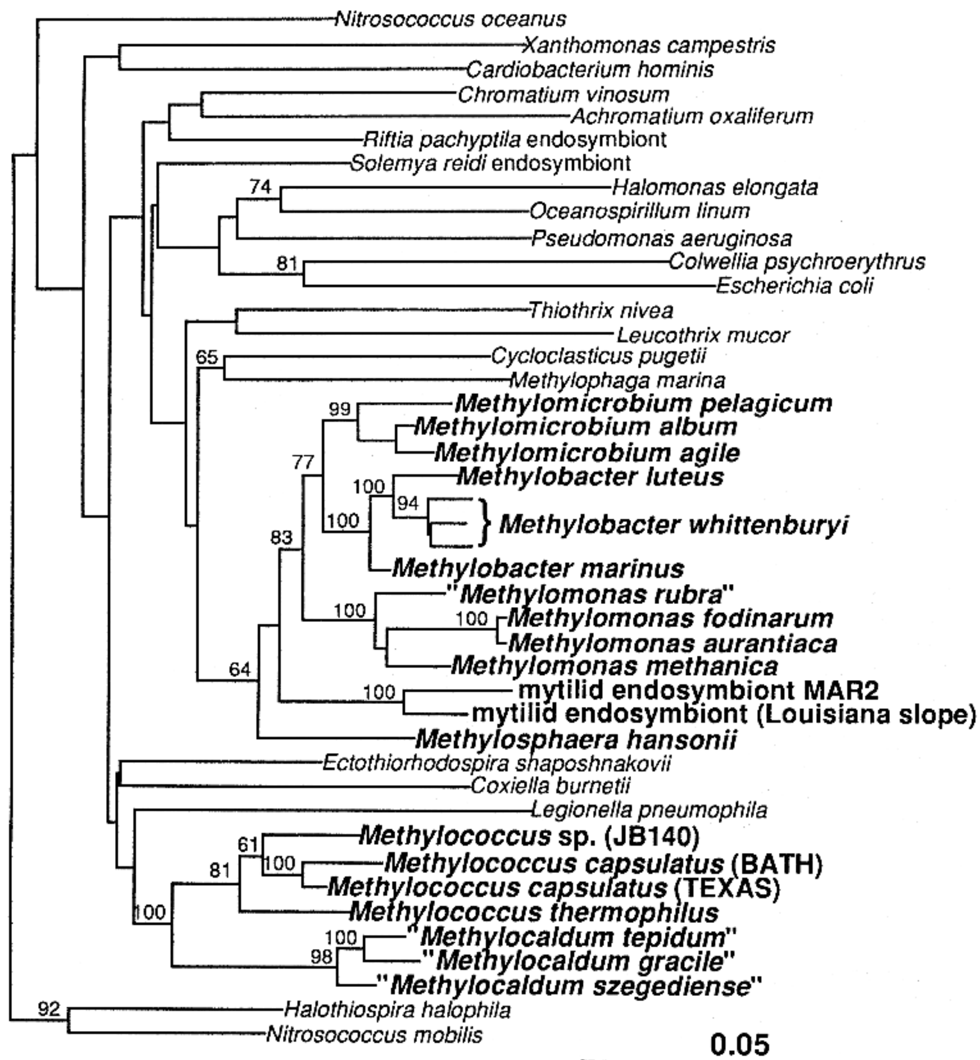

FIGURE BXII.γ.103. Unrooted phylogenetic tree based on 16S rRNA sequences, showing the position of the various genera belonging to the Order *Methylococcales*, Family *Methylococcaceae* (shown in bold type) in the *Gammaproteobacteria*. The tree is based on maximum likelihood values and joined by the neighborliness algorithm (outgrouped with the sequence for *Desulfovibrio desulfuricans*) using the PHYLIP v. 3.57c software package (Phylogenetic Inference Package, J. Felsenstein, University of Washington, Seattle). Values at the branch nodes are bootstrap percentage values generated from 250 replicated analyses. Bar = a taxonomic distance of 0.05.

as a major nutrient and thus presumably contain methanotroph symbionts (Hovland and Judd, 1988). The invertebrates can exist on methane as a primary carbon source, as shown by stable carbon isotope analyses (Southward et al., 1981; Cavanaugh, 1993). Methanotrophs growing in the gills of mytilids have been identified as type I methanotrophs by the presence of key enzymes of the RuMP pathway and characteristic fatty acids, as well as by oligonucleotide probes (Cavanaugh, 1993; Distel and Cavanaugh, 1994; Jahnke et al., 1995). Phylogenetic analyses indicate that mytilid symbionts form a distinct lineage within the *Methylococcaceae* (Distel and Cavanaugh, 1994). Cultivation of methanotroph symbionts has been unsuccessful to date.

Taxonomic Comments

The use of 16S rRNA-based phylogenetic analysis has helped to resolve many of the previously identified nomenclatural problems affecting methanotrophs (Bratina et al., 1992; Brusseau et al., 1994; Bowman et al., 1995). On the basis of 16S rDNA sequencing, type I methanotrophs belong in the *Gammaproteobacteria* and in 1994-1995 were thought to comprise a single clade. However, in most phylogenetic trees based on currently available sequences, the *Methylococcales* is now made up of two separate clades (Fig. BXII.γ.103). The first cluster includes the "group X" methanotrophs—thermotolerant and thermophilic methanotrophs of *Methylococcus* and *"Methylocaldum"*. This clade represents a relatively deep lineage within the *Gammaproteobacteria*, with *Ectothiorhodospira* and *Legionella* being among the closest relatives. The second cluster contains mesophilic and psychrophilic type I methanotrophs, including the genera *Methylosphaera*, *Methylobacter*, *Methylomicrobium*, and *Methylomonas*. This cluster is most closely related to *Methylophaga*, *Cycloclasticus*, and various chemoautotrophic endosymbionts. From this, it could be argued that because the *Methylococcales* does not have phylogenetic coherency, it should be divided into two families. However, sequence analysis still indicates that the type I and group X methanotrophic clades are similar (evolutionary distance 0.10–0.13). More importantly, both groups possess a number of traits, not the least being methane oxidation, that sets them apart from other members of the *Gammaproteobacteria*. It can be safely assumed that many novel methanotrophic species remain to be isolated and that their 16S rDNA sequences could hypothetically introduce topological changes to current phylogenetic trees. Thus, until a broader knowledge of methanotroph phylogeny and evolution is obtained it seems prudent to retain the family *Methylococcaceae* as it currently stands.

Differentiation of the Genera of the Family *Methylococcaceae*

A key to the genera of the family *Methylococcaceae* is provided below. In addition, Table BXII.γ.67 lists phenotypic features that differentiate the genera and Table BXII.γ.68 indicates differences in fatty acid composition between the genera.

Key to the genera of the family Methylococcaceae

I. Can grow at at 45°C or higher. Form cysts and possess ribulose-1,5-diphosphate carboxylase activity. Cells are cocci or rods that may be motile. Colonies are light tan to dark brown. $C_{16:0}$ and $C_{16:1\ \omega7c}$ are the major fatty acid components in cells. The major lipoquinone is MQ-8. The mol% G + C content of the DNA ranges from 59–65 (T_m).

Genus *Methylococcus*

II. Mesophilic. Elliptical rod-like morphology. Usually motile. Colonies on agar are light tan to brown with either a light brown pigment diffusing into agar media or a yellow pigment that may or may not diffuse into agar media. Cells are desiccation resistant. Nitrogenase activity is absent. $C_{16:1\ \omega7c}$ is the major fatty acid component in cells. The major lipoquinone is Q-8. The mol% G + C content of the DNA ranges from 49–55 (T_m).

Genus *Methylobacter*

III. Growth at temperatures > 40°C. Cells coccoid to long rods. Form cysts. Motile or non-motile. Not resistant to desiccation. Colonies buff to brown. Nitrogenase absent. Mol% G + C 57–59 (Bd).

Genus *Methylocaldum*

IV. Mesophilic. Rod-like morphology. Motile. Grows at 25°C and may be slightly halophilic. Colonies on agar are non-pigmented. Nitrogenase activity is absent. Major fatty acids include $C_{16:0}$, $C_{16:1\ \omega8c}$, $C_{16:1\ \omega7c}$, and $C_{16:1\ \omega5c}/C_{16:1\ \omega5t}$. The major lipoquinone is Q-8. The mol% G + C content of the DNA ranges from 48–60 (T_m).

Genus *Methylomicrobium*

V. Mesophilic. Rod-like morphology. Motile. Colonies on agar contain red, pink, or orange non-diffusible carotenoid pigments. Cells are desiccation sensitive. Nitrogenase activity may be present. $C_{14:0}$ and $C_{16:1\ \omega8c}$ are the major fatty acids in cells. The major lipoquinone is MQ-8. The mol% G + C content of the DNA ranges from 50–59 (T_m).

Genus *Methylomonas*

VI. Growth at temperatures ≤37°C. Cells coccoid or fusiform; form packets. Motile. Form cysts. Colonies buff to brown. Nitrogenase absent. Major fatty acids $C_{16:0}$, $C_{16:1\ \omega5t}$, $C_{16:1\ \omega6c}$, $C_{16:1\ \omega7c}$, $C_{16:1\ \omega8c}$. Mol% G + C 54–55 (HPLC).

Genus *Methylosarcina*

VII. Psychrophilic, growing only at −2–20°C. Cells are coccoidal, lack cysts, form gas vesicles, and are nonmotile. No pigmentation. No growth on solid agar media. Oxygen-tolerant nitrogenase activity present. Contains high levels of $C_{16:1\ \omega8c}$ and lacks $C_{16:1\ \omega5c}/C_{16:1\ \omega5t}$. The mol% G + C content of the DNA ranges from 43–46 (T_m).

Genus *Methylosphaera*

John P. Bowman

Me.thy.lo.coc'cus. Fr. n. *méthyle* the methyl radical; Gr. n. *coccus* a grain, berry; M.L. n. *Methylococcus* methyl coccus.

Cells appear as **cocci or rods**, 0.8–1.5 × 1.0–1.5 µm. Usually occur singly or in pairs. Form a polysaccharide-containing **cyst-like resting stage** that is desiccation sensitive. Poly-β-hydroxybutyrate granules present. **Gram negative.** If motile, cells are propelled by single polar flagellum. Catalase and oxidase positive. **Strictly aerobic respiratory metabolism** with oxygen as the electron acceptor. **Obligate utilizers of methane and methanol for carbon and energy.** Contain a **partially functional Benson–Calvin cycle** (phosphoribulokinase and ribulose-1,5-diphosphate carboxylase activity present); however, incorporation of CO_2 for cellular carbon occurs only in the presence of methane. **Fix atmospheric nitrogen** via an oxygen-sensitive nitrogenase. **Thermotolerant or moderately thermophilic** with optimal growth between 40–60°C. Major fatty acids include **$C_{16:0}$ and $C_{16:1\ \omega7c}$**. **18-Methyleneubiquinone-8** (MQ-8) is the predominant lipoquinone. Isolated from sediments of freshwater lakes and rivers, wetland muds, activated sludge, and wastewater. Belongs to the *Gammaproteobacteria* as part of the Order *Methylococcales*, Family *Methylococcaceae*.

The mol% G + C of the DNA is: 59–65 (T_m).

Type species: **Methylococcus capsulatus** Foster and Davis 1966, 1929.

Further descriptive information

Morphology and ultrastructure Cells of *Methylococcus capsulatus* are usually spherical in shape; however, in stationary growth phase cultures, a significant proportion of cells may appear as coccobacilli or short rods. *Methylococcus thermophilus* has a more pleomorphic morphology, with cells ranging from cocci to rods. Cells usually occur singly, in pairs, and sometimes in chains; however, rosette formations are absent. Although *Methylococcus capsulatus* strains lack flagella, *Methylococcus thermophilus* cells are usually vigorously motile upon isolation. Motility is spontaneously lost in many isolates of *Methylococcus thermophilus* (including the type strain) after several serial transfers. Motility is also more pronounced in younger cultures and in cultures grown on methanol.

The cell envelope of *Methylococcus* species is typical of Gram-negative bacteria. Hydroxy fatty acids from the outer membrane lipopolysaccharide have been analyzed in detail in *Methylococcus capsulatus*, *Methylococcus thermophilus*, and *Methylococcus* sp. JB140 (Bowman et al., 1991a). The major components include $C_{10:0\ 3OH}$, $C_{12:0\ 3OH}$, $C_{14:0\ 3OH}$, and $C_{16:0\ 3OH}$. Cells are covered by an exopolysaccharide capsule (Whittenbury et al., 1970a), which often causes a degree of cell aggregation.

The cells of *Methylococcus* species possess the intracytoplasmic membrane (ICM) and cyst formation that commonly occur in many members of the Family *Methylococcaceae.* The ICM formation and ultrastructure have been examined most extensively in *Methylococcus capsulatus* ATCC 33009 (strain "Bath") (Hyder et al., 1979). ICMs are formed when *Methylococcus capsulatus* is grown on methane or methanol, and ICM levels increase in proportion to methane oxidation rates. Growth in the absence of copper (levels less than 1.0 µmol/g dry weight) suppresses formation of ICMs, as well as drastically reducing pMMO activity and derepressing sMMO activity (Prior and Dalton, 1985).

Cysts Single-bodied spherical cysts similar to those observed in *Azotobacter chroococcum*, but comparatively simpler and less defined in structure, are formed by *Methylococcus capsulatus* and *Methylococcus thermophilus*, usually in the stationary growth phase (Whittenbury et al., 1970a; Malashenko et al., 1975b). Increased cyst formation is usually associated with increasing cell refractility,

but cyst formation is not as profuse as in species of *Methylobacter*. Cysts can be visualized by light microscopy after staining (Vela and Wyss, 1964). The cysts are mainly made up of glucan-type polysaccharides (Sutherland and MacKenzie, 1977), which are discarded as cells revert to a normal vegetative state. Production of cysts allow *Methylococcus capsulatus* to survive methane starvation for several weeks even though vegetative cells die rapidly in the absence of methane. The cysts, however, do not confer desiccation or heat resistance. In addition, *Methylococcus capsulatus* cells contain granules of poly-β-hydroxybutyrate, which also contribute to changes in cell refractility. Cells may also contain polyphosphate (volutin) inclusions.

Nutrition and growth conditions *Methylococcus* strains grow well in nitrate mineral salts (NMS) liquid media[1] *Methylococcus thermophilus* tends to produce dark brown colonies with an associated diffusible melanin-like brown pigment; the diffusible pigment is usually lost rapidly upon subculture. *Methylococcus capsulatus* colonies appear off-white to light tan in color and never produce diffusible pigments. Both *Methylococcus* species, depending on the strain, can readily form both rough and smooth colonial variants, with rough colonies possessing a somewhat cartilaginous consistency. This property appears to be particularly prevalent in isolates of *Methylococcus thermophilus* and phenotypically similar species (Bodrossy et al., 1997). With constant subculture, colonies tend to become consistently more butyrous and mucoid.

Methylococcus species are thermotolerant or moderately thermophilic, with optimal growth temperatures of 40–60°C. No strains have been found so far that can grow at temperatures higher than 65°C or below ~25°C.

No growth factors are required, and the strains are nonhalophilic. Some *Methylococcus capsulatus* strains can utilize methylamine, formate, and/or formamide as sole carbon and energy sources. However, *Methylococcus thermophilus* strains, the type strain of *Methylococcus capsulatus* ATCC 19069 (strain "Texas"), and the more heavily studied strain ATCC 33009 cannot utilize any of these compounds. No carbon–carbon bonded compounds can be used for growth.

Nitrogen sources are usually provided in the form of a nitrate or ammonium salt, although *Methylococcus* strains can also use yeast extract, Casamino acids (Difco), and amino acids. In addition, *Methylococcus capsulatus* and most strains of *Methylococcus thermophilus* can also fix atmospheric nitrogen by means of an oxygen-sensitive nitrogenase (Murrell and Dalton, 1983; Zhivotchenko et al., 1995b). A modified acetylene reduction procedure is used to detect nitrogenase activity in methanotrophic cultures (Takeda, 1988).

Some *Methylococcus capsulatus* strains can form sMMO, which allows these strains to grow fairly well in media lacking copper (Prior and Dalton, 1985). Evidence that a strain lacks sMMO is indicated by poor growth in copper-free mineral media; production of sMMO can also be rapidly detected by oxidation of naphthalene to α-naphthol (Brusseau et al., 1990). PCR detection using sMMO-specific primers or detection by filter or colony hybridization techniques can be used to definitively detect the presence of sMMO genes (Stainthorpe et al., 1991; Miguez et al., 1997).

Methylococcus species primarily uses the RuMP pathway to fix formaldehyde for cell carbon. However, the key enzyme for the serine pathway (α-hydroxypyruvate reductase) has also been detected (Strom et al., 1974). The tricarboxylic acid cycle is incomplete, lacking 2-oxoglutarate dehydrogenase activity, but an NAD-dependent isocitrate dehydrogenase is present. *Methylococcus* species also contain a partially functional Benson–Calvin pathway for CO_2 fixation, including activity of the enzymes ribulose-1,5-diphosphate carboxylase and phosphoribulokinase (Whittenbury and Krieg 1984a; Bowman et al., 1993b). The importance of this ability with respect to the cell carbon budget is still not understood, since autotrophic growth of *Methylococcus* species has not been obtained in the absence of methane.

Lipid composition The major fatty acids in *Methylococcus* species have been found to be $C_{16:0}$ and $C_{16:1\ \omega7c}$ (Table BXII.γ.68 of the chapter describing the family *Methylococcaceae*). The high level of $C_{16:0}$ is a characteristic that distinguishes this species from psychrophilic and mesophilic type I methanotrophs. The neutral lipid fraction of *Methylococcus capsulatus* is unusual among procaryotes as it contains squalene, methylated sterols, and hopanoids (Bird et al., 1971; Neunlist and Rohmer, 1985). The unusual distribution of cyclic triterpenes and cyclopropane fatty acids (which become more prevalent with growth under reduced oxygen tension) is believed to improve the stability of outer and intracytoplasmic membranes (Jahnke and Nichols, 1986; Jahnke et al., 1992). The major respiratory coenzyme Q in *Methylococcus capsulatus* and *Methylococcus thermophilus* is 18-methylene-ubiquinone-8 (MQ-8) (Collins and Green, 1985).

Ecology Little information exists on the specific ecology of *Methylococcus* species; however, they have been isolated from a range of aquatic and terrestrial habitats, including soils and sediments of rivers and ponds, sewage sludge, and in the vicinity of various thermal environments (Malashenko et al., 1975a).

Enrichment and Isolation Procedures

Methylococcus species can be enriched and isolated from the microaerobic and aerobic sediments of freshwater lakes and rivers, soil, activated sludge, and near certain thermal environments. A small amount of a sample is added to NMS liquid mineral medium in serum vials or in cotton-stoppered flasks placed within airtight containers. Methane is added directly to the vials and containers, usually by first removing a portion of the headspace. The best methane/air ratio is equivocal but should be in a range of 1:10–1:1. Methane should be of high purity, as natural gas may contain acetylene, which is a suicide substrate of pMMO and sMMO and will hinder or prevent growth, even at low concentrations. Static incubation should then proceed at 40–60°C. Successful enrichments of *Methylococcus* strains develop a white to brown turbidity that is often accompanied by a surface pellicle. Growth from the enrichments can be plated onto mineral salts agar plates, which are then incubated under 1:1 methane/air at 45–60°C.

One of the most problematic areas of methanotroph study is that of obtaining pure cultures. In practically all situations, methanotroph enrichments are severely contaminated by nonmethanotrophic (often methylotrophic) bacteria, which can easily overgrow and/or predate cultures. Due to the relatively slow growth of *Methylococcus* species and the humid conditions in

1. Nitrate mineral salts medium is slightly modified from Whittenbury et al. (1970b) and consists of (per liter of tap water): $MgSO_4 \cdot 7H_2O$, 1.0 g; $CaCl_2 \cdot 6H_2O$, 0.2 g; ferric-EDTA, 10 mg; NH_4Cl, 0.5 g or KNO_3, 1.0 g; trace element solution, 1.0 ml. The trace element solution solution contains (per liter of distilled water): $CuSO_4 \cdot 5H_2O$, 0.2 g; $ZnSO_4 \cdot 7H_2O$, 10 mg; $MnCl_2 \cdot 4H_2O$, 3 mg; H_3BO_4, 30 mg; $CoCl_2 \cdot 6H_2O$, 10 mg; and $Na_2MoO_4 \cdot 7H_2O$, 10 mg; pH 4.0. The medium is adjusted to pH 6.8 before autoclaving. The autoclaved medium is allowed to cool, and 2 ml of 1.0 M sodium phosphate buffer (pH 6.8) is added. Addition of extra copper as $CuSO_4 \cdot 5H_2O$ promotes the growth of methanotrophs (Zhivotchenko et al.,1995a).

which plates are incubated, fungal contamination is also frequent unless containers are thoroughly cleaned with ethanol before each use. Fungicides, such as cycloheximide or nystatin, added to the medium are usually effective in reducing this problem.

A straightforward method for the isolation of *Methylococcus* and other methanotrophs uses mineral agar media that contain small amounts of yeast extract (0.05% w/v) and methanol (0.05% v/v) (Malashenko et al., 1975a), with incubation occurring under a methane/air atmosphere. The enrichment culture is then serially diluted onto the media to the point of extinction. Single colonies from these spread-plates are then transferred to liquid media. A number of passages from liquid media to spread-plates and back to liquid media are often required. The purity of the culture can be assessed by assuring that strains show no growth on nutrient media in the presence or absence of methane and that cells possess a reasonably consistent morphology. More details on enrichment, isolation, and potential problems have been detailed by Whittenbury et al. (1970b) and Hanson et al. (1992).

Maintenance Procedures

Cryopreservation (with cyroprotectants such as DMSO or glycerol) at −80°C and lyophilization are generally ineffective for storing *Methylococcus* strains, as dramatic losses in viability follow freezing (Nesterov et al., 1986). *Methylococcus* strains can be stored in liquid nitrogen (with 20–30% v/v glycerol) for up to 6 months before recoverability becomes problematic. The storage of cultures at low temperature (4°C) under a methane atmosphere has been found to be very effective for short-term storage of up to 6 months.

Procedures for Testing Special Characters

Nitrogen fixation in methanotrophs cannot be tested by the standard acetylene reduction technique because acetylene acts as a suicide substrate of methane monooxygenase. Instead, resting cultures are used. First, the methanotroph is cultured with methanol or methane in vials using nitrogen-free NMS media prepared with 0.2–0.3% (w/v) purified agar to make it semisolid, thereby reducing oxygen diffusion and creating a microaerobic environment that promotes nitrogen fixation. After adequate growth has occurred, acetylene is injected into the headspace (final concentration 2–5%, v/v) and the vials are incubated for several hours. During this time, samples are taken periodically and tested by gas chromatography-thermal conductivity to detect ethylene in the headspace (Murrell and Dalton, 1983; Takeda, 1988).

Putative soluble methane monooxygenase activity of methanotrophs can be rapidly assessed using the naphthalene oxidation technique (Brusseau et al., 1990). First, the methanotroph to be tested is cultured in copper-free NMS liquid medium. Glassware used for cultivation should be washed with 1% (v/v) nitric acid to strip off contaminating copper ions. An equal volume of a saturated naphthalene solution (~30 mg/l at 25°C) is added to a suspension of methanotrophic cells (degassed briefly of residual methane, using nitrogen). The mixture is incubated at room temperature for approximately one hour. To the suspension, 20 μl of a freshly prepared solution of 1% (w/v) tetraotized *o*-dianisidine (Fast Blue salt B) is then added and mixed. The presumptive presence of soluble methane monooxygenase is indicated by the immediate production of a reddish semi-soluble diazo compound, formed from α-naphthol, which can be measured by spectrophotometry at 540 nm.

Differentiation of the genus *Methylococcus* from other genera

Phenotypic characteristics and fatty acid profiles distinguishing *Methylococcus* from other type I methanotrophic genera are shown in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Taxonomic Comments

Numerical taxonomic analysis suggested that several of the methanotrophic groups described by Whittenbury et al. (1970b) were related to *Methylococcus*. These groups were subsequently published as new species of *Methylococcus* (Romanovskaya et al., 1978), and their names subsequently appeared in validation list No. 7 as *Methylococcus bovis*, *Methylococcus chroococcus*, *Methylococcus luteus*, *Methylococcus vinelandii*, and *Methylococcus whittenburyi* (*"Methylobacter capsulatus"*). Subsequent studies using immunological, protein electrophoresis, and fatty acid analysis indicated that this expanded version of the genus *Methylococcus* was clearly heterogeneous (Andreev and Gal' chenko, 1978; Gal' chenko and Nesterov, 1981; Bezrukova et al., 1983; Meyer et al., 1986; Bowman et al., 1991a). Moreover, genomic characteristics demonstrated that the genus was made up of two major groups (Bowman et al., 1991b). This nomenclatural problem was resolved only by retention of *M. capsulatus* and *M. thermophilus* in the genus *Methylococcus*, with the description of *Methylococcus* appropriately emended (Bowman et al., 1993b) and transfer of the other species to the genus *Methylobacter*, which was created to accommodate them.

"Methylococcus fulvus" Malashenko, Romanovskaya and Kvashnikov 1972, 877 possesses phenotypic traits highly similar to those of *Methylobacter luteus* (Romanovskaya et al., 1978) and lacks a type strain.

The single strain making up the species *Methylococcus mobilis* Hazeu et al., 1980b, 676 has been lost, and this species should be regarded as invalid until a replacement strain has been isolated and described. *Methylococcus* species form a deeply branching clade within the *Gammaproteobacteria* (Fig. BXII.γ.103). Outside of this clade, the closest bacterial relative in terms of 16S rRNA sequence similarity is the photosynthetic species *Ectothiorhodospira shaposhnikovii* (evolutionary distance 0.09–0.10). The *Methylococcus* clade groups separately from the remaining type I methanotrophs, but evolutionary distances are roughly equivalent to the interposing genera (evolutionary distance 0.10–0.14).

DNA–DNA hybridization analysis indicates that *Methylococcus capsulatus* ATCC 19069 possesses high levels of hybridization with strain ATCC 33009 (Bowman et al., 1993b). A DNA hybridization range of 40–43% is found with the non-extant strain JB140; however, only negligible levels of DNA hybridization (<25%) is found between strains of *Methylococcus capsulatus* and *Methylococcus thermophilus*. Moderately thermophilic methanotrophs were recently described by Bodrossy et al. (1997) as the genus *Methylocaldum*, which includes the species *Methylocaldum szegediense* (the type species), *Methylocaldum tepidum*, and *Methylocaldum gracile*. (The latter was renamed from *"Methylomonas gracilis"* NCIMB 11128.) Bodrossy and colleagues have noted phenotypic similarity between *Methylococcus thermophilus* and *Methylocaldum* species; moreover, high levels of DNA hybridization have been reported between *Methylococcus thermophilus* IMV-2Yu and *"Methylomonas gracilis"* NCIMB 11912 (Bowman et al., 1993b). The phenotypic differences between *Methylococcus* and *Methylocaldum* appear to be trivial in nature and, based on the current description of *Methylo-*

coccus, it is nearly impossible to differentiate *Methylococcus* from *Methylocaldum*. Both groups possess similar fatty acid profiles, mol% G + C contents of the DNA, genomic characteristics, and *pmo*A sequences. On the other hand, 16S rDNA analysis suggests that the two groups are phylogenetically distinct (evolutionary distance ~0.08). This is in contrast to the above-mentioned similarities between the two groups, particularly the hybridization data for *Methylococcus thermophilus* IMV-2Yu and *"Methylomonas gracilis"* NCIMB 11128 (Bowman et al., 1993b), and this anomaly suggests that the 16S rDNA sequence of *Methylococcus thermophilus* needs to be verified. It is certainly clear that, based on DNA hybridization data, *Methylocaldum gracile* is a subjective synonym of *Methylococcus thermophilus* and is thus misnamed. Further DNA hybridization analysis is needed to confirm or deny the genotypic distinctiveness of other *Methylocaldum* species from *Methylococcus thermophilus*.

Differentiation of the species of the genus *Methylococcus*

Phenotypic and genotypic characteristics differentiating the species of *Methylococcus* are shown in Table BXII.γ.69, while additional characteristics are shown in Table BXII.γ.70. The phenotypic characteristics possessed by strains of *Methylococcus thermophilus* are essentially the same as those possessed by *Methylocaldum* strains.

List of species of the genus Methylococcus

1. **Methylococcus capsulatus** Foster and Davis 1966, 1929[AL]
cap.su.la'tus. M.L. adj. *capsulatus* encapsulated.

Cells are coccoidal and nonmotile. Colonies are white to light tan, round, convex, entire- or lobate-edged, with a cartilaginous or butyrous consistency. Other characteristics are as described for the genus and as listed in Tables BXII.γ.69 and BXII.γ.70. For further descriptive information, see Foster and Davis (1966) and Bowman et al. (1993b).

Optimum temperature for growth, ~45°C. pH range for growth, 5.5–8.5; optimum, 6.5–7.0.

Isolated from lakes and river mud, wetland muds, activated sludge, and wastewater.

The mol% G + C of the DNA is: 62.5 (Bd), type strain. Analysis of several other strains using the thermal denaturation method found a range of 62–65 mol% (Bowman et al., 1991b).

Type strain: Texas, ACM 1292, ATCC 19069 NCIMB 11853.

GenBank accession number (16S rRNA): X72770.

Additional Remarks: Another important strain is Bath (ATCC 33009, NCIMB 11132, VKM-TRMC, IMET 10544).

2. **Methylococcus thermophilus** Malashenko, Romanovskaya, Bogachenko and Shved 1975b, 779[AL]
ther.mo'phil.us. Gr. n. *therme* heat; Gr. adj. *philus* loving; M.L. adj. *thermophilus* heat loving.

Cells are coccoidal and usually motile on initial isolation. Motile strains usually lose motility after several subcultures. Colonies are light to dark brown, round, raised convex, with entire to irregular edges, and have a viscid or cartilaginous consistency. Produce a diffusible brown pigment, which is usually lost during the strain purification process. Other characteristics are as described for the genus and as listed in Tables BXII.γ.69 and BXII.γ.70. For further descriptive information, see Bowman et al. (1993b).

Optimum growth temperature, 50–55°C. pH range for growth, 5.5–9.0; optimum, 7.0.

Isolated from therapeutic mud, moist subtropical–tropical soils, creek mud, and pond sediment.

TABLE BXII.γ.69. Characteristics differentiating the species of the genus *Methylococcus*[a,b]

Characteristic	1. *M. capsulatus*	2. *M. thermophilus*
Motile cells	−	+
Melanin-like pigment production	−	+
Growth at 55°C	−	+
Mol% G + C of DNA (T_m)	62.5–65.2	59.1–60.8

trimethylamine *N*-oxide	−	−

[a]For symbols see standard definitions; nd, not determined.

[b]Phenotypic data from Bowman (1992) and Bowman et al. (1993b).

The species *Methylocaldum gracile* is a synonym of *Methylococcus thermophilus*, as indicated by DNA–DNA hybridization data (Bowman et al., 1993b). The phylogenetic discrepancy between strain IMV-2Yu and NCIM 11912 is attributed to a potentially erroneous *Methylococcus thermophilus* 16S rRNA sequence.

The mol% G + C of the DNA is: 59–61 (T_m).

Type strain: VKM-2Yu, V 2YU, ACM 3585.

GenBank accession number (16S rRNA): X73819.

Additional Remarks: GenBank accession number for *Methylocaldum gracile* is U89298.

Species Incertae Sedis

1. **"Methylococcus fulvus"** Malashenko, Romanovskaya and Kvashnikov 1972, 877.

   ful'vus. L. adj. *fulvus* tawny, yellowish brown.

   See Taxonomic Comments.

2. **Methylococcus mobilis** Hazeu, Batenburg-van der Vegte and de Bruyn 1980b, 676^{VP} (Effective publication: Hazeu Batenburg-van der Vegte and de Bruyn 1980a, 211.)

   mo'bi.lis. L. masc. adj. *mobilis* motile.

   See Taxonomic Comments

   The mol% G + C of the DNA is: unknown.

Genus II. **Methylobacter** *Bowman, Sly, Nichols and Hayward 1993b, 749^{VP} emend. Bowman, Sly and Stackebrandt 1995, 184.*

John P. Bowman

Me.thy.lo.bac'ter. Fr. n. *méthyle* the methyl radical; Gr. n. *bacter* rod; M.L. n. *Methylobacter* methyl rod.

Cells are **spherical or elliptical**, 0.8–1.5 × 1.2–3.0 μm. Usually occur singly, in pairs, and occasionally in chains. **Gram negative.** When motile, form single polar flagellum. Form a **glucan-containing cyst-like resting stage,** which usually confers **desiccation resistance**. Poly-β-hydroxybutyrate granules present. **Strictly aerobic respiratory metabolism** with oxygen as the electron acceptor. **Obligate utilizers of methane for carbon and energy.** Carbon–carbon bonded compounds are not utilized. Oxidase and catalase positive. Uses the **ribulose monophosphate pathway** to fix formaldehyde for cell carbon. Key enzyme activity of the serine transhydroxymethylase pathway is absent. **Nitrogen fixation is absent.** Not susceptible to lysis by 0.2% sodium dodecyl sulfate. **Mesophilic**, with optimal growth between 30°C and 35°C. One species requires sodium ions and other factors for growth. The major fatty acid is $\mathbf{C_{16:1\ \omega7c}}$. **Ubiquinone-8 (Q-8)** is the predominant lipoquinone. Habitat: Isolated from sediments of freshwater lakes and rivers, wetland muds, activated sludge, and wastewater. Belongs to the *Gammaproteobacteria* as part of the Order *Methylococcales*, Family *Methylococcaceae*.

Type species: **Methylobacter luteus** (Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993b, 749 (*Methylococcus luteus* Romanovskaya, Malashenko and Bogachenko 1978, 124; *Methylococcus bovis* Romanovskaya, Malashenko and Bogachenko 1978, 124.)

Further descriptive information

Morphology and ultrastructure Cells of *Methylobacter* species possess a characteristic elliptical, rod-like morphology, with a width of 0.8–1.5 × 1.2–3.0 μm. They occur mostly singly or in pairs, although chain formation is prevalent in some strains in the late exponential growth phase. When motile, the cells are propelled by a single polar flagellum. *Methylobacter luteus* is nonmotile, while *Methylobacter whittenburyi* strains are usually motile when first isolated but can spontaneously lose this ability after extensive subculture. Motility appears most pronounced in young cultures of *M. whittenburyi* and *Methylobacter marinus*; older cultures are often devoid of motile cells (Romanovskaya et al., 1978; Bowman et al., 1993b). Cell walls have an ultrastructure that is typical of Gram-negative bacteria. Cells are surrounded by capsular material that is detectable by India ink staining.

Cells contain type I intracytoplasmic membranes, typical for other members of the family *Methylococcaceae*. *Methylobacter* species form well-defined *Azotobacter*-type cysts, which give cells a refractile appearance (Whittenbury et al., 1970a). Cyst formation is most pronounced in stationary-growth-phase cultures and appears to be stimulated when oxygen becomes limiting for growth. The cysts are readily detectable by the *Azotobacter* cyst-staining procedure of Vela and Wyss (1964). The cysts are not heat resistant, but they are relatively desiccation resistant. Spontaneous loss of cysts has been noted in one study and usually leads to problems in maintaining culture viability (Lidstrom, 1988). Though the cysts may be a mechanism for surviving times of oxygen deprivation and desiccation, *Methylobacter* strains are still susceptible to methane starvation and eventually lose viability within 1–3 weeks without methane or methanol substrate. Poly-β-hydroxybutyrate granules tend to be formed by *Methylobacter* strains, particularly in younger cultures.

Cultural features *Methylobacter* strains form an even turbidity in NMS liquid medium, with little or no pellicle development. On agar, colonies are uniformly circular and convex with entire edges, possess a creamy consistency, and reach a diameter of 1–2 mm after 7–14 days under methane/air atmosphere (1:1, v/v). *M. whittenburyi* and *M. marinus* strains form colonies that are initially an off-white color but become increasingly tan to brown after prolonged incubation. At the same time, a tan diffusible melanin-like pigment is slowly released into the medium. *M. luteus* differs by forming lemon-yellow colonies, with some strains also releasing a water-soluble yellow pigment. Detailed chemical analysis of the yellow pigment has yet to be performed, but preliminary spectrophotometric scans indicated that it is not carotenoid in nature, nor does it undergo a bathochromic shift if exposed to strong alkaline solutions.

Methylobacter species are mesophilic, and most strains grow in the range of 15–40°C, with optimal growth occurring at about 30°C. The pH range for growth ranges from 5.5–9.0, with optimal growth occurring at about pH 7.0. No *Methylobacter* strains require growth factors, and all are nonhalophilic. The estuarine species *M. marinus* grows optimally with about 0.1 M NaCl in tap water or with half-strength seawater salts. One strain of *Methylobacter marinus* requires nicotinic acid for growth (Lidstrom, 1988).

Nutrition and metabolism *Methylobacter* strains are strictly aerobic obligate methanotrophs, with carbon and energy substrates limited to methane and methanol. A few strains, however, can

also utilize methylamine. No strains have been demonstrated to grow on carbon–carbon bonded compounds. Upon isolation, most *Methylobacter* strains may be sensitive to methanol and do not grow on media containing 0.1% (v/v) methanol. However, good growth occurs when methanol is provided only as a vapor. It is possible to acclimate strains to methanol by slowly adding increasingly higher concentrations of methanol to media while growing the strain on methane. Methane appears to be oxidized by only the particulate form of methane monooxygenase. The presence of soluble methane monooxygenase has not been demonstrated in *Methylobacter* strains so far (Stainthorpe et al., 1991; Smith et al., 1997c). Formaldehyde is fixed by the ribulose monophosphate pathway, and key enzymes for the serine pathway are absent. Ribulose-1,5-diphosphate carboxylase activity is also absent. *Methylobacter* strains can utilize nitrate and ammonia salts, yeast extract, Casamino acids, and various amino acids as nitrogen sources, but high levels (>0.5% w/v) of complex organic compounds are inhibitory to growth. Some strains, particularly those of *M. luteus*, can produce a urease and can use urea as a sole nitrogen source. No *Methylobacter* strain has been found to be capable of fixing atmospheric nitrogen.

Fatty acid composition The outer membrane lipopolysaccharide hydroxy fatty acids have been analyzed in detail in *M. luteus* and *M. whittenburyi*. The major components in *M. luteus* include $C_{10:0\ 3OH}$ and $C_{16:0\ 3OH}$, with smaller quantities of $C_{12:0\ 2OH}$, $C_{14:0\ 3OH}$, and $C_{15:0\ 3OH}$. *M. whittenburyi* contains almost entirely $C_{16:0\ 3OH}$ (Bowman et al., 1991a). The fatty acid profiles of *Methylobacter* species have been found to be very similar (Table BXII.γ.68 of the chapter describing the family *Methylococcaceae*; Andreev and Gal'chenko, 1978). The predominant fatty acid is $C_{16:1\ \omega7c}$, accompanied by lower levels of $C_{14:0}$, $C_{16:1\ \omega6c}$, $C_{16:1\ \omega5c}$, and $C_{16:0}$ (Bowman et al., 1991a). The lack of $C_{16:1\ \omega8c}$ and relatively low levels of $C_{14:0}$ and $C_{16:0}$ distinguish *Methylobacter* from other type I methanotrophs.

Ecology The specific ecology of *Methylobacter* species is generally unknown. Indirect immunofluoresence studies, however, indicate that they are common in surface sediments and in the water columns of various freshwater and brackish water environments making up as much as 10–40% of the total bacterial population (Malashenko et al., 1987; Gal'chenko et al., 1988; Gal'chenko, 1994; Saralov et al., 1984).

Enrichment and Isolation Procedures

The enrichment and isolation approach described for the genus *Methylococcus* can also be applied for *Methylobacter* strains. However, the incubation temperature is in this case lowered to 25–30°C. Salt composition and pH of the media all should closely reflect the habitat being investigated.

Maintenance Procedures

Methods for maintenance are the same as given for the genus *Methylococcus*.

Differentiation of the genus *Methylobacter* from other genera

Phenotypic, chemotaxonomic, and genotypic properties differentiating *Methylobacter* from other type I methanotrophs are shown in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Taxonomic Comments

The genus *Methylobacter* was formed from the genus *Methylococcus* (Bowman et al., 1993b). *Methylobacter* species are equivalent to a similarly named group first coined by Whittenbury et al. (1970b). DNA–DNA hybridization, fatty acid analyses, and phylogenetic analyses have further refined the genus, so that species lacking cyst formation and different fatty acid profiles have been moved into the genus *Methylomicrobium*. This has necessitated an emendation of the description of *Methylobacter* (Bowman et al., 1995).

Phylogenetic analysis using 16S rDNA sequences indicates that *Methylobacter* forms a relatively tight cluster within the *Gammaproteobacteria*. *Methylobacter* is part of a larger phylogenetic cluster that includes *Methylosphaera*, *Methylomicrobium*, *Methylomonas*, and methanotrophic mytilid endosymbionts. The genus is most closely related to the genera *Methylomicrobium* and *Methylomonas* (evolutionary distance 0.04–0.06) (Bratina et al., 1992; Bowman et al., 1995).

The mol% G + C of the DNA of *Methylobacter* ranges from 48–55 (T_m). (Malashenko et al., 1975b; Meyer et al., 1986; Lysenko et al., 1988; Bowman et al., 1991b) (Table BXII.γ.71); this value is similar to those for *Methylomonas* and *Methylomicrobium*. DNA–DNA hybridization has been found to be useful in sorting out some of the taxonomic problems affecting the genus *Methylococcus*. Various *Methylococcus* species, including *Methylococcus vinelandii*, *Methylococcus chroococcus*, *"Methylococcus ucrainicus"*, *Methylococcus bovis* IMET 10593 (a non-pigmented strain), *Methylococcus whittenburyi*, and phenotypically similar isolates, all exhibit high levels of DNA–DNA hybridization (54–93% similarity) with each other indicating that they were a single genospecies (Lysenko et al., 1988; Bowman et al., 1993b). This argument is supported by inherent phenotypic similarity, similar protein electrophore patterns (Gal'chenko and Nesterov, 1981), immunological cross-reactivity (Bezrukova et al., 1983), and close phylogenetic affiliation. (See Fig. BXII.γ.103 in the description of the order *Methylococcales*.). In addition, *Methylococcus luteus* shares very high levels of DNA–DNA hybridization (98% similarity) with the yellow-pigmented strain *Methylococcus bovis* IMV-B-3098 (Bowman et al., 1993b). Overall DNA–DNA hybridization levels among the three valid species of *Methylobacter* are 20–40%.

Recently, two species, *Methylobacter psychrophilus* (Omel'chenko et al., 1996) and *"Methylobacter alkaliphilus"* (Khmelenina et al., 1997), were proposed for strains isolated from tundra soil and soda lake habitats, respectively. *Methylobacter psychrophilus* possesses phenotypic properties and DNA base composition similar to those of *Methylosphaera hansonii*; both species consist of spherical nonmotile cells, lack cysts, possess gas vesicles, have psychrophilic growth requirements, and possess relatively low mol% G + C contents of their DNA (approximately 45–46). *"Methylobacter alkaliphilus"* possesses morphological traits typical of *Methylobacter* species but has a different fatty acid profile that includes high levels of $C_{16:0}$ and, depending on the growth conditions, $C_{16:0\ iso}$ (Khmelenina et al., 1997); $C_{16:1}$ fatty acid is only a relatively minor component. A 16S rDNA sequence for this species would be useful in confirming that it belongs to the genus *Methylobacter*.

Differentiation of the species of the genus *Methylobacter*

Phenotypic and genotypic characteristics differentiating the species of *Methylobacter* are shown in Table BXII.γ.71. Additional characteristics are shown in Table BXII.γ.72.

List of species of the genus Methylobacter

1. **Methylobacter luteus** (Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993b, 749[VP] (*Methylococcus luteus* Romanovskaya, Malashenko and Bogachenko 1978, 124 *Methylococcus bovis* Romanovskaya, Malashenko and Bogachenko 1978, 124.)
lu' te.us. L. adj. *luteus* golden-yellow.

Cells are nonmotile cocci or elliptical rods, 1.2–1.5 × 1.5–2.0 μm. Other characteristics are as described for the genus and as listed in Tables BXII.γ.71 and BXII.γ.72. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature for growth, ~30°C; range, 15–40°C. pH optimum, ~7.0; range, 5.5–9.0.

Isolated from sediments of freshwater lakes and ponds.

The mol% G + C of the DNA is: 50.3–51.1 (T_m).

Type strain: ACM 3304, IMET 10584, NCIMB 11914, VKM-53B.

GenBank accession number (16S rRNA): M95657.

Additional Remarks: "Methylococcus fulvus" Malashenko, Romanovskaya and Kvashnikov 1972, 877 is phenotypically indistinguishable from *Methylobacter luteus* (Romanovskaya et al., 1978); moreover, it lacks an available strain, thereby making genotypic comparisons impossible.

2. **Methylobacter marinus** Bowman, Sly, Nichols and Hayward 1993b, 749[VP]
mar' i.nus. L. adj. *marinus* from the sea.

Cells are motile elliptical rods, 0.8–1.2 × 1.5–2.0 μm. Requires 0.1 M NaCl and tap water (or half-strength natural or artificial seawater salts) for growth. May require nicotinic acid.

Other characteristics are as described for the genus and as listed in Tables BXII.γ.71 and BXII.γ.72. For further descriptive information, see Lidstrom (1988) and Bowman et al. (1993b).

Optimum temperature for growth, ~35°C; range, 15–40°C. pH optimum, ~7.0; range, 5.5–9.0.

Isolated from near a coastal sewage outfall in Pasadena, California.

[a]For symbols, see standard definitions.

[b]Phenotypic data from Bowman et al. (1993b).

[c]TTC, triphenyltetrazolium chloride.

[d]Compounds tested (at 0.1%) included formate, formamide, methylamine, dimethylamine, and trimethylamine.

The mol% G + C of the DNA is: 54.3–55.0 (T_m).
Type strain: A4, ACM 4717.
GenBank accession number (16S rRNA): M95658.

3. **Methylobacter whittenburyi** (Romanovskaya, Malashenko and Bogachenko 1978) Bowman, Sly, Nichols and Hayward 1993b, 750^{VP} (*Methylococcus whittenburyi* Romanovskaya, Malashenko and Bogachenko 1978, 125)
whit.ten.bur′y.i. L. n. *whittenburyi* after Whittenbury, in honor of British microbiologist Roger Whittenbury for his seminal research on methanotrophic bacteria.

Cells are motile elliptical rods, 1.2–1.5 × 1.5–3.0 µm. Other characteristics are as described for the genus and as listed in Tables BXII.γ.71 and BXII.γ.72. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature for growth, ~30–35°C; range, 15–40°C. pH optimum, ~7.0; range, 5.5–9.0.

Isolated from sediments of freshwater lakes and ponds.
The mol% G + C of the DNA is: 48.7–53.7 (T_m).
Type strain: Y, 1521, ACM 3310, NCIMB 11128.
GenBank accession number (16S rRNA): L20843, X72773.

Species Incertae Sedis

1. **"Methylobacter alkaliphilus"** Khmelenina, Kalyuzhnaya, Starostina, Suzina and Trotsenko 1997, 260.
al.ka.li.phi′lus. M.L. n. *alcali* (from Arabic *al* the end; *qaliy* soda ash); Gr. adj. *philus* loving; M.L. adj. *alkaliphilus* loving alkaline conditions.

Coccoidal to elliptical cells, 1.2–1.3 × 2.0–3.0 µm. Motile by a single polar flagellum. Multiply by binary division. *Azotobacter*-type cysts and type I intracytoplasmic membranes are formed. Possess a protein surface layer (cup-shaped units).

Colonies on agar are white to cream, circular, with entire margins, and 1–2 mm in diameter after sufficient incubation in methane/air. No water-soluble pigments are released.

Halophilic and alkaliphilic. Grows at 0.15–10% NaCl, optimum growth at 2–4% NaCl. Optimum temperature, 30°C; range, 8–37°C. Optimum pH, 9.0–9.5; range, 7.0–10.5.

Strictly aerobic. Obligate methanotroph: growth occurs only on methane and methanol. Carbon is assimilated by the ribulose monophosphate pathway. The serine-pathway enzyme α-hydroxypyruvate reductase is absent. The tricarboxylic-acid-cycle enzyme 2-oxoglutarate dehydrogenase is absent. Nitrate and ammonia are utilized as nitrogen sources via the glutamine and glutamate synthetase system.

Major fatty acids (when grown under optimal growth conditions, 0.7 M NaCl, pH 9.0) include $C_{16:0}$ (50.1%), $C_{16:0\ cyc}$ (11.6%), $C_{16:0\ iso}$ (8.7%), $C_{14:0}$ (8.0%), and $C_{16:1}$ (7.4%). At suboptimal growth conditions (low salt and neutral pH), cells produce more $C_{16:0\ iso}$ than $C_{16:0}$. Major phospholipids (under optimal growth conditions) include phosphatidylcholine, phosphatidylglycerol, and diphosphatidyglycerol (cardiolipin).

Isolated from soda lakes (pH 9.5, 1–3% salinity) in the Tuva region of Central Asia.
The mol% G + C of the DNA is: 47.6–47.9 (T_m).
Deposited strain: VKM B-2133.

2. **Methylobacter psychrophilus** Omel'chenko, Vasil'eva, Zavarzin, Savel'eva, Lysenko, Mityushina, Khmelenina and Trotsenko 2000, 423^{VP} (Effective publication: Omel'chenko, Vasil'eva, Zavarzin, Savel'eva, Lysenko, Mityushina, Khmelenina and Trotsenko 1996, 342.)
psy.chro′phi.lus. Gr. n. *psychros* cold; Gr. adj. *philus* loving; L. adj. *psychrophilus* cold loving.

Cells are coccoidal, 1.0–1.7 µm in diameter, occurring singly or in pairs. Possess a thin capsule. Multiply by binary division. Do not form cysts or other resting stages. Possess type I intracytoplasmic membranes and gas vesicles. Gas vesicles are more common in cells grown at higher cultivation temperatures and are cigar-shaped, 80–110 nm wide and up to 300 nm long.

Colonies are cream, circular, and convex, with an entire edge and a smooth shiny surface and possessing an aqueous consistency. Water-soluble pigments are not formed.

Psychrophilic. Optimum temperature, 3.5–10°C; range, 1.0–20°C. Optimum pH, 6.8–7.2; range, 5.9–7.6. Nonhalophilic. Growth factors are not required for growth.

Strictly aerobic obligate methanotroph. Growth occurs only on methane and methanol. Carbon is assimilated by the ribulose monophosphate pathway. Isocitrate dehydrogenase is NAD-specific, and 2-oxoglutarate dehydrogenase activity is absent. Ribulose-1,5-diphosphate carboxylase activity is absent.

The predominant fatty acid is $C_{16:1}$ with lower levels of $C_{14:0}$ and $C_{16:0}$.

Isolated from swampy soil of dwarf birch tundra in Russia.
The mol% G + C of the DNA is: 45.6 (T_m).
Deposited strain: Z-0021, VKM B-2103.
GenBank accession number (16S rRNA): AF152597.

Genus III. **Methylocaldum** *Bodrossy, Holmes, Holmes, Kovács and Murrell 1998, 631^{VP} (Effective publication: Bodrossy, Holmes, Holmes, Kovács and Murrell 1997, 501)*

THE EDITORIAL BOARD

Me.thy.lo.cal.dum. N.L. n. *methylo* the methyl radical; L. adj. *caldus* hot; M.L. n. *Methylocaldum* heat-loving methylotroph.

Gram-negative, **coccoidal to long rods**. Moderately thermophilic; growth at temperatures >40°C. **Utilize methane as sole carbon and energy source. No growth on compounds containing carbon–carbon bonds.** Enzymes for ribulose monophosphate and serine pathways of formaldehyde assimilation are present. No soluble methane monooxygenase. Produce large cysts. Habitat: soil, hot springs.

The mol% G + C of the DNA is: 57–59.

Type species: **Methylocaldum szegediense** Bodrossy, Holmes, Holmes, Kovács and Murrell 1998, 631 (Effective publication: Bodrossy, Holmes, Holmes, Kovács and Murrell 1997, 501.)

List of species of the genus Methylocaldum

1. **Methylocaldum szegediense** Bodrossy, Holmes, Holmes, Kovács and Murrell 1998, 631[VP] (Effective publication: Bodrossy, Holmes, Holmes, Kovács and Murrell 1997, 501.)
sze.ged.i.en.se. Hung. n. *Szeged* the town of Szeged; M.L. adj. *szegediense* from the town of Szeged.

   Gram-negative, coccoidal to long rods, 0.6–1.0 × 1.0–1.5 µm. Motile at some stages of growth. Chains may occur in late exponential phase. Pleomorphic in stationary phase. Nondiffusible pigments produced in later stages of growth. Colonies mucoid or cartilaginous, buff to light brown after 1 week. Older colonies may be shiny and smooth with entire margins or dry and rough with irregular margins. Utilizes methane as sole carbon and energy source. No growth on compounds containing carbon–carbon bonds. Sensitive to desiccation. Produces an extracellular polymeric substance in liquid culture. Optimum temperature 55°C (range 37–62°C). No growth on methanol, formate, formamide, or methylamine. Does not fix N_2. Resistant to heating at 80°C. Enzymes for ribulose monophosphate and serine pathways of formaldehyde assimilation are present. No soluble methane monooxygenase. Produces large cysts. Habitat: soil, hot springs.
   The mol% G + C of the DNA is: 57.
   Type strain: OR2, NCIMB.
   GenBank accession number (16S rRNA): U89300.

2. **Methylocaldum gracile** (ex Romanovskaya, Malashenko and Bogachenko 1978) Bodrossy, Holmes, Holmes, Kovács and Murrell 1998, 631[VP] (Effective publication: Bodrossy, Holmes, Holmes, Kovács and Murrell 1997, 502.)
gra.cil.e. L. adj. *gracile* slim, slender, thin.

   Gram-negative, coccoidal to long rods, 0.4–0.5 × 1.0–1.5 µm. Motile. No chain formation. Pleomorphic in stationary phase. Nondiffusible pigments produced in later stages of growth. Colonies are pasty or cartilaginous, buff to light brown after 1 week. Older colonies can turn dark brown. Utilizes methane as sole carbon and energy source. No growth on compounds containing carbon–carbon bonds. Optimum temperature 42°C (range 20–47°C). No growth above 50°C. Sensitive to desiccation and heating to 80°C. Does not fix N_2. Enzymes for ribulose monophosphate and serine pathways of formaldehyde assimilation are present. No soluble methane monooxygenase. Produces large cysts. Habitat: soil, hot springs.
   The mol% G + C of the DNA is: 59.
   Type strain: VKM-14L, NCIMB 11912.
   GenBank accession number (16S rRNA): U89298.

3. **Methylocaldum tepidum** Bodrossy, Holmes, Holmes, Kovács and Murrell 1998, 631[VP] (Effective publication: Bodrossy, Holmes, Holmes, Kovács and Murrell 1997, 502.)
te.pi.dum. M.L. adj. *tepidum* lukewarm.

   Gram-negative, coccoidal to long rods, 1.0–1.2 × 1.0–1.5 µm. Chains may occur in late exponential phase. Pleomorphic in stationary phase. Nondiffusible pigments produced in later stages of growth. Colonies are buff and butyrous or cartilaginous after 1 week. Older colonies can turn light brown. Utilize methane as sole carbon and energy source. No growth on compounds containing carbon–carbon bonds. Sensitive to desiccation. Optimum temperature 42°C (range 30–47°C). No growth above 50°C. Does not fix N_2. Enzymes for ribulose monophosphate and serine pathways of formaldehyde assimilation are present. No soluble methane monooxygenase. Produces large cysts. Habitat: soil, hot springs.
   The mol% G + C of the DNA is: 59.
   Type strain: LK6.
   GenBank accession number (16S rRNA): U89297.

Genus IV. **Methylomicrobium** *Bowman, Sly and Stackebrandt 1995, 183*[VP]

JOHN P. BOWMAN

Me.thy.lo.mi.cro′ bi.um. Fr. n. *méthyle* the methyl radical; Gr. adj. *micros* small; Gr. n. *bios* life; M.L. n. *Methylomicrobium* a small organism able to utilize methyl units.

Rods 0.5–1.0 × 1.5–2.5 µm. Usually occur singly or in pairs. **Gram negative. Motile**, propelled by a single, unsheathed, polar flagellum. **Lack cysts** or other differentiated resting stages. Desiccation and heat-sensitive. Colonies are **nonpigmented**. **Have a strictly aerobic respiratory metabolism,** with oxygen as the electron acceptor. **Obligate utilizers of methane and methanol for carbon and energy.** Carbon–carbon bonded compounds are not utilized. Oxidase and catalase positive. Uses the **ribulose monophosphate pathway** to fix formaldehyde for cell carbon. Key enzyme activity of the serine transhydroxymethylase pathway is absent. Nitrogen fixation is absent. Not susceptible to lysis by 0.2% SDS. **Mesophilic** with optimal growth at 20–30°C. One species requires seawater salts for growth. Major fatty acids are **$C_{16:1\ \omega8c}$, $C_{16:1\ \omega7c}$, $C_{16:1\ \omega5c}$, $C_{16:1\ \omega5t}$, and $C_{16:0}$. Ubiquinone-8 (Q-8)** is the predominant lipoquinone. Isolated from sediments of freshwater lakes and rivers, wetland muds, agricultural and swampy soils, upper mixing layers of oceans, and estuarine waters. Belongs to the *Gammaproteobacteria* as part of the Order *Methylococcales*, Family *Methylococcaceae*.

The mol% G + C of the DNA is: 48–60.

Type species: **Methylomicrobium agile** (Bowman, Sly, Nichols and Hayward 1993b) Bowman, Sly and Stackebrandt 1995, 183 (*Methylobacter agilis* Bowman, Sly, Nichols and Hayward 1993b, 749.)

FURTHER DESCRIPTIVE INFORMATION

Morphology and ultrastructure Cells of *Methylomicrobium* species are regular short rods, 0.5–1.5 × 1.5–2.5 µm, occurring singly or in pairs. There is no propensity to form chains or rosettes. All species are actively motile by means of single polar flagellum. Cell walls are of the standard Gram-negative type and are surrounded by a thin slime capsule. Cells contain type I intracytoplasmic membranes typical for other members of the family *Methylococcaceae* but do not form glucan-containing cysts. Most strains contain poly-β-hydroxybutyrate and polyphosphate granules. Cells are not heat or desiccation-resistant and are somewhat sensitive to methane starvation, losing viability in only a few days when exposed to a methane-free atmosphere.

Lipopolysaccharide The carbohydrate fraction of the outer membrane lipopolysaccharide in *Methylomicrobium album* includes D-glucose, L-fucose, and D-heptose (Sutherland and Kennedy, 1986). The hydroxy fatty acids from the lipopolysaccharide fraction of cell material of *Methylomicrobium album* and *Methylomicrobium agile* (Bowman et al., 1991a) are predominantly composed of $C_{16:0\ 3OH}$.

Cultural features *Methylomicrobium* strains form an even turbidity in NMS liquid media without pellicle formation—a trait that is much more prevalent in *Methylomonas* and *Methylococcus* species. On agar, colonies are uniformly circular and convex, with entire edges, possessing a creamy consistency, and reaching a diameter of 1–2 mm after 7–14 days under a methane/air (1:1, v/v) atmosphere. Colonies are nonpigmented, with a translucent to opaque appearance, and no diffusible pigments are formed. *Methylomicrobium* species are mesophilic, growing at 10–30°C. *Methylomicrobium agile* and *Methylomicrobium album* grow best at 25–30°C, while *Methylomicrobium pelagicum* grows optimally at about 20–25°C. The pH range for growth ranges from 6.0–9.0, with optimal growth occurring at about pH 7.0. Neither *Methylomicrobium agile* nor *Methylomicrobium album* requires growth factors, and both are nonhalophilic. The marine species *Methylomicrobium pelagicum* grows optimally in media containing either natural or artificial seawater (Sieburth et al., 1987).

Nutrition and metabolism *Methylomicrobium* strains are strictly aerobic methanotrophs, with carbon and energy substrates limited to methane and some other C_1 compounds; however, one strain of *Methylomicrobium agile* has the capacity utilize methylamine, dimethylamine, and trimethylamine (the type strain of *M. agile* can use only methylamine). No strains have been demonstrated to grow on carbon–carbon bonded compounds. Upon isolation, most *Methylomicrobium* strains are able to tolerate methanol and grow quite well on it. Methane appears to be oxidized predominantly by a particulate methane monooxygenase. The presence of soluble methane monooxygenase has not been demonstrated in *Methylomicrobium* strains so far (Stainthorpe et al., 1991). Formaldehyde is fixed by the ribulose monophosphate pathway, and key enzymes for the serine pathway, as well as ribulose-1,5-diphosphate carboxylase activity, are absent. *Methylomicrobium* species can utilize nitrate and ammonia salts, yeast extract, Casamino acids, and various amino acids as nitrogen sources, although high levels (>0.5% w/v) of complex organic compounds are inhibitory to growth. Urease and nitrogen fixation activities are absent.

Fatty acid composition Fatty acid profiles of *Methylomicrobium* species have been found to all be quite similar, with the predominant fatty acids including $C_{16:1\ \omega 5c}$, $C_{16:1\ \omega 5t}$, $C_{16:1\ \omega 8c}$, $C_{16:1\ \omega 7c}$, and $C_{16:0}$ being the most abundant components (Table BXII.γ.68 of the chapter describing the family *Methylococcaceae*) (Bowman et al., 1991a). The low level of $C_{14:0}$ and abundance of $C_{16:1\ \omega 5t}$ and $C_{16:1\ \omega 8c}$ distinguish *Methylomicrobium* from *Methylobacter* and *Methylomonas* species. The high level of the *trans* fatty acid $C_{16:1\ \omega 5t}$ is unusual and does not appear to be due to stressful cultivation conditions. The primary respiratory lipoquinone has been found to be ubiquinone-8 (Q-8) (Collins and Green, 1985).

Ecology The ecology and distribution of *Methylomicrobium* species is generally unknown. Indirect immunofluorescence studies indicate that *Methylomicrobium pelagicum* appears to be the dominant methanotrophic inhabitant of the upper mixing layers of ocean waters but is significantly less common in estuarine waters (Sieburth et al., 1993).

Enrichment and Isolation Procedures

The enrichment and isolation approach described for the genus *Methylomicrobium* can be applied for *Methylobacter* strains, provided that the incubation temperature is lowered to 20–30°C. The salt composition and pH of the media should closely reflect the habitat being investigated. For isolation of *Methylomicrobium pelagicum*, cycloheximide should be added to media to eliminate predation of cells by protozoa (Sieburth et al., 1987).

Maintenance Procedures

Methods for maintenance are the same as those described for the genus *Methylococcus*.

Differentiation of the genus *Methylomicrobium* from other genera

Phenotypic, chemotaxonomic, and genotypic properties differentiating *Methylomicrobium* from other type I methanotrophs are shown in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Taxonomic Comments

Phylogenetic analysis using 16S rDNA sequences indicates that *Methylomicrobium* forms a tight cluster within the *Gammaproteobacteria* and is part of a larger phylogenetic cluster that includes *Methylosphaera*, *Methylobacter*, *Methylomonas*, and methanotrophic mytilid endosymbionts. The genus is most closely related to *Methylobacter* and *Methylomonas* (evolutionary distance 0.04–0.06) (Bowman et al., 1995).

DNA–DNA hybridization analysis indicates that the three known *Methylomicrobium* species are genotypically distinct, with only relatively low levels of hybridization occurring between the species (Bowman et al., 1993b).

Differentiation of the species of the genus *Methylomicrobium*

Phenotypic and genotypic characteristics differentiating the species of *Methylomicrobium* are shown in Table BXII.γ.73 and additional characteristics are shown in Table BXII.γ.74.

List of species of the genus Methylomicrobium

1. **Methylomicrobium agile** Bowman, Sly, Nichols and Hayward 1993b) Bowman, Sly and Stackebrandt 1995, 183[VP] (*Methylobacter agilis* Bowman, Sly, Nichols and Hayward 1993b, 749.)

   a′gi.le. L. adj. *agilis* agile, nimble.

   Characteristics are as described for the genus and as listed in Tables BXII.γ.73 and BXII.γ.74. For further descriptive information, see Bowman et al. (1993b).

   Optimum temperature, 25–30°C range, 10–37°C. pH optimum, ~7.0; range, 6.0–9.0.

   Isolated from freshwater sediments and swampy soil.

[b]Phenotypic data from Bowman et al. (1993b).

The mol% G + C of the DNA is: 58.1–59.6 (T_m).

Type strain: A30, ACM 3308, ATCC 35068, NCIMB 11124.

GenBank accession number (16S rRNA): X72767.

2. **Methylomicrobium album** (Bowman, Sly, Nichols and Hayward 1993b) Bowman, Sly and Stackebrandt 1995, 184[VP] (*Methylobacter albus* Bowman, Sly, Nichols and Hayward 1993b, 749.)
al′bum. L. adj. *album* white.

Characteristics are as described for the genus and as listed in Tables BXII.γ.73 and BXII.γ.74. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature, 25–30°C; range, 10–37°C. pH optimum, ~7.0; range, 6.0–9.0.

Isolated from freshwater sediments and swampy soil.

The mol% G + C of the DNA is: 54.4–56.1 (T_m).

Type strain: ACM 3314; IMET 10526, NCIMB 11123, VKM-BG8.

GenBank accession number (16S rRNA): X72777.

3. **Methylomicrobium pelagicum** (Sieburth, Johnson, Eberhardt, Sieracki, Lidstrom and Laux 1987) Bowman, Sly and Stackebrandt 1995, 184[VP] (*Methylomonas pelagica* Sieburth, Johnson, Eberhardt, Sieracki, Lidstrom and Laux 1987, 291; *Methylobacter pelagicus* Bowman, Sly, Nichols and Hayward 1993b, 749.)
pe.la′gi.cum. L. adj. *pelagicus* belonging to the sea.

Characteristics are as described for the genus and as listed in Tables BXII.γ.73 and BXII.γ.74. Requires seawater for optimal growth. For further descriptive information, see Sieburth et al. (1987) and Bowman et al. (1993b).

Optimum temperature, ~20–25°C; range, 10–30°C. pH optimum, ~7.0; range, 6.0–8.5. Isolated from the upper mixing zone of oceans and, to a lesser extent, from estuarine waters.

The mol% G + C of the DNA is: 48.5 (T_m).

Type strain: AA-23, ACM 3505, NCIMB 2265.

GenBank accession number (16S rRNA): X72775.

Genus V. **Methylomonas** *Whittenbury and Krieg 1984b, 355^{VP} (Effective publication: Whittenbury and Krieg 1984a, 260) emend. Bowman, Sly, Nichols and Hayward 1993b, 746.*

JOHN P. BOWMAN

Me.thy.lo.mo' nas. Fr. n. *méthyle* the methyl radical; Gr. n. *monas* unit; M.L. n. *Methylomonas* methyl monad or methyl unit.

Straight or slightly curved rods 0.5–1.0 × 1.0–4.0 μm, occurring singly or in pairs. Form a polysaccharide-containing **cyst** that is desiccation sensitive. Poly-β-hydroxybutyrate granules usually present. **Motile** by means of a single polar flagellum. **Gram negative. Have a strictly aerobic respiratory metabolism**, with oxygen as the electron acceptor. **Obligate utilizers of methane and methanol for carbon and energy.** No growth occurs on carbon–carbon bonded compounds. Fix formaldehyde by the **ribulose monophosphate pathway**. Ribulose-1,5-diphosphate carboxylase activity is absent. Some species fix atmospheric nitrogen via an oxygen-sensitive nitrogenase. Form **red, pink, and orange carotenoid non-water soluble pigments**. **Mesophilic**, growing between 10–40°C, optimal growth temperatures 25–30°C. Non-halophilic. Major fatty acids **include $C_{14:0}$ and $C_{16:1\ \omega 8c}$. 18-Methyleneubiquinone-8 (MQ-8)** is the predominant lipoquinone. Habitat: Isolated from sediments of freshwater lakes and rivers, wetland muds, activated sludge and wastewater, and coal mine drainage waters. Belongs to the *Gammaproteobacteria* as part of the Order *Methylococcales*, Family *Methylococcaceae*.

The mol% G + C of the DNA is: 50–59 (T_m).

Type species: **Methylomonas methanica** Whittenbury and Krieg 1984b, 355 (Effective publication: Whittenbury and Krieg 1984a, 260.)

FURTHER DESCRIPTIVE INFORMATION

Morphology and ultrastructure The cells of *Methylomonas* species are regularly shaped rods that are either straight or slightly curved and are occasionally branched. Cells occur singly, in pairs, and sometimes as chains. All species are motile by single, unsheathed, polar flagellum. Cell walls are of the standard Gram-negative type, and well-defined slime capsules occur. *Methylomonas* species contain standard type I intracytoplasmic membranes (see Fig. BXII.γ.102 in the description of the order *Methylococcales*), and cells contain simple, single-bodied cysts similar to, but less poorly defined than, those typically observed in *Azotobacter chroococcum*. The cysts are similar to those observed in *Methylococcus* species and do not confer either desiccation or heat resistance. Most strains possess short shelf lives, dying off within a matter of days when lacking methane.

Lipopolysaccharides The hydroxy fatty acids from the outer membrane lipopolysaccharide have been analyzed in detail in *Methylomonas methanica*, *Methylomonas fodinarum*, and *Methylomonas aurantiaca* (Bowman et al., 1991a). The major component hydroxy fatty acid detected was $C_{16:0\ 3OH}$. Smaller proportions of $C_{12:0\ 3OH}$, $C_{13:0\ iso\ 3OH}$, and $C_{14:0\ 2OH}$ are also present, though their levels vary considerably between the species.

Cultural features In static liquid cultures, growth is usually restricted to a surface pellicle, which is pink-red or orange in color. On agar, *Methylomonas methanica* forms bright pink colonies that are circular, entire or lobate-edged, and butyrous in consistency, and that reach a diameter of 1–2 mm in diameter after 2 weeks under a methane/air atmosphere. The colonies of *Methylomonas fodinarum* are similar except that they have a bright orange color. The colonies of *Methylomonas aurantiaca* are larger, orange-pigmented, circular to irregular in shape, and possess a raised convex elevation and a mucoid–viscid or cartilaginous consistency. Strains of *Methylomonas methanica* and *Methylomonas aurantiaca* often segregate into rough and smooth colonial variants, and the rough colonies usually have a somewhat cartilaginous consistency. Pigments formed by *Methylomonas* species are carotenoid in nature, lacking solubility in water but readily extractable in chloroform and acetone (Bowman et al., 1990a). Preliminary HPLC analysis of the pigments of *Methylomonas fodinarum* ACM 3268 shows the presence of as many as 24 different carotenoid components (S. Liaaen-Jensen, personal communication). *Methylomonas methanica* has been reported to form blue diffusible pigments when grown on iron deficient agar media (Whittenbury et al., 1970b).

All *Methylomonas* species have a mesophilic and nonhalophilic ecophysiology and do not require growth factors. Growth occurs between 10°C and 42°C. *Methylomonas fodinarum* strains have a temperature optimum of approximately 25–30°C. The temperature optima of *Methylomonas methanica* and *Methylomonas aurantiaca* range from 30–35°C. The pH range is 5.5–8.5, and best growth occurs at approximately pH 7.0.

Nutrition and metabolism *Methylomonas* species are obligate methanotrophs, with their sole carbon and energy sources restricted to methane and methanol. *Methylomonas aurantiaca* strains, however, can also utilize methylamine and, in some cases, dimethylamine. Other C_1 compounds are not utilized; these include formate, trimethylamine, and trimethylamine N-oxide. Methane is oxidized by a particulate methane monooxygenase; however, two *Methylomonas methanica* strains have been found to contain soluble methane monooxygenase (Koh et al., 1993; Shen et al., 1997). The ribulose monophosphate pathway is clearly the major route for fixation of formaldehyde, although *Methylomonas* strains may possess weak activity for α-hydroxypyruvate reductase, the key enzyme of the serine pathway. Ribulose-1,5-diphosphate carboxylase activity is absent, and isocitrate dehydrogenase activity is usually NAD-specific (Bowman et al., 1990a).

Nitrogen sources include nitrate, ammonia, yeast extract, Casamino acids, and various amino acids. The addition of complex nutrient sources, such as yeast extract, generally does not lead to growth stimulation and can be growth inhibitory at concentrations greater than 0.25% (w/v). Most *Methylomonas* strains are urease-positive and can use urea as a nitrogen source. *Methylomonas fodinarum* and *Methylomonas aurantiaca* are also able to fix atmospheric nitrogen by an oxygen-sensitive nitrogenase, whereas nitrogenase activity has been detected in only a few *Methylomonas methanica* strains. However, southern blot analysis has detected in several *Methylomonas methanica* strains (including the type strain ATCC 35067) a gene homologous to *nifH*, with a size of approximately 9 kb (Oakley and Murrell, 1993).

Fatty acid composition Fatty acid profiles of *Methylomonas* species are similar to one another, with the fatty acids $C_{16:1\ \omega 8c}$, $C_{14:0}$, $C_{16:1\ \omega 7c}$, and $C_{16:1\ \omega 5t}$ being the most abundant components. The relatively high levels of $C_{14:0}$ and $C_{16:1\ \omega 8c}$ distinguish *Methylomonas* species from those of *Methylobacter* and *Methylomicrobium*. The primary respiratory lipoquinone has been found to be 18-methylene-ubiquinone-8 (MQ-8) (Collins and Green, 1985).

Ecology Knowledge of the specific ecology of *Methylomonas* species is currently limited. Indirect immunofluorescence studies suggest that *Methylomonas* species are common in surface sediments and the water columns of various fresh and brackish water environments and swampy soils (Reed and Dugan, 1978; Saralov et al., 1984; Malashenko et al., 1987; Gal'chenko et al., 1988). High populations of *Methylomonas methanica* are found in the littoral sediments of various subtropical rivers in Eastern Australia, with most probable number counts reaching 10^8–10^9 cells per gram of sediment. *Methylomonas aurantiaca* is extremely populous in activated sludge samples, while *Methylomonas fodinarum* is the most common methanotroph in Australian coal mine drainage water (Bowman, 1992).

Enrichment and Isolation Procedures

The enrichment and isolation approach described for the genus *Methylococcus* can also be applied for *Methylomonas* strains, provided that the incubation temperature is lowered to 20–30°C. The salt composition and pH of the media should closely reflect the habitat being investigated.

Maintenance Procedures

Methods for maintenance are the same as those given for the genus *Methylococcus*.

Differentiation of the genus *Methylomonas* from other genera

Phenotypic, chemotaxonomic, and genotypic properties differentiating *Methylomonas* from other type I methanotrophs are shown in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Taxonomic Comments

The genus *Methylomonas* previously contained several species that were either obviously misclassified or invalid owing to lack of descriptions, validation, and/or type strains. A number of these nomenclatural and taxonomic problems have been resolved. Several invalid species are now recognized as being synonymous with *Methylobacillus glycogenes* (Urakami and Komagata, 1986b); these include *"Methylomonas methylovora"* (Kuono et al., 1973), *"Methylomonas methanolica"*, *"Methylomonas espexii"*, *"Methylomonas methanocatalesslica"*, and *"Methylomonas methanofructolica"* (Urakami and Komagata, 1986a). *"Methylomonas clara"* (Faust et al., 1977) is synonymous with *Methylophilus methylotrophus* (Jenkins et al., 1987). All of these species are restricted methylotrophs utilizing methanol and methylamine as primary carbon and energy sources but without the capacity to utilize methane. *"Methylomonas methaninitrificans"* (Davis et al., 1964) Leadbetter 1974b, 269 and *"Methylomonas methanooxidans"* (Brown and Strawinski, 1958) Leadbetter 1974b, 269 in all probability are synonymous with the genus *Methylosinus* (Whittenbury et al., 1970a, 1970b), based on nitrogen fixing ability and morphology; however, this cannot be verified because no representative strains are extant. The species *"Methylomonas margaritae"* Takeda, Motomatsu, Hachiya, Fukuoka and Takahara 1974, 795 and *"Methylomonas flagellata"* Morinaga, Yamanaha, Otsuka and Hirose 1976, 1544 possess traits similar to *Methylomicrobium agile* or *Methylomicrobium album*, but there are no extant cultures of either species. The species *"Methylomonas gracilis"* Romanovskaya, Malashenko and Bogachenko 1978, 122 is synonymous with *Methylococcus thermophilus* (see comments for the genus *Methylococcus*).

Phylogenetic analysis using 16S rDNA sequences indicates that *Methylomonas* forms a relatively tight cluster within the *Gammaproteobacteria* and is part of a larger phylogenetic cluster that includes *Methylosphaera*, *Methylobacter*, *Methylomicrobium*, and methanotrophic mytilid endosymbionts. The genus is most closely related to *Methylobacter* and *Methylomicrobium* (evolutionary distance 0.05–0.06) (Bratina et al., 1992; Bowman et al., 1995).

The mol% G + C of the DNA of *Methylomonas* cover a relatively broad range of 50–59 (T_m), much like those for *Methylomonas* and *Methylobacter* (Table BXII.γ.75). DNA–DNA hybridization analysis has found the three valid *Methylomonas* species to be genotypically distinct; however, significant DNA homology (30–50%) is present between *Methylomonas fodinarum* and *Methylomonas aurantiaca*. This corresponds with the high level of phylogenetic similarity shared by these species (See Fig. BXII.γ.103 in the description of the order *Methylococcales*.). *Methylomonas methanica* is more distinct, sharing less than 25% DNA homology with its sister species. Very high levels of homology are present between *Methylomonas methanica* and *"Methylomonas rubra"*, indicating that *"Methylomonas rubra"* is a junior subjective synonym of *Methylomonas methanica*. This result agrees with the high levels of phenotypic similarity that these species share (Bowman et al., 1990a; 1993b). Phylogenetic analysis, however, indicates that *Methylomonas methanica* is somewhat distinct from other *Methylomonas* species (evolutionary distance 0.03–0.04) (Bratina et al., 1992). The genotypic relationship of *"Methylomonas rubra"* to *Methylomonas methanica* requires further verification.

Differentiation of the species of the genus *Methylomonas*

Phenotypic and genotypic characteristics differentiating the species of *Methylomonas* are shown in Table BXII.γ.75 and additional characteristics are shown in Table BXII.γ.76.

TABLE BXII.γ.75. Characteristics differentiating the species of the genus *Methylomonas*[a,b]

List of species of the genus Methylomonas

1. **Methylomonas methanica** Whittenbury and Krieg 1984b, 355[VP] (Effective publication: Whittenbury and Krieg 1984a, 260.)

me.tha′ ni.ca. M.L. adj. *methanica* related to or associated with methane.

Cells are motile rods. Gram negative. Characteristics are as described for the genus and as listed in Tables BXII.γ.75 and BXII.γ.76. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature, ~25–30°C; range, 10–37°C. pH optimum ~7.0; range, 5.5–9.0.

Isolated from freshwater sediment, lake and pond water, and swampy soil.

The mol% G + C of the DNA is: 50.6–54.0 (T_m).

Type strain: ACM 3307, ATCC 35067, IMET 10543, NCIMB 11130.

GenBank accession number (16S rRNA): AF304196.

2. **Methylomonas aurantiaca** Bowman, Cox, Sly and Hayward 1990b, 470[VP] (Effective publication: Bowman, Cox, Sly and Hayward 1990a, 285.)

au.ran.ti′ a.ca. M.L. adj. *aurantiacus* orange-colored.

Cells are motile rods. Gram negative. Characteristics are as described for the genus and as listed in Tables BXII.γ.75 and BXII.γ.76. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature, ~30–35°C; range, 10–40°C. pH optimum, ~7.0; range, 5.0–9.0.

Isolated from activated sludge, wastewater and swampy soil.

The mol% G + C of the DNA is: 57.6–59.1 (T_m).

Type strain: JB103, UQM 3406.

GenBank accession number (16S rRNA): X72776.

3. **Methylomonas fodinarum** Bowman, Cox, Sly and Hayward 1990b, 470[VP] (Effective publication: Bowman, Cox, Sly and Hayward 1990a, 283.)

fo.di.na′ rum. M.L. n. *fodinarum* of coal mine.

Cells are motile rods. Gram negative. Characteristics are as described for the genus and as listed in Tables BXII.γ.75 and BXII.γ.76. For further descriptive information, see Bowman et al. (1993b).

Optimum temperature, ~25–30°C; range, 10–35°C. pH optimum ~7.0; range, 5.5–9.0.

Isolated from coal mine drainage water and freshwater sediments.

The mol% G + C of the DNA is: 55.3–57.6 (T_m).

Type strain: LD2, UQM 3268.

GenBank accession number (16S rRNA): X72778.

4. **Methylomonas scandinavica** Khalyuzhnaya, Khmelenina, Kotelnikova, Holmquist, Pedersen and Trotsenko 2000, 949[VP] (Effective publication: Khalyuzhnaya, Khmelenina, Kotelnikova, Holmquist, Pedersen and Trotsenko 1999, 571[VP]

Cells are motile rods which are single or which form short chains. Gram negative. Single polar flagellum. Colonies are pigmented pink. Carbon sources include only methane and methanol metabolized using the RuMP pathway. Use ammonia and nitrate as nitrogen sources via the glutamate cycle and by reductive amination of pyruvate and 2-oxoglutarate. Optimum temperature, ~17°C; range 5–30°C. pH optimum 6.8–7.6; range 5.0–9.0. Generation time

for growth is about 15 h. Nonhalophilic. Cells contain phosphatidylglycerol and phosphatidylethanolamine but not cardiolipin. Major lipoquinone is MQ-8. Isolated from groundwater of the Äspö Hard Rock Laboratory tunnel, southeastern Sweden.

The mol% G + C of the DNA is: 53.8 (T_m).

Type strain: SR-5, VKM B-2140.

GenBank accession number (16S rRNA): AJ131369.

Species Incertae Sedis

1. **"Methylomonas margaritae"** Takeda, Motomatsu, Hachiya, Fukuoka and Takahara 1974, 795.
2. **"Methylomonas flagellata"** Morinaga, Yamanaha, Otsuka and Hirose 1976, 1544.
3. **"Methylomonas methaninitrificans"** (Davis, Coty and Stanley 1964) Leadbetter 1974b, 269 (*"Pseudomonas methaninitrificans"* Davis, Coty and Stanley 1964, 471.)

   "Methylomonas methaninitrificans" is probably a strain of the genus *Methylosinus*.
4. **"Methylomonas methanooxidans"** (Brown and Strawinski 1958) Leadbetter 1974b, 269 (*"Methanomonas methanooxidans"* Brown and Strawinski 1958.)

   "Methylomonas methanooxidans" is probably a strain of the genus *Methylosinus*.

Genus VI. Methylosarcina *Wise, McArthur and Shimkets 2001, 620*[VP]

The Editorial Board

Me.thyl.o.sar.ci′ na. N.L. neut. n. *methylum* the methyl group; L. fem. n. *sarcina* pack, bundle; N.L. fem. n. *Methylosarcina* methane-utilizing bundle of cells.

Gram-negative strictly aerobic short, coccoid, or fusiform rods. Form aggregates in slime layer or capsule. Catalase positive; oxidase negative. **Form cysts. Only carbon sources methane and methanol.** Major fatty acids include $C_{16:0}$, $C_{16:1\ \omega 8c}$, $C_{16:1\ \omega 7c}$, $C_{16:1\ \omega 5t}$.

The mol% G + C of the DNA is: 54.

Type species: **Methylosarcina fibrata** Wise, McArthur and Shimkets 2001, 620.

Further descriptive information

Cells of both species of *Methylosarcina* contain inclusion bodies and stacked membranes such as are found in other type I methanotrophs. *Methylosarcina fibrata* cells are often embedded in a fibrillar matrix. At the end of growth, cells of both species enlarge to produce cysts; these cysts do not survive pasteurization or drying for 7 d (Wise et al., 2001).

Both *Methylosarcina* species use only methane and methanol as carbon and energy sources; both use ammonia, nitrate, and a variety of organic nitrogen sources, and are unable to fix N_2. Both species reduce nitrate to nitrate but do not grow using nitrate as an electron acceptor and methane or methanol as the source of carbon and electrons under anaerobic conditions. Both possess the enzyme hexulose phosphate synthase of the ribulose monophosphate pathway for carbon assimilation and the *pmoA* gene for particulate methane monooxygenase (Wise et al., 2001).

Analysis of 16S rDNA sequences showed that the type strains of *Methylosarcina fibrata* and *Methylosarcina quisquiliarum* are most closely related to each other and form a cluster distinct from other type I methylotrophs. The *Methylosarcina* 16S sequences were most similar to those of *Methylobacter*. Analysis of partial *pmoA* sequences showed that the *Methylosarcina* sequences were most closely related to those of *Methylomicrobium album* (Wise et al., 1999, 2001).

Enrichment and Isolation Procedures

These methanotrophs were obtained from liquid enrichments of landfill soil serially diluted in varying concentrations of a mineral salts medium adjusted to different pH values and incubated under atmospheres of differing air/CH_4/CO_2 mixtures. They were isolated by streaking onto agar of the same composition. *Methylosarcina fibrata* was more common in acidic (pH 4.8) enrichments; *Methylosarcina quisquiliarum*, in enrichments at pH 6.8 (Wise et al., 1999).

Differentiation of the genus *Methylosarcina* from other genera

Wise et al. (2001) provide a comparison of the fatty acid profiles of the type strains of *Methylosarcina fibrata* and *Methylosarcina quisquiliarum* with those of members of the genera *Methylomonas*, *Methylobacter*, *Methylomicrobium*, and *Methylococcus*.

List of species of the genus Methylosarcina

1. **Methylosarcina fibrata** Wise, McArthur and Shimkets 2001, 620[VP]

   fi.bra′ ta. L. fem. adj. *fibra* a fiber or filament; M.L. fem. adj. *fibrata* covered with fibers or fibrils.

   Description as for the genus with the following additional characteristics. Cells coccoid (diameter 0.8–1.5 μm). Form packets. Single cells, diplococci, and tetrads may be motile. Fibrils on cell surface.

   The mol% G + C of the DNA is: 54.1 ± 0.2 (HPLC).

   Type strain: AML-C10, ATCC 700909, DSM 13736.

   GenBank accession number (16S rRNA): AF177296.

2. **Methylosarcina quisquiliarum** Wise, McArthur and Shimkets 2001, 620[VP]

   quis.qui.li.a′ rum. L. pl. fem. n. *quisquiliae* rubbish, trash, or refuse; L. gen. pl. fem. n. *quisquiliarum* of rubbish, trash, etc., denoting strains that were isolated from a landfill site.

   Description as for the genus with the following additional characteristics. Cells pleomorphic: ovoid, fusiform, or rods (1 × 1–6 μm). Coccoid cells occur in packets. No fibrils on cell surface.

   The mol% G + C of the DNA is: 54.3 ± 0.3 (HPLC).

   Type strain: AML-D4, ATCC 700908, DSM 13737.

   GenBank accession number (16S rRNA): AF177297.

Genus VII. **Methylosphaera** *Bowman, McCammon and Skerratt 1998d, 327[AL] (Effective publication: Bowman, McCammon and Skerratt 1997c, 1457)*

JOHN P. BOWMAN

Me.thy.lo.sphae' ra. Fr. n. *méthyle* the methyl radical; Gr. n. *spaira* sphere; M.L. n. *Methylosphaera* methyl sphere.

Cells are spherical, 1.5–2.0 μm in diameter. Occur singly or in pairs. Cysts or other differentiated **resting stages are not formed**. **Gas vesicles present**. Poly-β-hydroxybutyrate granules present. **Gram negative. Nonmotile. Nonpigmented. Strictly aerobic respiratory metabolism**, with oxygen as the electron acceptor. **Obligate utilizer of methane and methanol for carbon and energy.** Carbon–carbon bonded compounds are not utilized. Oxidase and catalase positive. The **ribulose monophosphate pathway** is used to fix formaldehyde for cell carbon. Key enzyme activity of the serine transhydroxymethylase pathway is absent. Nitrate, ammonium salts, and L-glutamine are used as nitrogen sources. Nitrate is reduced to nitrate. **Fix atmospheric nitrogen.** Ribulose-1,5-diphosphate carboxylase activity is not present. **Psychrophilic**, growing at −2–20°C with an optimal temperature range of 10–15°C. **No growth occurs on solid agar media. Seawater salts are required for optimal growth.** Major fatty acids include $\mathbf{C_{16:0}}$, $\mathbf{C_{16:1\ \omega 8c}}$, $\mathbf{C_{16:1\ \omega 7c}}$, **and** $\mathbf{C_{16:1\ \omega 6c}}$. Habitat: Isolated from hypolimnetic and benthic zones of an Antarctic meromictic lake of marine salinity. Belongs to the *Gammaproteobacteria* as part of the Order *Methylococcales*, Family *Methylococcaceae*.

The mol% G + C of the DNA is: 43–46 (T_m).

Type species: **Methylosphaera hansonii** Bowman, McCammon and Skerratt 1998d, 327 (Effective publication: Bowman, McCammon and Skerratt 1997c, 1457.)

FURTHER DESCRIPTIVE INFORMATION

Morphology and ultrastructure During all phases of growth *Methylosphaera hansonii* strains appear as featureless spherical cells that exhibit varying degrees of refractility under phase contrast microscopy. Although cells show signs of uneven binary division, evidence for budding division is still lacking. Cells possess cell walls of the standard Gram-negative type and possess type I intracytoplasmic membranes when grown under methane but not methanol. Strains are nonmotile and possess no flagella. They also do not form cysts or other types of resting stages typically found in other methanotrophic bacteria. Thus, *M. hansonii* cells have no desiccation or heat resistance and die rapidly in the absence of methane or methanol substrate. A strong accumulation of poly-β-hydroxybutyrate may occur in some cells. Preliminary electron microscopic examination indicates the occurrence of gas vesicles 0.05–0.1 × 0.2 μm (Bowman et al., 1997c; Bowman, unpublished data.).

Cultivation *M. hansonii* can be grown in nitrate mineral salts media supplemented with natural or artificial seawater salts. Strangely, strains exhibit no growth on solid agar media including those with high purity agars at relatively low concentrations. Agars tested included Bacto-agar (Difco), noble agar, agarose type V, and low melting point agarose at concentrations of 0.3–1.5% (w/v). This inability to grow on agar media has been previously observed with unidentified type I methylotrophs isolated from seawater off the British Isles (Lees et al., 1991). Those strains, however, were able to grow on semisolid noble agar whereas *M. hansonii* does not. When growing in statically incubated liquid media, *M. hansonii* forms a white turbidity with a distinct layer of sediment. It requires seawater for growth, with growth occurring only at 0.25–1.5× strength seawater salts. Poor growth occurs if only NaCl, rather than seawater, is provided, implying that strains require additional components found in seawater, although these components have yet been identified. All strains are psychrophilic, with optimum and maximum growth temperatures varying slightly between strains. Optimal growth occurs at 10–15°C; no growth occurs at 25°C. A doubling time of 20–24 h has been determined for strains growing at or close to their optimum temperature. In NMS–seawater liquid media, growth occurs between pH 6.0–8.0, and the optimum pH is approximately 7.5.

Nutritional and metabolic features *M. hansonii* is metabolically specialized, with only methane and methanol serving as suitable sources of carbon and energy. Methane monooxygenase activity appears to be restricted to the particulate (pMMO) form. No putative sMMO activity has been detected with the naphthalene oxidation assay. That this species lacks sMMO activity is supported by the fact that strains grow very poorly in media lacking copper. Growth on methanol (at 0.1%, v/v) is slower than that on methane but results in similar growth yields. However, no growth has been found to occur on a range of other C_1 compounds, including formate, formamide, methylamine, dimethylamine, trimethylamine, and trimethylamine *N*-oxide. Strains use the ribulose monophosphate pathway to fix formaldehyde for cell carbon, as demonstrated by the presence of hexulose-6-phosphate synthase activity. However, activity of α-hydroxypyruvate reductase, a key enzyme of the serine pathway, is absent. Ribulose-1,5-diphosphate carboxylase activity is also absent. Growth is strictly aerobic, and no growth occurs anaerobically in the presence of an alternative electron acceptor, such as nitrate or ferric chloride.

Strains utilize nitrate, ammonia and L-glutamine for nitrogen. L-Glutamine also stimulates growth yield and growth rate. More complex sources of nitrogen, such as yeast extract or Casamino acids (Difco), are less suitable, causing partial inhibition of growth when tested at 0.05–0.1% (w/v) and complete inhibition of growth at concentrations of 0.25–0.5% (w/v). Urease is not formed, and urea does not serve as a nitrogen source. Nitrogen fixation occurs and is not quite as oxygen sensitive as in other methanotrophs; at an oxygen level of about 10% (v/v), nitrogen fixation occurs in *Methylosphaera hansonii* but is substantially inhibited or abolished in *Methylosinus trichosporium* and *Methylococcus capsulatus* (Murrell and Dalton, 1983; Zhivotchenko et al., 1995b).

Genetic features The DNA base composition values of *Methylosphaera hansonii* are the lowest among the known methanotrophs, with a range of 43–46 mol% G + C. The type strain ACAM 549 (AM6) has a mol% G + C of 44.8.

Ecology Little is known about the ecology of *Methylosphaera*. Populations are known to become concentrated in the surface benthic sediments and the oxygen gradient zones of sulfate-depleted, marine-salinity lakes (Ace Lake and Burton Lake) found in the Vestfold Hills area of Eastern Antarctica. The waters of these lakes have an average annual temperature of about 2°C.

The distribution of *Methylosphaera hansonii* outside of these lakes is unknown; however, the Vestfold Hills lakes are of recent origin (8000–10000 years old), formed from a marine uplift (Franzmann, 1996) that followed the retreat of the ice sheet after the last ice age. This leads to the hypothesis that *Methylosphaera hansonii* may also be common in Antarctic coastal sediments.

Enrichment and Isolation Procedures

Low temperature marine sediments and hypolimnetic zones of polar marine-salinity lakes (and possibly coastal marine zones) are the best sites for isolation of *Methylosphaera* strains. Enrichment is performed in mineral salts media prepared in serum vials with either natural or artificial seawater. A headspace of 1:1 methane/air is created and the vials incubated at 2–4°C. After 3–4 weeks, a white turbidity forms that is accompanied by white sedimented material. *Methylosphaera hansonii* enrichments contain a high population of nonmethanotrophic, usually methylotrophic, co-contaminants. Known strains of *Methylosphaera* cannot be grown on solid agar and, consequently, the isolation procedure described for most methanotrophs (see enrichment and isolation details for the genus *Methylococcus*) is not possible. Isolation can be achieved by serially diluting enrichments to extinction in 96-well plastic microtiter trays (Bowman et al., 1997c) containing NMS seawater liquid media and incubated in containers containing 1:1 methane/air. Several strains may be purified in the same tray simultaneously. After sufficient incubation, the wells containing the highest dilutions that show growth are examined by microscopy. A number of separate transfers may be required to eventually obtain morphologically homogenous cultures.

Maintenance Procedures

Long term preservation of *Methylosphaera hansonii* is currently problematic. The best procedure is to keep strains in serum vials with NMS seawater media under a methane/air atmosphere held at about 2°C, periodically subculturing them. Viability is rapidly lost following freezing, including snap freezing in liquid nitrogen.

Differentiation of the genus *Methylosphaera* from other genera

Phenotypic, genotypic, and chemotaxonomic traits that differentiate *Methylosphaera* from other type I methanotrophs are shown in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Taxonomic Comments

16S rDNA based phylogenetic analysis indicates that *Methylosphaera hansonii* forms a separate branch at the periphery of the cluster of type I methanotrophs that includes the genera *Methylobacter*, *Methylomicrobium*, and *Methylomonas*. The closest relatives are methanotrophic mytilid endosymbionts (evolutionary distance 0.09–0.10).

DNA–DNA hybridization analysis indicates that strains from different lake isolation sites are closely related, showing 65–100% hybridization with ACAM 549.

List of species of the genus Methylosphaera

1. **Methylosphaera hansonii** Bowman, McCammon and Skerratt 1998d, 327[VP] (Effective publication: Bowman, McCammon and Skerratt 1997c, 1457.)
han.son'i.i. M.L. gen. n. *hansonii* of Hanson, named after American microbiologist R.S. Hanson.

Cells are coccoidal and nonmotile. Colonies do not form on solid agar media. Liquid media cultures possess no pigment. Characteristics are as described for the genus and as listed in Tables BXII.γ.67 and BXII.γ.68 of the chapter describing the family *Methylococcaceae*.

Optimum temperature for growth, ~10–15°C; range, −2–20°C. pH range for growth, 6.0–8.5; optimum, ~7.5.

Known habitat includes certain Antarctic marine-salinity meromictic lakes.

The mol% G + C of the DNA is: 43.5–45.9 (T_m).

Type strain: AM6, ACAM 549.

GenBank accession number (16S rRNA): U67929.

Order VIII. **Oceanospirillales** *ord. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

O.ce.an.o.spi.ril.la' les. M.L. neut. n. *Oceanospirillum* type genus of the order; *-ales* ending to denote order; M.L. fem. n. *Oceanospirillales* the *Oceanospirillum* order.

The order *Oceanospirillales* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the order contains the families *Oceanospirillaceae*, *Alcanivoraceae*, *Hahellaceae*, *Halomonadaceae*, *Oleiphilaceae*, and *"Saccharospirillaceae"*.

Most genera halotolerant or halophilic. Motile except for *Alcanivorax*. Aerobic, microaerophilic, or facultatively anaerobic chemoorganotrophs.

Type genus: **Oceanospirillum** Hylemon, Wells, Krieg and Jannasch 1973, 361[AL].

The distribution of *Methylosphaera hansonii* outside of these lakes is unknown; however, the Vestfold Hills lakes are of recent origin (8000–10000 years old), formed from a marine uplift (Franzmann, 1996) that followed the retreat of the ice sheet after the last ice age. Most genera halotolerant or halophilic. Motile except for *Alcanivorax*. Aerobic, microaerophilic, or facultatively anaerobic chemoorganotrophs.

Type genus: **Oceanospirillum** Hylemon, Wells, Krieg and Jannasch 1973, 361[AL].

Family I. **Oceanospirillaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

O.ce.an.o.spi.ril.la′ ce.ae. M.L. neut. n. *Oceanospirillum* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Oceanospirillaceae* the *Oceanospirillum* family.

The family *Oceanospirillaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the family contains the genera *Oceanospirillum* (type genus), *Balneatrix*, *Marinomonas*, *Marinospirillum*, *Neptunomonas*, *Oceanobacter*, *Oleispira*, and *Pseudospirillum*. *Oceanobacter*, *Pseudospirillum* and *Oleispira* were proposed after the cut-off date for inclusion in this volume (June 30, 2001) and are not described here (see Satomi et al. (2002) and Yakimov et al. (2003a), respectively).

Motile by polar flagella. Aerobic; strictly respiratory except for *Neptunomonas*, which gives weak fermentation reactions. Aquatic; *Balneatrix* is found in fresh water, whereas other genera are marine.

Type genus: **Oceanospirillum** Hylemon, Wells, Krieg and Jannasch 1973, 361[AL].

Genus I. **Oceanospirillum** *Hylemon, Wells, Krieg and Jannasch 1973, 361[AL]**

Bruno Pot and Monique Gillis

O.ce.an.o.spi.ril′ lum. M.L. n. *oceanus* ocean; Gr. n. *spira* a spiral; M.L. dim. neut. n. *spirillum* spirillum a small spiral; *Oceanospirillum* a small spiral (organism) from the ocean (seawater).

Rigid, helical cells 0.4–1.2 µm in diameter. Motile by bipolar tufts of flagella. A polar membrane underlies the cytoplasmic membrane at the cell poles in all species so far examined by electron microscopy. **Intracellular poly-β-hydroxybutyrate is formed. All species form thin-walled coccoid bodies that predominate in old cultures.** Gram negative. **Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate respiration does not occur. Nitrate can be reduced to nitrite in all oceanospirilla. Optimum temperature for growth, 25–32°C. **Oxidase positive.** Indole and aryl sulfatase negative. Casein, starch, hippurate, and esculin are not hydrolyzed. **Seawater is required for growth. Carbohydrates are neither oxidized nor fermented.** Amino acids or the salts of organic acids serve as carbon sources. Growth factors are not usually required. Isolated from coastal seawater, decaying seaweed, and putrid infusions of marine mussels.

The mol% G + C of the DNA is: 45–50.

Type species: **Oceanospirillum linum** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973, 374 (*Spirillum linum* Williams and Rittenberg 1957, 82.)

Further descriptive information

All species of *Oceanospirillum* consist of helical cells; however, variants having less curvature may arise after prolonged transfer. For example, the type strain of *O. japonicum* consisted initially of long, helical cells with several turns (Watanabe, 1959), but now consists of slightly curved or S-shaped cells. The cells have a constant and characteristic type of clockwise (right-handed) helix. Only one phylogenetically unrelated species (*O. pusillum*) has a counterclockwise (left-handed) helix (Terasaki, 1972). Photographs showing the size and shape of various species of oceanospirilla and *O. minutulum* (now *Marinospirillum minutulum*) are presented in Fig. BXII.γ.104.

An unusual elaboration of the plasma membrane, the "polar membrane", occurs in all of the species so far examined (Beveridge and Murray, unpublished results). It is attached to the inside of the plasma membrane by bar-like links and is located, most commonly, in the region surrounding the polar flagella (Murray and Birch-Andersen, 1963). Such a membrane has been found mainly in genera of helical bacteria, such as *Spirillum*, *Campylobacter*, *Aquaspirillum*, *Ectothiorhodospira*, and *Rhodospirillum*.

All species have intracellular poly-β-hydroxybutyrate, but granules may not be evident in cells having a small diameter and chemical analysis may be required to demonstrate the polymer.

All species have bipolar tufts of flagella and all species show extensive formation of coccoid bodies (sometimes termed "microcysts") in old cultures. These bodies have thin walls and resemble spheroplasts; however, they are resistant to lysis in distilled water (Kelly, 1959). Whether coccoid bodies are resistant to desiccation is not known. Three main modes of formation of coccoid bodies were described by Williams and Rittenberg (1957), as follows: (a) two cells may entwine and apparently fuse. The cells become shorter and thicker and a protuberance develops at the point of fusion. This gradually enlarges and absorbs the organisms to form the coccoid body. More than one coccoid body may develop from a pair of entwined spirilla; (b) a spirillum may become shorter and thicker and a protuberance arises from the center of the cell or from each end of the cell. The protuberances enlarge and eventually merge into a single coccoid body as the helical cell is absorbed; (c) a spirillum may undergo a gradual shortening and rounding to form a coccoid body. The majority of coccoid bodies present in old cultures appears to be viable and can "germinate" when placed into a fresh medium (Williams and Rittenberg, 1956). Germination is by unipolar or bipolar growth of a helical cell from the coccoid body, with the latter being absorbed into the developing helical cell.

Seawater is required for the growth of all species. Media prepared with natural seawater or with 2.75% NaCl have been used for enrichment and isolation (Williams and Rittenberg, 1957; Terasaki, 1963, 1970, 1980). Commonly used culture media for

**Editorial Note:* The genus *Oceanospirillum* has recently undergone taxonomic reevaluation. *O. minutulum* has been transferred to the genus *Marinospirillum* as *Marinospirillum minutulum* (Satomi et al., 1998); see the Taxonomic Comments section in this chapter. *O. commune* and *O. vagum* are homotypic synonyms of *Marinomonas communis* and *Marinomonas vaga*, respectively. After the cut-off date for inclusion of taxonomic changes in this volume of the *Systematics*, Satomi et al. (2002) emended the description of *Oceanospirillum* and proposed the transfer of *O. jannaschii* to the genus *Marinobacterium* as *Marinobacterium jannaschii*, the transfer of *O. japonicum* to the new genus *Pseudospirillum* as *Pseudospirillum japonicum*, the transfer of *O. kriegii* to the new genus *Oceanobacter* as *Oceanobacter kriegii*, and the transfer of *O. pusillum* to the new genus *Terasakiella* as *Terasakiella pusilla*.

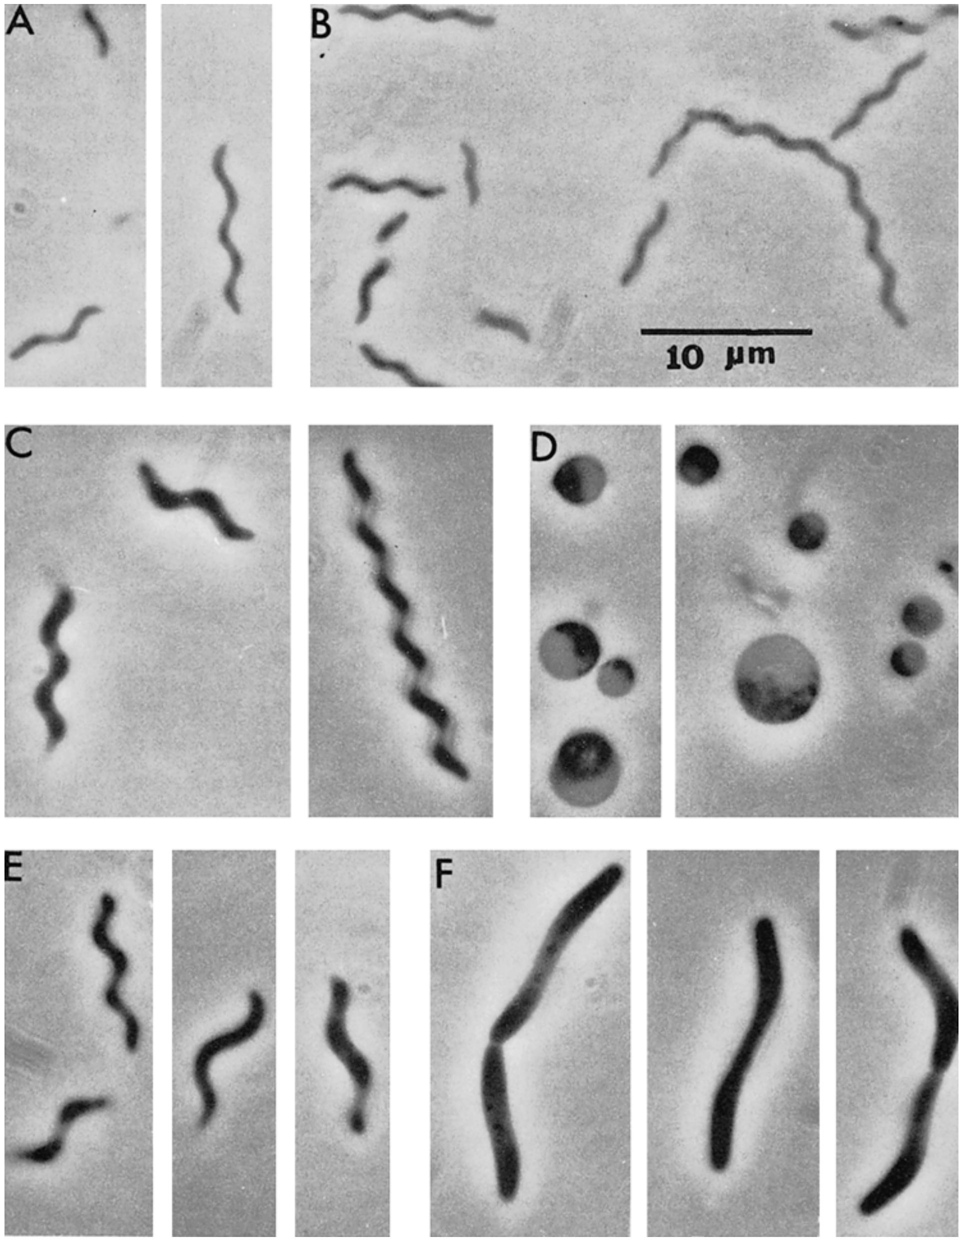

FIGURE BXII.γ.104. Phase contrast photomicrographs of several species of the genus *Oceanospirillum*. All photomicrographs were taken at the same magnification. *A*, *Marinospirillum minutulum* ATCC 19193. *B*, *O. linum* ATCC 11336. *C*, *O. maris* ATCC 27509. *D*, coccoid bodies of *O. maris* formed after 7 d of incubation. *E*, *O. beijerinckii* subsp. *beijerinckii* ATCC 12754. *F*, *O. japonicum* ATCC 19191. oceanospirilla are nutrient broth prepared with natural seawater and PSS, or MPSS broth[1] prepared with artificial seawater[2].

Oceanospirilla generally produce moderate to abundant, turbid growth in 2–3 d in PSS seawater broth (Hylemon et al., 1973). In seawater-nutrient broth, membranous masses are often formed at the surface and can be dispersed with shaking to yield turbid cultures (Terasaki, 1972).

Colonies of oceanospirilla generally develop within 2–3 d on PSS seawater agar and are usually white, circular, and convex, ranging from pinpoint to 1.5 mm in diameter (Hylemon et al., 1973). Colonies on seawater-nutrient agar are generally pinpoint in size at 48 h but become larger (up to 2.0 mm in diameter) at 7 d; they are usually convex or umbonate, glistening, opaque, pale yellow, and butyrous (Terasaki, 1972). Rough (R) colonies may arise on prolonged transfer; for example, the colonies of the type strain of *O. japonicum* are presently of the R type. Some species produce a water-soluble, yellow-green fluorescent pigment on PSS seawater agar.

Most species grow best at a temperature of 30–32°C; however, *O. maris* subsp. *hiroshimense* grows best at 25°C (Terasaki, 1972).

1. See the genus *Aquaspirillum* for recipes for these media.

2. Artificial sea water for use in PSS broth, g/l of distilled water: NaCl, 27.5; $MgCl_2$, 50; $MgSO_4$, 2.0; $CaCl_2$, 0.5; KCl, 1.0; and $FeSO_4$, 0.01.

The nutrition of oceanospirilla is generally simple. Most species grow in simple defined media with amino acids or the salts of organic acids as carbon sources and ammonium ions as the nitrogen source. However, *O. linum* is specifically stimulated by methionine in a medium containing succinate and malate as carbon sources, and *O. maris* subsp. *williamsae* has a growth factor requirement that has not yet been identified. A listing of the carbon sources for oceanospirilla is given below in Table BXII.γ.77. Some apparent contradictions occur between the results obtained from different laboratories, although the results within each laboratory are reproducible. These differences are likely attributable to differences in definitions of what constitutes a positive growth response, and in some cases to the use of different strains.

The use of antisera in agglutination tests with a limited number of strains has indicated that the species of *Oceanospirillum* can be distinguished serologically (McElroy and Krieg, 1972). The antisera were prepared against whole cells and adsorbed with heated cells, leaving only antibodies against thermolabile antigens.

Oceanospirilla have been isolated from coastal seawater (Williams and Rittenberg, 1957), decaying seaweed (Jannasch, 1963), and putrid infusions of marine mussels (Terasaki, 1963, 1970, 1980). By direct microscopic counts of the bacteria present in clear and turbid seawaters near Port Aransas, Texas, Oppenheimer and Jannasch (1962) found that spirilla comprised only 0.1–2.5% of the total bacteria present. Whether oceanospirilla occur in the open sea is not known. Based on chemostat experiments, Jannasch (1963) suggested that the growth of oceanospirilla might be restricted to environments of higher nutrient concentration than is found in ordinary seawater, such as in zones surrounding decaying particulate matter. With regard to occurrence of oceanospirilla in putrid infusions of marine mussels, the source is most likely marine mud adherent to the mussels (Terasaki, 1970).

Enrichment and Isolation Procedures

The enrichment and isolation method used by Williams and Rittenberg (1957) is as follows. A seawater sample is mixed with an equal volume of Giesberger's base medium (NH_4Cl, 0.1%; K_2HPO_4, 0.05%; $MgSO_4$, 0.05%) plus 1.0% calcium lactate. After incubation and appearance of spirilla, a portion of the initial culture is sterilized and mixed with an equal volume of sterile Giesberger's medium lacking NH_4Cl. This mixture is then inoculated from the unsterilized portion of the initial culture. One to three subcultures done in this manner are sufficient to establish the spirilla as the predominant type. For isolation, the enrichment is diluted 1:100 to 1:100,000 with sterile seawater. The dilution bottles are shaken vigorously and allowed to stand at room temperature for 20 min to allow migration of spirilla to the surface of the dilution. Isolation is then accomplished by streaking the surface water onto a suitable agar medium such as nutrient agar prepared with seawater and containing 0.3% yeast autolysate. Plates are incubated at 30°C and after 24 h examined for distinctive, granular, umbonate or pulvinate colonies with a ground-glass appearance.

The method of Terasaki (1970) has yielded excellent results for the isolation of oceanospirilla from putrid infusions. Marine mussels are smashed with a hammer and placed in a Petri dish with a teaspoon of marine mud. Sterilized seawater is poured into the dish until the mussels sink completely in the solution. The infusion is incubated at 27–28°C and examined for the development of spirilla after 1, 2, 4, and 7 d. Isolation is accomplished by streaking dilutions onto suitable agar media.

For enrichment by use of continuous cultures, see Jannasch (1967).

Maintenance Procedures

Oceanospirilla may be maintained in semisolid PSS seawater medium (containing 0.15% agar to give a jelly-like consistency) at 30°C with weekly transfer (Hylemon et al., 1973). Cultures may also be maintained as stabs in seawater-nutrient agar at room temperature with monthly transfer (Terasaki, 1972).

Preservation is most easily accomplished by suspending a dense concentration of cells in seawater-nutrient broth containing 10% (v/v) dimethylsulfoxide, with subsequent freezing in liquid nitrogen. A method for freeze-drying oceanospirilla has been reported by Terasaki (1975).

Procedures for Testing Special Characters

Characterization methods for oceanospirilla have been described in detail by Terasaki (1972, 1979) and Hylemon et al. (1973). The comments given in this *Manual* for the genus *Aquaspirillum* also apply to the genus *Oceanospirillum*, except that media containing natural or artificial seawater must be used for all characterization tests.

Differentiation of the genus *Oceanospirillum* from other genera

See the genus *Aquaspirillum*, in Volume 2 Part C in this *Manual*, for characteristics of *Oceanospirillum* that distinguish the genus from other morphologically or physiologically similar genera.

Taxonomic Comments

In the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Krieg, 1974), a single genus, *Spirillum*, contained all of the various aerobic and microaerophilic spirilla, including freshwater and marine species. However, the DNA base composition for the genus ranged from 38 to 65 mol% G + C and appeared to be unusually broad for a bacterial genus. Moreover, three groups were evident within the genus: (a) the aerobic, freshwater spirilla that could not tolerate 3% NaCl (mol% G + C 50–65); (b) the aerobic, marine spirilla that required seawater for growth (mol% G + C = 42–48); and (c) the large, microaerophilic spirilla that belong to the species *S. volutans* (mol% G + C = 38). Accordingly, Hylemon et al. (1973) divided the genus into the three genera *Spirillum*, *Aquaspirillum*, and *Oceanospirillum*, with the marine organisms comprising the latter genus. This subdivision was used in the first edition of *Bergey's Manual of Systematic Bacteriology* (Krieg, 1984a). Although this scheme proved useful for practical purposes, it was only gradually that the phylogenetic aspects of the three subdivisions were revealed.

In an analysis of the 16S rRNA oligonucleotide catalogs of the species *O. minutulum* (now *Marinospirillum minutulum*) and *Oceanospirillum maris*, Woese et al. (1982) found that both organisms belonged to group III of the phototrophic bacteria as defined by Gibson et al. (1979), but they were not closely related to each other. Later, Woese et al. (1985) studied three additional species of *Oceanospirillum*—*O. japonicum*, *O. linum*, and *O. beijerinckii*. These species, together with the families *Enterobacteriaceae* and *Vibrionaceae*, constituted the core of 'subgroup 3' of the *Gammaproteobacteria* (Stackebrandt et al., 1988).

An organism known as *"Spirillum lunatum"* (Williams and Rit-

[a]Method A (Hylemon et al., 1973): A turbidimetrically standardized cell suspension in synthetic seawater was inoculated into a defined, vitamin-free medium containing the carbon sources (0.1%) and ammonium sulfate as the nitrogen source. Growth responses were measured turbidimetrically after one 72-h serial transfer from the initial cultures, using a Klett colorimeter with the blue (420 nm) filter and 16-mm cuvettes. Symbols: +, 10 or more Klett units of turbidity for all strains tested; −, less than 10 Klett units of turbidity; d, differs among strains; nd, not determined.

[b]Method B (Terasaki, 1972, 1979): A cell suspension washed in basal, defined, vitamin-free medium (Williams and Rittenberg, 1957) containing natural seawater and lacking carbon sources. The cells were inoculated into similar media containing the test compounds (0.05%) and ammonium chloride as the nitrogen source. After 7 d, growth was estimated turbidimetrically. Symbols: +, a turbidity of 0.025 absorbance units or greater for all strains tested; −, a turbidity of less than 0.025; d, differs among strains; nd, not determined.

[c]Strain ATCC 12753 failed to grow with any sole carbon source, while strain ATCC 11336 grew only with acetate. Both strains grew abundantly when succinate plus malate were supplied as carbon sources and L-methionine as the nitrogen source.

[d]Strain OF3 (Terasaki, 1972, 1973) differs from the results given in the table in that it grows with a large veriety of sole carbon sources: citrate, succinate, fumarate, malate, pyruvate, lactate, acetate, propionate, and butyrate. Whether this strain should be included in the species *O. linum* is uncertain.

[e]The results are given for *O. maris* subsp. *maris*. *O. maris* subsp. *williamsae* fails to grow with any sole carbon (or sole nitrogen) source and, therefore, appears to have an auxotrophic growth requirement. This requirement has not yet been defined.

[f]As reported by Bowditch et al. (1984a).

tenberg, 1957) was included in the genus *Oceanospirillum* by Hylemon et al. (1973), but this posed taxonomic problems. The characteristics of the type strain (ATCC 11337 or NCMB 54) did not fit the original description of the species, and Linn and Krieg (1978) found that NCMB strain 54 consisted of a mixture of two dissimilar organisms. The first type was a short, vibrioid rod that possessed a single polar flagellum, grew in either the presence or absence of seawater, catabolized sugars, did not form coccoid bodies, and had a mol% G + C of 63–64. The second type was a larger, helical organism that possessed bipolar flagellar tufts, required seawater, failed to attack sugars, formed coccoid bodies, and had a mol% G + C of 45. The smaller organism did not appear to belong to either *Oceanospirillum* or *Aquaspirillum* and it remains unclassified. The larger organism had characteristics more in accord with the original description of *"S. lunatum"* but differed in certain respects; it has been classified as a new subspecies of *O. maris*: *O. maris* subsp. *williamsae*.

Bowditch et al. (1984a, b) added four species to the genus *Oceanospirillum*, mainly based on immunological relationships. These species were *Oceanospirillum commune*, for the organism previously named *Marinomonas communis* (Van Landschoot and De Ley, 1983, 1984), *Oceanospirillum vagum* for *Marinomonas vaga* (Van Landschoot and De Ley, 1983, 1984), and two species *Oceanospirillum jannaschii* and *Oceanospirillum kriegii* for two groups of unnamed marine bacteria I-1 and H-1, respectively. As a result, the genus definition of *Oceanospirillum* needed to be changed drastically, with the unfortunate loss of most of the readily determinable phenotypic features from the genus definition (Krieg, 1984a) and the extension of the upper mol% G + C limit for the genus from 51 to 57. By this extension, a considerable overlap of mol% G + C range was introduced between the genera *Aquaspirillum* (49–65 mol% G + C) and *Oceanospirillum* (42–51 mol% G + C). In this way, one of the most reliable genotypic features discriminating both genera was lost. Phylogenetic data (Pot et al. 1989, Pot, 1996; Satomi et al., 1998), however, have since shown that all four species cannot be regarded as members of the genus *Oceanospirillum*.

On the basis of a polyphasic approach including DNA–DNA and DNA–rRNA hybridizations, Pot et al. (1989) showed that only five species, including the type species, constituted a separate rRNA branch in the *Gammaproteobacteria* and redefined the genus *Oceanospirillum* to contain *O. linum*, *O. maris*, *O. beijerinckii*, *O. multiglobuliferum*, and, more distantly, *O. japonicum*. Based on DNA–DNA hybridizations (as suggested by Krieg, 1984a) and numerical comparison of whole-cell proteins, *O. maris* subsp. *hiroshimense* and *O. beijerinckii* subsp. *pelagicum* were created for the former species *O. hiroshimense* and *O. pelagicum*. *O. pusillum* was shown to belong to the *Alphaproteobacteria*, and *O. commune* and *O. vagum* were relegated to their original generic positions as *Marinomonas communis* and *Marinomonas vaga*, respectively. The two species *O. jannaschii* and *O. kriegii* were shown to be phylogenetically too remote to be considered members of the genus *Oceanospirillum*, and, together with *O. minutulum*, they constituted separate rRNA branches in the *Gammaproteobacteria*.

Subsequently, this phylogenetic heterogeneity was confirmed by studies of fatty acid, quinone, and polyamine compositions (Hamana et al., 1994; Sakane and Yokota, 1994; Bertone et al., 1996). All species, except *O. pusillum*, contained ubiquinone-8 (Q-8) as a major respiratory quinone (Table BXII.γ.78). Like other spirilla from the *Alphaproteobacteria* (see the genus *Aquaspirillum* in this book), *O. pusillum* contained over 90% Q-10. The thirteen strains of *Oceanospirillum* that have been investigated for their fatty acid composition by Sakane and Yokota were divided into three groups (Table BXII.γ.79 and BXII.γ.80). Group I included the 10 strains belonging to *O. linum*, *O. maris* subsp. *hiroshimense*, *O. maris* subsp. *williamsae*, *O. beijerinckii* subsp. *beijerinckii*, *O. beijerinckii* subsp. *pelagicum*, *O. multiglobuliferum*, and *O. japonicum*, all of which have a low mol% G + C (42.5–48.4). Group II included the two type strains of *O. jannaschii* and *O. kriegii* and had a high mol% G + C content (54.8–54.9). Group III included only *O. pusillum* and could be clearly distinguished from other marine spirilla in having $C_{14:0\ 3OH}$ as the major 3-hydroxy fatty acid, besides Q-10 (Table BXII.γ.80). Bertone et al. (1996) confirmed the separate position of *O. japonicum*, *O. jannaschii*, and *O. kriegii*.

All *Oceanospirillum* species including *O. jannaschii* and *O. kriegii* contain both putrescine and spermidine. The relative content (Table BXII.γ.81) of putrescine is very small when compared with the level found in members of the *Alphaproteobacteria*. The relative concentration of putrescine for *O. pusillum* corresponds with that of other members of the *Alphaproteobacteria*. The absence of 2-hydroxy putrescine and homospermidine is a unifying character for the *Gammaproteobacteria*. The polyamine profile of *Oceanospirillum* I and II is not different, nor are their fatty acid profiles.

Later, 16S rDNA sequence analysis of all *Oceanospirillum* spe-

[d]–, absent; +, present

cies confirmed the above findings. Kawasaki et al. (1997), in a phylogenetic study of helically shaped bacteria in the *Alphaproteobacteria*, showed that *O. pusillum* was not related to other taxa of spirilla and constituted a separate branch in the *Alphaproteobacteria*, also confirming previous findings of Woese et al. (1985) and Pot (1996). Therefore, *O. pusillum* cannot belong to the genus *Oceanospirillum* (Kawasaki et al., 1997). Phenotypic characteristics support the removal of *O. pusillum* from the genus: a single flagellum at each pole, a counterclockwise type of helix, and a mol% G + C of 51, which is slightly higher than the range of 42–48 for the rest of the genus. As a formal transfer has not been proposed, *O. pusillum* is therefore listed below as "Species assigned but phylogenetically not belonging in *Oceanospirillum*".

Satomi et al. (1998) determined and compared 16S rDNA sequences of all the *Oceanospirillum* species. They found that *O. linum*, *O. maris*, *O. beijerinckii*, and *O. multiglobuliferum* constituted a single rRNA cluster, separate from the branches formed by *Marinobacter*, *Marinobacterium*, and *Marinomonas*. Based on their findings, they also excluded *O. japonicum* from the genus *Oceanospirillum*. Phenotypically, *O. japonicum* is different from other *Oceanospirillum* species since it does not form coccoid bodies and its flagella appear to be crescent shaped with less than one helical turn, whereas those of other species have one or more helical turns. Moreover, *O. japonicum* grows best at 35–37°C. As a formal new description has not been proposed, *O. japonicum* is therefore listed below as a "Species assigned but phylogenetically not belonging in *Oceanospirillum*".

In the same study, it was shown that *O. minutulum* clustered on a separate branch together with new isolates from kusaya gravy (Satomi et al., 1998). For this branch, a new genus *Marinospirillum* has been proposed, containing the two species *M. minutulum* and *M. megaterium* (Satomi et al., 1998).

Compared to the other *Oceanospirillum* species, *O. jannaschii* and *O. kriegii* both have a higher mol% G + C (54.8–54.9) and occupy a separate phylogenetic position (Satomi et al., 1998). Many phenotypic characteristics discriminate these species from the genus *Oceanospirillum* (Table BXII.γ.82). Although not discussed separately by the authors, *O. jannaschii* occurred on the same branch as *Marinobacterium* (González et al., 1997). Further taxonomic research, including DNA–DNA hybridizations, should be performed to substantiate the exact level of genotypic relationship between *O. jannaschii* and *Marinobacterium georgiense*. *O. kriegii* constituted a separate branch in the 16S rRNA dendrogram (Satomi et al., 1998).

[a]Cells were harvested at stationary growth phase.

[b]After Hamana et al. (1994).

[c]Abbreviations: Dap, diaminopropane; H-Put, 2-hydroxyputrescine; Put, putrescine; Cad, cadaverine; Spd, spermidine; HSpd, homospermidine; −, not detectable (<0.005).

[d]*Oceanospirillum maris* subsp. *maris* has not been investigated.

[e]Media:199, polyamine-free growth medium from Flow Lab., Irvine, U.K., pH 7.0.; 199S, medium 199 dissolved in 70% synthetic seawater, pH 7.0; 199SW, medium 199 dissolved in seawater, pH 7.0.

Based on 16S rRNA gene sequence analysis, the genus *Oceanospirillum* should therefore be limited to *O. linum*, *O. maris* subsp. *maris*, *O. maris* subsp. *hiroshimense*, *O. maris* subsp. *williamsae*, *O. beijerinckii* subsp. *beijerinckii*, *O. beijerinckii* subsp. *pelagicum*, and *O. multiglobuliferum*. Consequently, *O. japonicum*, *O. jannaschii*, *O. kriegii*, and *O. pusillum* should be removed from the genus. The genus definition described above has been adapted accordingly. The precise taxonomic affiliation of the last four species needs to be further determined.

Note added in proof: Satomi et al. (2002) have formally revised the taxonomic status of the genus *Oceanospirillum* and proposed the formal transfer of the species assigned to but not belonging to the genus *Oceanospirillum* to new and existing genera. (See Kimura et al., 2002 in Further Reading section below.)

Acknowledgments

We acknowledge Dr. N.R. Krieg for the template text, figures, and tables on which this chapter has been based.

Differentiation of the species of the genus *Oceanospirillum*

Morphological and physiological characteristics of the species of *Oceanospirillum* are indicated in Tables BXII.γ.77 and BXII.γ.82. Chemotaxonomic characteristics of the species are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, and BXII.γ.81.

List of species of the genus Oceanospirillum

1. **Oceanospirillum linum** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973, 374[AL] (*Spirillum linum* Williams and Rittenberg 1957, 82.)
li′ num. L. n. *linum* flax, thread.

The morphological characters are depicted in Fig. BXII.γ.104 and listed in Table BXII.γ.82. The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources are listed in Table BXII.γ.77. Growth in defined media is usually poor; however, abundant growth occurs in defined media containing malate plus succinate as carbon sources and methionine as the nitrogen source. Nitrate is not used.

Strain OF3, isolated by Terasaki (1972, 1973), differs from other strains of *O. linum* in that it can grow well in defined media with a variety of sole carbon sources and

Mol% (G + C) of DNA	48–50	47–49	45–47	46	56–57	45	54–56	51	42–44

[a]Phenotypic data are from Krieg (1984a), Baumann et al. (1972), and Bowditch et al. (1984a); +, present in all strains; –, lacking in all strains; d, depending on the strain; w, weak reaction; nd, not determined.

[b]C, clockwise helix; CC, counterclockwise helix (determined by focusing on the bottom of the cells.

[c]SR, straight rod; BT, bipolar tufts, BS, bipolar single; M1-2, 1–2 flagella at one pole; MS, monopolar single.

[d]Characteristic has not been tested in *O. maris* subsp. *hiroshimense* and *O. beijerinckii* subsp. *pelagicum*.

[e]No granules are visible microscopically in *Marinospirillum minutulum* but chemical analysis indicates presence of the polymer.

[f]Data from Terasaki (1972, 1979).

[g]Data from Hylemon et al. (1973).

[h]*Oceanospirillum kriegii* grows at 35°C but not at 40°C; *Oceanospirillum jannaschii* does not grow at either 35°C or 40°C.

[i]*Oceanospirillum maris* subsp. *hiroshimense* has an optimal growth temperature of 25°C; catalase reaction can be negative, weak, or positive; phosphatase reaction can be positive or negative. For detailed information: see Hylemon et al. (1973), Terasaki (1972, 1979), and Table BXII.γ.83.

[j]Gelatin liquefaction was not tested in *O. maris* subsp. *maris*. It was negative in *O. maris* subsp. *hiroshimense*, positive in *O. beijerinckii* subsp. *beijerinckii*, and differed depending on the strain in *O. beijerinckii* subsp. *pelagicum*.

[k]*Oceanospirillum linum* grows poorly or not at all in a defined medium with a single carbon source and ammonium ions as the nitrogen source; however, abundant growth ocurs in a defined medium containing succinate plus malate as carbon source and methionine as the nitrogen source. (See also footnote [d] in Table BXII.γ.82.) *Oceanospirillum maris* subsp. *williamsae* ATCC 2954[T] does not grow in vitamin-free medium and requires an unidentified growth factor.

ammonium ions as the nitrogen source (see footnote d, Table BXII.γ.77). Other characteristics of this strain are similar to those of the type strain (Terasaki, 1973), but whether it should be included in this species is uncertain.

The species includes organisms previously assigned to the two species *Spirillum linum* and *Spirillum atlanticum* by Williams and Rittenberg (1957). The two species were combined into the single species *O. linum* by Hylemon et al. (1973), based on a high degree of similarity in phenotypic characters and in DNA base composition.

Isolated from coastal seawater.

The mol% G + C of the DNA is: 48–50 (T_m).

Type strain: ATCC 11336, DSM 6292, NCMB 56.

2. **Oceanospirillum beijerinckii** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973, 374[AL] (*Spirillum beijerinckii* Williams and Rittenberg 1957, 90.)
bei.jer.inck′ i.i. M.L. gen. n. *beijerinckii* of Beijerinck; named after Prof M.W. Beijerinck of Delft, Holland.

The morphological characters are depicted in Fig. BXII.γ.104 and listed in Table BXII.γ.82. The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources are listed in Table BXII.γ.77. Ammonium ions can serve as a sole nitrogen source; nitrate is not used.

Isolated from coastal seawater.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: ATCC 12754, DSM 7166, NCMB 52.

a. **Oceanospirillum beijerinckii** *subsp.* **beijerinckii** (Williams and Rittenberg 1957) Hylemon, Wells, Krieg and Jannasch 1973, 375[AL] (*Spirillum beijerinckii* Williams and Rittenberg 1957, 90.)

Differs from *O. beijerinckii* subsp. *pelagicum* as indicated in Table BXII.γ.83.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: ATCC 12754 , DSM 7166, NCMB 52.

b. **Oceanospirillum beijerinckii** *subsp.* **pelagicum** (Terasaki 1973) Pot, Gillis, Hoste, Van de Velde, Bekaert, Kersters and De Ley 1989, 32[VP] (*Spirillum pelagicum* Terasaki 1973, 65.)
pe.la′ gi.cum. L. neut. adj. *pelagicum* belonging to the sea.

Differs from the *O. beijerinckii* subsp. *beijerinckii* as indicated in Table BXII.γ.83.

Isolated from putrid infusions of marine mussels.

The mol% G + C of the DNA is: 49 (T_m).

Type strain: ATCC 33337, DSM 6288, IFO 13612, NCMB 2228.

GenBank accession number (16S rRNA): AB006761.

3. **Oceanospirillum maris** Hylemon, Wells, Krieg and Jannasch 1973, 376[AL]
ma′ ris. L. n. *mare* the sea; L. gen. n. *maris* of the sea.

The morphological characters are depicted in Fig. BXII.γ.104 and listed in Table BXII.γ.82. The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources are listed in Table BXII.γ.77.

Isolated from coastal seawater (Jannasch, 1967).

The mol% G + C of the DNA is: 45–46 (T_m).

Type strain: ATCC 27509, DSM 6286, LMG 5213.

GenBank accession number (16S rRNA): AB006771.

TABLE BXII.γ.83. Differentiating characteristics for the subspecies of *Oceanospirillum beijerinckii*[a]

Characteristic	*O. beijerinckii* subsp. *beijerinckii*	*O. beijerinckii* subsp. *pelagicum*
Temperature range for growth (°C)	14–37	8–41
Growth with:		
Lactate, citrate, malate, pyruvate, acetate, propionate, tartrate	−	+
p-Hydroxybenzoate, ethanol, *n*-propanol	−	d
Gelatin liquified at 20°C	+	d
Growth after 7 d in peptone water with:		
0.5–6.0% NaCl	+	−
0.5–8.0% NaCl	−	+
Mol% G + C of DNA	47	49

[a]Phenotypic data from Terasaki (1972, 1979); +, present in all strains; −, lacking in all strains; d, depending on the strain

c. **Oceanospirillum maris** *subsp.* **maris** Hylemon, Wells, Krieg and Jannasch 1973, 376[AL]

Differs from the *O. maris* subsp. *williamsae* and the *O. maris* subsp. *hiroshimense* as indicated in Table BXII.γ.84.

The mol% G + C of the DNA is: 46 (T_m).

Type strain: ATCC 27509, DSM 6286, LMG 5213.

GenBank accession number (16S rRNA): AB006771.

d. **Oceanospirillum maris** *subsp.* **hiroshimense** (Terasaki 1973) Pot, Gillis, Hoste, Van de Velde, Bekaert, Kersters and De Ley 1989, 33[VP] (*Spirillum hiroshimense* Terasaki 1973, 62.)
hi.ro.shi.men′ se. M.L. neut. adj. *hiroshimense* pertaining to Hiroshima. Japan.

Characters are as described for the species. Differs from the *O. maris* subsp. *maris* and the *O. maris* subsp. *williamsae* as indicated in Table BXII.γ.84.

Isolated from putrid infusions of marine mussels.

The mol% G + C of the DNA is: 47 (T_m).

Type strain: IFO 13616, DSM 9524.

e. **Oceanospirillum maris** *subsp.* **williamsae** Linn and Krieg 1984, 355[VP]
will′ iam.sae. M.L. gen. n. *williamsae* of Williams; named after Marion A. Williams, who was the first to describe species of marine spirilla.

Characters are as described for the species. Differs from the *O. maris* subsp. *maris* and the *O. maris* subsp. *hiroshimense* as indicated in Table BXII.γ.84.

Isolated from a mixture of organisms comprising NCMB strain 54 by Linn and Krieg (1978).

The mol% G + C of the DNA is: 45 (T_m).

Type strain: ATCC 29547, IFO 15468.

GenBank accession number (16S rRNA): AB006763.

4. **Oceanospirillum multiglobuliferum** (Terasaki 1973) Terasaki 1979, 143[AL] (*Spirillum multiglobuliferum* Terasaki 1973, 69.)
mul.ti.glo.bu.li′ fe.rum. L. adj. *multus* much, many; L. dim. n. *globulus* a small sphere, globule; L. v. *fero* to bear, carry; M.L. neut. adj. *multiglobuliferum* bearing many globules.

The morphological characters are listed in Table BXII.γ.82. The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources

TABLE BXII.γ.84. Differentiating characteristics for the subspecies of *Oceanospirillum maris*[a]

Characteristic	*O. maris* subsp. *maris*	*O. maris* subsp. *hiroshimense*	*O. maris* subsp. *williamsae*
Optimal growth temperature (°C)	30–32	25	30–32
Catalase reaction	strongly +	d	weakly +
Phosphatase activity	−	+	−
DNase activity	−		+
RNase activity	−		+
Growth with 1% glycine	+		−
Growth in vitamin-free, defined growth medium	+		−
Growth with:			
L-Glutamate, oxaloacetate	+		−
Succinate, pyruvate, lactate, tartrate, acetate, propionate	−	+	−
Mol% G + C of DNA	46	47	45

[a]Phenotypic data from Hylemon et al. (1973); +, present in all strains; −, lacking in all strains; d, depending on the strain

are listed in Table BXII.γ.77. Differs from other species by forming unusually large numbers of coccoid bodies even in 24- to 48-h-old broth cultures. Ammonium ions can serve as a sole nitrogen source; nitrate is not used.

Isolated from putrid infusions of marine mussels.

The mol% G + C of the DNA is: 46 (T_m).

Type strain: IFO 13614.

GenBank accession number (16S rRNA): AB006764.

Species assigned but phylogenetically not belonging in *Oceanospirillum*

1. **Oceanospirillum jannaschii** Bowditch, Baumann and Bauman 1984b, 503[VP] (Effective publication: Bowditch, Baumann and Bauman 1984a, 227.)
jan.nasch' i.i. M.L. gen. n. *jannaschii* of Jannasch; named after H.W. Jannasch.

Straight rods. Some morphological, physiological, and chemotaxonomic characters are listed in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82 (see also Baumann et al., 1972). Sole carbon sources are listed in Table BXII.γ.77. Utilize 39–46 organic compounds including fatty acids, tricarboxylic acid cycle intermediates, alcohols, amino acids, and amines. Utilizes γ-aminovalerate and histamine (Baumann et al., 1972).

Isolated from seawater after enrichment (Baumann et al., 1972).

The mol% G + C of the DNA is: 56–57 (T_m).

Type strain: ATCC 27135, DSM 6295, IFO 15466.

GenBank accession number (16S rRNA): AB006765.

2. **Oceanospirillum japonicum** (Watanabe 1959) Hylemon, Wells, Krieg and Jannasch 1973, 375[AL] (*Spirillum japonicum* Watanabe 1959, 78.)
ja.pon' i.cum. M.L. neut. adj. *japonicum* pertaining to Japan.

The morphological characters are depicted in Fig. BXII.γ.104 and listed in Table BXII.γ.82; however, the type strain presently has morphological features that differ from the original description, in that the cells are no longer helical with several waves but instead are curved, straight, or S-shaped; moreover, colonies of this strain are presently of the R (rough) type. Therefore, it is likely that the type strain has undergone alteration since its isolation in 1959. Three reference strains isolated by Terasaki (1972, 1973) have morphological features that more nearly correspond to those given in the original description (strains IF4, IF8, and UF3), and also they form colonies of the S (smooth) type.

The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources are listed in Table BXII.γ.77.

Isolated from putrid infusions of marine mussels.

The mol% G + C of the DNA is: 45 (T_m).

Type strain: ATCC 19191, DSM 7165.

3. **Oceanospirillum kriegii** Bowditch, Baumann and Bauman 1984b, 503[VP] (Effective publication: Bowditch, Baumann and Bauman 1984a, 227.)
krie' gi.i. M.L. gen. n. *kriegii* of Krieg; named after N.R. Krieg.

Straight rods. Some morphological and physiological characters are listed in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82 (see also Baumann et al., 1972). Sole carbon sources are listed in Table BXII.γ.77. Utilize 29–33 organic compounds including D-glucose and D-fructose but no other pentose, hexose, or disaccharide; also utilize tricarboxylic acid cycle intermediates, alcohols, amino acids, and amines. Produces an extracellular lipase (Baumann et al., 1972).

Isolated from see water after enrichment (Baumann et al., 1972).

The mol% G + C of the DNA is: 54–56 (T_m).

Type strain: ATCC 27133, DSM 6294, IFO 15467, NCMB 2042.

GenBank accession number (16S rRNA): AB006767.

4. **Oceanospirillum pusillum** (Terasaki 1973) Terasaki 1979, 142[AL] (*Spirillum pusillum* Terasaki 1973, 67.)
pu.sil' lum. L. dim. neut. adj. *pusillum* very small.

The morphological characters are listed in Table BXII.γ.82. The physiological and chemotaxonomic characters are indicated in Tables BXII.γ.78, BXII.γ.79, BXII.γ.80, BXII.γ.81, and BXII.γ.82. Sole carbon sources are listed in Table BXII.γ.77. Ammonium ions can serve as a sole nitrogen source; nitrate is not used.

Isolated from putrid infusions of marine mussels.

Belongs to the *Alphaproteobacteria*.

The mol% G + C of the DNA is: 51 (T_m).

Type strain: ATCC 33338, DSM 6293, IAM 14442, IFO 13613, NCMB 2229.

GenBank accession number (16S rRNA): AB006768.

Genus II. **Balneatrix** *Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993b, 624[VP] (Effective publication: Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993a, 42)*

CATHERINE DAUGA

Bal' ne.a.trix. L. fem. n. *balneatrix* bather.

Straight or curved rods, 0.5–0.7 × 2.8–5 µm, sometimes elongated and flexuous. Gram negative. **Motile by single polar flagellum. Aerobic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Produce convex, round, smooth colonies on solid media. Optimum temperature, 30°C; range, 20–46°C. Optimum pH, 6.5–7.5. Growth factors are not required. **No growth occurs in medium containing more than 1% NaCl.** Chemoorganotrophic. Acid is produced from glucose and certain other carbohydrates. **Oxidase positive.** Weakly catalase positive. **Indole positive.** Urease negative. Reduce nitrate to nitrite. Freshwater organisms; occasionally pathogenic for humans.

The mol% G + C of the DNA is: 54.

Type species: **Balneatrix alpica** Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993b, 624 (Effective publication: Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993a, 43).

FURTHER DESCRIPTIVE INFORMATION

Balneatrix strains grow after a 2-d incubation at 30°C. The center of the colony is pale yellow after 2–3 d, and pale brown after 4–5 d.

Balneatrix strains are nonfermentative, as verified by oxidation–fermentation medium (Casalta et al., 1989). All strains tested are Voges–Proskauer negative by the Barrit reference method. Nutritional tests can be done using Biotype-100 strips (BioMerieux, Marcy l' Etoile, France) with M70 minimal medium (Véron, 1975) supplemented with 0.15% agar. Strains of *Balneatrix* are nutritionally diverse, and some strains can grow with citrate, D-alanine, ethanolamine, D-glucosamine, L-histidine, DL-lactate, D(+)-malate (see Table BXII.γ.85). Arginine dihydrolase, lysine and ornithine decarboxylases, acetamide, and starch hydrolysis are invariably negative. Tetrathionate is not reduced. Gelatin is weakly hydrolyzed. Citrate can serve sometimes as the sole carbon source for growth. Tween-80 hydrolysis also differs among strains. Tributyrin is hydrolyzed, and the egg yolk reaction (lecithinase) is positive. The gamma-glutamyl transferase test is positive. There is no ONPG hydrolysis and no extracellular DNase (Casalta et al., 1989).

[a]Symbols : +, all strains positive ; −, all strains negative ; d, differs among strains. Numbers in parentheses indicate the number of strains that are positive.

[b]Based on results for eight strains.

Balneatrix strains are susceptible *in vitro* to a variety of antimicrobial agents, including β-lactam, macrolides, and aminoglycoside antibiotics, sulfamethoxazole–trimethoprim, chloramphenicol, deoxycycline, minocycline, ofloxacin, and nalidixic acid. They are resistant to clindamycin and vancomycin.

At this writing, *Balneatrix* strains have been isolated only from thermal water and clinical specimens at a spa therapy center in southern France. Thirty-five cases of pneumonia and two cases of meningitis have been caused by *Balneatrix* strains (Hubert et al., 1991). According to epidemiological data, the bacteria were present in the hot water spring spa, and favorable growing conditions were found only in vapor baths. After disinfection of water pipes by chlorination, no further cases of infection were observed.

ENRICHMENT AND ISOLATION PROCEDURES

Balneatrix strains can be isolated by traditional culture techniques and incubation under aerobic conditions at 20–41°C. Environmental and clinical strains can grow in 24 h in trypto-casein soy broth (Sanofi Diagnostics Pasteur, Marnes-la-Coquette, France). Brain–heart infusion and IsoVitaleX chocolate agar (Sanofi Diagnostics Pasteur) can be used for blood and CSF (cerebrospinal fluid) samples, respectively. Strains can be subcultured on trypto-casein soy agar or nutrient agar. Antimicrobial disks can be tested on Mueller–Hinton agar (Sanofi Diagnostics Pasteur).

MAINTENANCE PROCEDURES

The organisms survive at 30°C in trypto-casein soy broth for several weeks. They can survive for several years when frozen at −80°C in brain–heart infusion containing 50% glycerol.

DIFFERENTIATION OF THE GENUS *BALNEATRIX* FROM OTHER GENERA

The characteristics which differentiate *Balneatrix* from other genera are listed in Table BXII.γ.86.

Because *Balneatrix* shares some properties with *Flavobacterium*, such as isolation requirements, pigmented colonies, and biochemical reactions, it was initially compared with this genus; how-

TABLE BXII.γ.86. Phenotypic characteristics differentiating the genera *Balneatrix*, *Oceanospirillum*, *Marinomonas*, *Halomonas*, and *Flavobacterium*[a]

[b]Data from Holmes et al., 1984.

[c]Characteristics of *Halomonas elongata*. Data from Vreeland, 1984.

[d]Characteristics of *Marinomonas vaga* and *Marinomonas communis*, which were misnamed *Oceanospirillum vagum* and *O. commune* (Pot et al., 1989). Data from Baumann et al., 1972.

[e]Data from Krieg, 1984b.

ever, the mol% G + C value of 54 for the DNA of *Balneatrix* does not correspond to that of *Flavobacterium*.

Despite its environmental habitat and oxidative ability, *Balneatrix* is easily differentiated from such genera as *Oceanospirillum*, *Marinomonas*, or *Halomonas* based on salt tolerance, shape, flagellar arrangement, and ability to catabolize several carbohydrates. *Balneatrix* can be quickly differentiated from these genera by the inability to grow with more than 1% NaCl.

Taxonomic Comments

Strains of *Balneatrix* are closely related by DNA–DNA hybridization and belong to the same species. Strain 4-87, isolated from cerebrospinal fluid, has been selected as the type strain.

rRNA–DNA hybridization and 16S rDNA sequencing have shown that the genus *Balneatrix* belongs to the class *Gammaproteobacteria*. Phylogenetically, *Balneatrix* is located within a subline including many *Oceanospirillum* species (Fig. BXII.γ.105). In this group, bacteria are heterogeneous and difficult to classify. Like *Balneatrix*, *Halomonas halmophila* was first misidentified as *Flavobacterium halmophilum* (Franzmann et al., 1988). *Halomonas aquamarina*, *Halomonas halophila*, and *Halomonas marina* were first assigned to the genus *Deleya* (Dobson et al., 1993).

Phylogenetically, *Balneatrix* branches in the vicinity of *Oceanospirillum* species, but *O. vagum*, *O. commune*,* *O. jannaschii*, and *O. kriegii* are misnamed according to DNA–rRNA hybridization (Pot et al., 1989). This, in addition to the fact that *Balneatrix alpica* is the only freshwater pathogenic bacterium in the subline, argues that *Balneatrix* is a new genus.

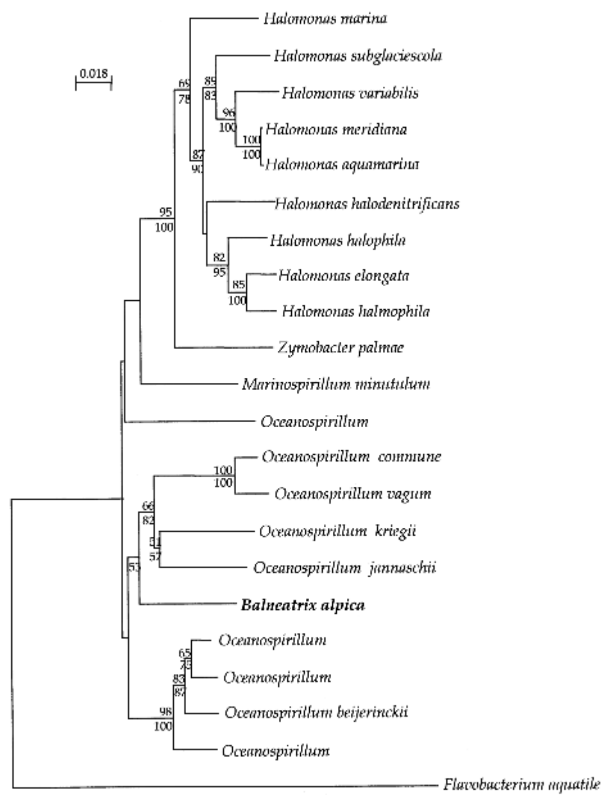

FIGURE BXII.γ.105. Relationships between the marine bacteria of the class *Gammaproteobacteria* and *Balneatrix*. *Flavobacterium aquatile*, which shares some phenotypic characteristics with *Balneatrix*, served as an outgroup. The tree shown is the result of distance analysis (NEIGHBOR routine in PHYLIP 3.5c, Kimura 2-parameters). The same tree topology was obtained with parsimony analysis (heuristic search option in PAUP 3.1.1 with 1000 replicates of the random-addition sequence). Percentages of bootstrap replicates supporting a branching pattern are given above and below the corresponding branches; the value above the branch is the parsimony analysis bootstrap percentage, and that below is from the distance analysis (100 bootstrap replicates).

*Editorial Note: *Oceanospirillum vagum* and *O. commune* are junior objective synonyms of *Marinomonas vaga* and *M. communis*.

List of species of the genus Balneatrix

1. **Balneatrix alpica** Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993b, 624[VP] (Effective publication: Dauga, Gillis, Vandamme, Ageron, Grimont, Kersters, De Mahenge, Peloux and Grimont 1993a, 43.)

   al′pi.ca. L. fem. adj. *alpica* pertaining to the Alps.

The description is the same as that given for the genus. Other characteristics are listed in Table BXII.γ.85. The type strain has all the properties given for the species and hydrolyses Tween-80.

The mol% G + C of the DNA is: 54 (HPLC).

Type strain: 4-87, CIP 103589.

GenBank accession number (16S rRNA): Y17112.

Genus III. **Marinomonas** *Van Landschoot and De Ley 1984, 91[VP] (Effective publication: Van Landschoot and De Ley 1983, 3071)*

Antonio Sanchez-Amat and Francisco Solano

Ma.ri.no.mo′nas. L. adj. *marinus* pertaining to the sea; Gr. n. *monas* a unit, monad; M.L. *Marinomonas* sea monad.

Gram-negative, straight or curved rods. Motile by means of polar flagella at one or both poles. **Aerobic**, having a strictly respiratory type of metabolism. **Oxidase positive or negative**. **Na^+ is required for growth**. **Do not accumulate poly-β-hydroxybutyrate**. Do not require organic growth factors. **Do not produce extracellular amylase**. **Utilize acetate but not butyrate or valerate**. Utilize glutamate, sorbitol, and malate. Commonly isolated from seawater.

The mol% G + C of the DNA is: 45–50.

Type species: **Marinomonas communis** (Baumann, Baumann, Mandel and Allen 1972) Van Landschoot and De Ley 1984, 91 (Effective publication: Van Landschoot and De Ley 1983, 3071) (*Alteromonas communis* Baumann, Baumann, Mandel and Allen 1972, 420.)

Further descriptive information

Species of *Marinomonas* are rods, either curved such as *M. communis*, or straight such as *M. vaga* and *M. mediterranea* (Fig. BXII.γ.106). They are motile; *M. communis* and *M. vaga* show a single, unsheathed, polar flagellum inserted at one or both poles of the cell. *M. mediterranea* shows only a single flagellum at one pole of the cell (Fig. BXII.γ.106).

Marinomonas strains grow in typical marine media such as Marine Agar (Zobell, 1941). In this complex medium, only *M. mediterranea* shows pigmentation; it synthesizes a brown to black melanin pigment derived from L-tyrosine as main precursor. This pigment is observed both in the colonies and diffusing into the surrounding medium (Fig. BXII.γ.107). *Marinomonas* strains also grow in basal marine agar (BMA) containing 0.2% D-glucose as carbon and energy source (Baumann et al., 1972). This basal medium is used in studies of carbon and energy source utilization. No organic growth factor is required; however, growth of *M. mediterranea* is favored in media containing organic compounds as the nitrogen source. The most suitable chemically defined medium for growing this species is MMM[1]. All culture media for *Marinomonas* must contain a marine salts base composition. *Marinomonas* species show an absolute requirement for Na^+ ion.

The physiological characteristics of the *Marinomonas* species are listed in Tables BXII.γ.87 and BXII.γ.88. Thirty-three strains of *M. communis* and 17 *M. vaga* strains isolated from the Pacific Ocean have been phenotypically characterized (Baumann et al., 1972). In contrast, only a single *M. mediterranea* strain—isolated from the Mediterranean Sea as its species name indicates—has been described (Solano et al., 1997). Unless otherwise indicated, the characterization of this strain has been also performed according to the protocols of Baumann et al. (1972), described as well by Gauthier and Breittmayer (1992).

Members of the genus *Marinomonas* are aerobic and use oxygen as a universal electron acceptor. No *Marinomonas* species is able to denitrify, although *M. mediterranea* is able to reduce nitrate to nitrite. *M. communis* is oxidase positive whereas the other two species are oxidase negative. In some cases permeabilization of *M. vaga* strains with toluene will allow a positive oxidase reaction to occur. It has been suggested that this result is due to a low level of cytochrome *c* in *M. vaga* cells (Baumann et al., 1984d); however, *M. mediterranea* always gives a negative result in cytochrome *c* oxidase tests, even when the cells are toluene-treated (Solano et al., 1997).

In assays for extracellular degradative activities, *Marinomonas* species give negative results, with the exception of *M. mediterranea*, which shows lipase and gelatinase activities. Gelatin hydrolysis was detected by comparison of the solidification of Marine Broth, supplemented with 12% gelatin and inoculated with *M. mediterranea*, with an uninoculated control. Under these conditions, a weak gelatinase activity was detected (Solano et al., 1997).

Marinomonas species are able to utilize acetate, but not butyrate or valerate, as a sole carbon and energy source. All of the *M. communis* and *M. vaga* strains metabolize *m*-hydroxybenzoate, *p*-hydroxybenzoate, and quinate by means of *meta* cleavage of the intermediate protocatechuate (Baumann et al., 1972). In contrast, *M. mediterranea* is unable to metabolize *m*-hydroxybenzoate. All *Marinomonas* species can use D-glucose. *Marinomonas communis* and *M. vaga* metabolize D-glucose and D-fructose via the Entner–Doudoroff pathway (Sawyer et al., 1977a). Aspartate kinase activity has been detected in these two species (Baumann and Baumann, 1974). All species can use glutamate as a sole carbon and energy source, but none can use glycine or L-tyrosine. Data for other carbon sources are listed in Tables BXII.γ.87 and BXII.γ.88.

1. MMM is a chemically defined medium containing (per liter): NaCl, 20 g; $MgSO_4 \cdot 7H_2O$, 7.0 g; $MgCl_2 \cdot 6H_2O$, 5.3 g; KCl, 0.7 g; $CaCl_2$, 1.25 g; $FeSO_4 \cdot 7H_2O$, 25 mg; $CuSO_4 \cdot 5H_2O$, 5 mg; K_2HPO_4, 75 mg; sodium glutamate, 2 g; and Tris base, 6.1g. The pH of this medium is adjusted to 7.4.

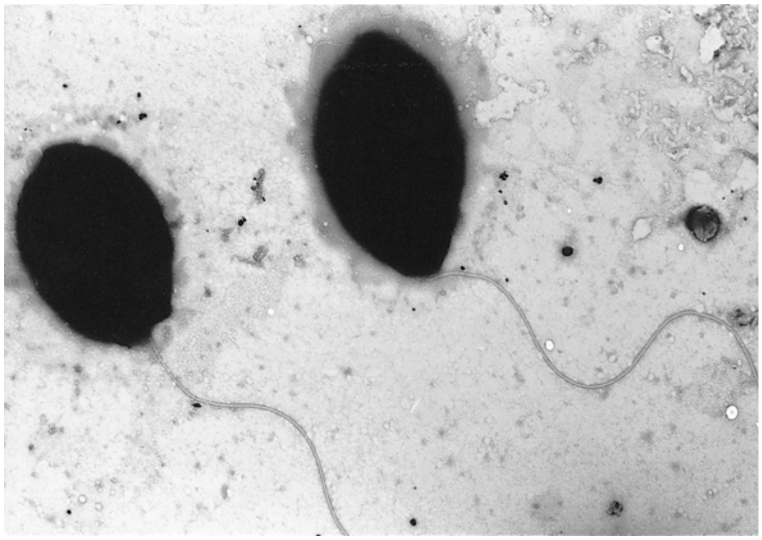

FIGURE BXII.γ.106. Electron micrograph of *Marinomonas mediterranea* MMB-1. Negatively stained with phosphotungstic acid (× 20,000).

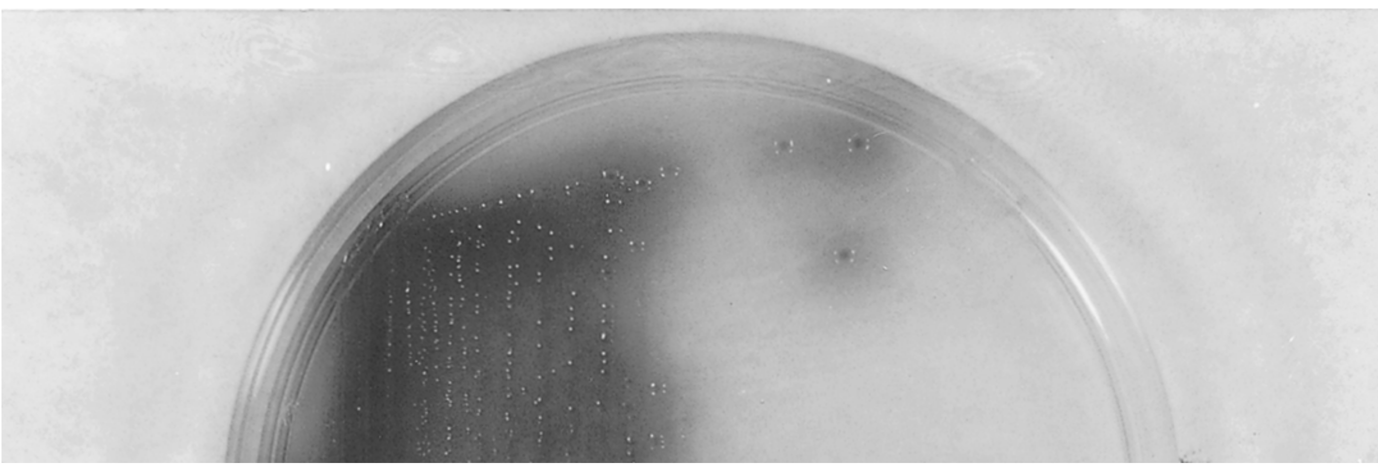

FIGURE BXII.γ.107. Colonies of *Marinomonas mediterranea* MMB-1 on Marine Agar after four days of incubation at 25°C (× 2.1).

Marinomonas communis and *M. vaga* can serve as prey for the growth of marine bdellovibrios (Taylor et al., 1974).

The mol% G + C content of the DNA of *M. communis* and *M. vaga* has been calculated using the buoyant density method. The mol% G + C of the DNA of *M. mediterranea* strain MMB-1 was determined by HPLC analysis after DNA hydrolysis and dephosphorylation (Solano et al., 1997). In this strain, the chromatogram revealed two additional peaks besides those of the four expected standard deoxynucleosides. The base modifications in the compounds giving these peaks remain unidentified, although their UV adsorption spectra suggest that they are methylated derivatives of the purine deoxynucleosides. The method used to estimate the mol% G + C content in the other two species of *Marinomonas* does not allow one to know whether this feature is shared by all the *Marinomonas* species.

Resistance of *M. mediterranea* to some antimicrobial agents was tested in order to evaluate them as genetic markers. This species was sensitive to ampicillin (50 μg/ml), chloramphenicol (10 μg/ml), gentamicin (10 μg/ml), kanamycin (40 μg/ml), streptomycin (10 μg/ml), rifampicin (50 μg/ml), and tetracycline (10 μg/ml). Resistance to the latter compound was assayed in media lacking Mg^{2+}.

Several molecular techniques have been applied to *M. mediterranea* (Solano et al., 2000). Vectors containing the RP4 *mob* site are mobilizable by conjugation. Conjugation can be performed at 25°C on the surface of plates containing the medium LB2216[2]. Plasmids, such as pKT230, with the p15 origin of replication are stable in this species and hence can be used as cloning vectors. On the contrary, plasmids containing the *oriR6K* behave as suicidal vectors in *M. mediterranea*, which makes them useful as transposon delivery vectors. Tn*5* and Tn*10* derivatives have been assayed for this purpose. Higher transposition frequencies were obtained with Tn*10* derivatives encoding kanamycin and gentamicin resistance than with Tn*10* transposons with a different marker, or with Tn*5* transposons. Other genetic markers such as ampicillin and chloramphenicol resistance were not properly expressed in *M. mediterranea* even if they were present in plasmids. *M. mediterranea* is normally lac(−), but after transposon mutagenesis with one mini-Tn10 derivative containing the *lacZ* reporter gene, approximately 55% of the colonies showed blue coloration when grown in media containing X-Gal, thus indicating the usefulness of *lacZ* as a reporter gene in *M. mediterranea*. Mutants of *M. mediterranea* can also be obtained by nitrosoguanidine mutagenesis (Solano et al., 1997). UV radiation is not an efficient mutagen for this strain, however.

A relevant feature in *M. mediterranea* is its capacity to synthesize melanins. These pigments are made from L-tyrosine as precursor and by the involvement of the enzyme tyrosinase (EC 1.14.18.1) (Solano et al., 1997). Tyrosinase is a copper protein that belongs to the group of polyphenol oxidases (PPOs). The other important copper enzyme in this group is laccase (EC 1.10.3.2). *M. mediterranea* also shows this activity, due to a multipotent enzyme showing both tyrosinase and laccase activities (Sanchez-Amat and Solano, 1997).

Some other aerobic, Gram-negative, marine proteobacteria are able to synthesize brown to black pigments in complex media. However, aside from *M. mediterranea*, actual PPO activity has been described only in the strain 2-40 (Kelley et al., 1990; Solano and Sanchez-Amat, 1999). In some cases, melanins result from spontaneous oxidation of intermediates of L-tyrosine catabolism, such as homogentisate in *Shewanella colwelliana* (Ruzafa et al., 1994; Kotob et al., 1995). In this case, melanin-like pigments are synthesized only in aerated media with a high amount of tyrosine. These pigments, designated pyomelanins, are very similar in their chemical properties to melanins obtained by activity of the enzyme tyrosinase. To differentiate between these two possibilities, actual PPO activity should be determined spectrophotometrically or revealed by staining after PAGE (Solano et al., 1997).

A high number of *M. communis* and *M. vaga* strains have been isolated using enrichment methods with different compounds as carbon sources (Baumann et al., 1972). These isolations led to the view that *Marinomonas* is a usual component of the bacterial flora in marine waters; however, there are no data about the ecological distribution of *M. mediterranea.* The single strain of this species was detected after screening thousands of colonies of marine microorganisms for the ability to synthesize melanins. No other strains with pigmentation identical to *M. mediterranea* were detected, which suggests that it may not be very abundant. It is important to bear in mind that it is not easy to differentiate between *Marinomonas* and other aerobic marine bacteria using only phenotypic characteristics (see below). Strains for which 16S rDNA sequence analyses clearly indicate they belong to the genus *Marinomonas* have been isolated from North Sea bacterioplankton (Eilers et al., 2000). In addition, a clone showing a close relationship to the genus *Marinomonas* was detected in a 16S rDNA sequence clone library obtained from bacterial communities associated with the seagrass *Halophila stipulacea* (Weidner et al., 2000).

Enrichment and Isolation Procedures

Marinomonas species can be isolated by direct plating of seawater samples on a complex medium such as Marine Agar (Zobell, 1941). *M. communis* and *M. vaga* are able to use *m*-hydroxybenzoate, and this property can be used for an enrichment method. Seawater (500 ml) is transferred to a 2-liter Erlenmeyer flask and supplemented with 25 ml 1M Tris-HCl (pH 7.5), 0.5 g NH_4Cl, 38 mg K_2HPO_4, 14 mg $FeSO_4 \cdot 7H_2O$, and 0.5 g *m*-hydroxybenzoate. The culture is incubated at 20–25°C for up to 10 d. When growth is observed, the culture is streaked onto BMA containing 0.1% (w/v) *m*-hydroxybenzoate in order to obtain pure cultures (Baumann et al., 1984d).

Maintenance Procedures

Long-term preservation of *Marinomonas* species can be achieved by lyophilization. A suitable protocol for preparation of the cells has been described by Gauthier and Breittmayer (1992). The lyophilized cultures are reconstituted by adding 0.5 ml of Marine Broth. A few drops are streaked onto Marine Agar and the remaining is transferred to a tube containing 4 ml of Marine Broth. It is advisable to avoid high aeration of the culture during the first hours of incubation. Growth is observed after 2–3 d.

An alternative method of preservation is freezing. Glycerol is added to an overnight culture in Marine Broth to a final concentration of 20% and the culture is immediately stored at −75°C. Using this protocol, frozen *M. mediterranea* cells have remained viable for more than five years.

Strains can be maintained by serial transfer on Marine Agar for routine work in the lab. After 2–3 days of growth at 25°C, the plates can be preserved for 3–4 weeks at 15°C. It is not recommended to keep the cultures at 4°C, because viability is lost much faster than when the cultures are stored at 15°C.

2. LB2216 is obtained by mixing—after autoclaving—equal amounts of LB medium (containing 1.5% NaCl) and Marine Agar 2216.

[a]Symbols: see standard definitions; nd, not determined.

[b]*M. communis* and *M. vaga* are able to use the following compounds as principal sources of carbon and energy: D-gluconate, fumarate, DL-lactate, aconitate, D-mannitol, γ-aminobutyrate, sarcosine, putrescine, saccharate, pyruvate, *m*-inositol, L-alanine, D-alanine, L-ornithine, L-histidine, L-proline, betaine.

The following compounds are not used as sole or principal sources of carbon and energy by *Marinomonas communis* or *M. vaga*: sucrose, melibiose, salicin, D-fucose, inulin, cellulose, mucate, L-threonine, L-leucine, L-isoleucine, L-valine, L-tryptophan, D-tryptophan, L-norleucine, DL-α-aminobutyrate, DL-α-aminovalerate, δ-aminovalerate, formate, isobutyrate, isovalerate, oxalate, malonate, maleate, glutarate, adipate, pimelate, suberate, azelate, sebacate, D-tartrate, *meso*-tartrate, glycolate, levulinate, D-mandelate, L-mandelate, citraconate, itaconate, mesaconate, ethyleneglycol, 2,3-butanediol, methanol, isopropanol, isobutanol, *n*-butanol, propyleneglycol, benzoylformate, DL-kynurenine, kynurenate, anthranilate, *m*-aminobenzoate, *p*-aminobenzoate, methylamine, benzylamine, histamine, tryptamine, butylamine, α-amylamine, 2-amylamine, pentylamine, creatine, hippurate, pantothenate, acetamide, nicotinate, nicotinamide, allantoin, adenine, guanine, cytosine, thymine, uracil, *n*-dodecane, phenylethanediol, phenol, naphthalene.

11–89% of the strains included in *M. communis* and *M. vaga* are able to use the following compounds as principal sources of carbon and energy: D-xylose, D-trehalose, D-glucuronate, D-galacturonate, caprate, L-tartrate, L-aspartate, L-phenylalanine, L-citrulline.

Differentiation of the genus *Marinomonas* from other genera

The characteristics that differentiate *Marinomonas* species from other aerobic, marine, Gram-negative bacteria are listed in Table BXII.γ.89. Further characterization of more strains might help to establish other phenotypic criteria for differentiating these genera; however, all of these genera share many physiological and biochemical features and their differentiation can be problematic. In this regard, some chemotaxonomic markers such as isoprenoid quinone and fatty acid composition have been tested (Akagawa-Matsushita et al., 1992a; Ivanova et al., 2000c). Molecular analysis, such as rRNA–DNA hybridization and particularly rDNA sequencing, have shown that *Marinomonas* species form a well-defined cluster (Van Landschoot and De Ley 1983; Solano and Sanchez-Amat, 1999). 16S rDNA sequencing of additional *Marinomonas* strains could be useful for designing nucleic acid probes for the identification and quantification in natural habitats of microorganisms belonging to this genus.

Taxonomic Comments

There are many Gram-negative, nonfermentative, heterotrophic, marine bacteria with polar flagella. Those with mol% G + C contents below 50 were temporarily assigned to the genus *Alteromonas*, and those with a mol% G + C of 57–64 were included in the genus *Pseudomonas* (Baumann et al., 1972). Further characterization of the genus *Alteromonas* revealed a great diversity

[h] *Pseudoalteromonas nigrifaciens* is negative.

(Van Landschoot and De Ley, 1983; Gauthier et al., 1995a). Two of the species originally included in the genus *Alteromonas* were *A. communis* and *A. vaga*. Immunological analysis of Fe-containing superoxide dismutase and glutamine synthetase established a relationship between these species and the genus *Oceanospirillum*, and hence their assignment to this genus under the species names *Oceanospirillum commune* and *O. vagum* was proposed (Bowditch et al., 1984a). DNA–rRNA hybridization studies applied to some Gram-negative bacteria, including those initially assigned to the genus *Alteromonas*, revealed that *A. communis* and *A. vaga* constituted a separate rRNA branch (Van Landschoot and De Ley, 1983). Taking into consideration this fact and also phenotypic traits, the genus *Marinomonas* was created to contain the two species as *M. communis* and *M. vaga*. Phylogenetic analysis based on 16S rDNA sequences of these two species and a new strain, MMB-1, revealed that they were closely related, with percentage identities greater than 95% (Fig. BXII.γ.108). These data supported creation of the genus *Marinomonas*, in which the strain MMB-1 constituted the third species, namely *M. mediterranea* (Solano and Sanchez-Amat, 1999). The data also showed that these species were more closely related to members of the genus *Oceanospirillum* than to the species remaining in the modified genus *Alteromonas* or *Pseudoalteromonas*.

List of species of the genus Marinomonas

1. **Marinomonas communis** (Baumann, Baumann, Mandel and Allen 1972) Van Landschoot and De Ley 1984, 91[VP] (Effective publication: Van Landschoot and De Ley 1983, 3071) (*Alteromonas communis* Baumann, Baumann, Mandel and Allen 1972, 420.)
com.mu′nis. L. adj. *communis* common.

The characteristics are as described for the genus and as listed in Tables BXII.γ.87 and BXII.γ.88. Curved rods, 0.7–1.5 × 1.8–3.0 μm. Motile by means of polar flagella at one or both poles. Oxidase positive. Metabolize *m*-hydroxybenzoate, *p*-hydroxybenzoate, and quinate, but not benzoate or *o*-hydroxybenzoate, by means of *meta* cleavage of the intermediate protocatechuate.

The mol% G + C of the DNA is: 45–48 (Bd).
Type strain: ATCC 27118, DSM 5604, LMG 2864.

2. **Marinomonas mediterranea** Solano and Sanchez-Amat 1999, 1245[VP]
med.i.terr.an′e.a. L. gen. n. *mediterranea* of the Mediterranean, referring to the isolation of the type strain from the Mediterranean Sea in the region of Murcia, on the southeastern Spanish coast.

The characteristics are as described for the genus and as listed in Tables BXII.γ.87 and BXII.γ.88. Gram-negative rods, 0.5–0.9 × 1.1–1.8 μm. Motile by a single polar flagellum. Cytochrome oxidase negative. No denitrification occurs. Lipase positive; gelatinase weakly positive. Utilize D-glucose, D-mannose, D-sorbitol, citrate, β-hydroxybutyrate, succinate, glycerol, and malate. Produce melanin. Contain a pluripotent polyphenol oxidase and a tyrosinase activated by SDS.

The mol% G + C of the DNA is: 46.3 ± 0.9 (HPLC).
Type strain: MMB-1, ATCC 700492, CECT 4803.
GenBank accession number (16S rRNA): AF063027.

3. **Marinomonas vaga** (Baumann, Baumann, Mandel and Allen 1972) Van Landschoot and De Ley 1984, 91[VP] (Effective publication: Van Landschoot and De Ley 1983, 3071) (*Alteromonas vaga* Baumann, Baumann, Mandel and Allen 1972, 420.)
va′ga. L. adj. *vaga* wandering.

The characteristics are as described for the genus and as listed in Tables BXII.γ.87 and BXII.γ.88. Straight rods 0.7–1.5 × 1.8–3.0 μm. Motile by means of polar flagella at one or both poles. Oxidase negative. Metabolize *m*-hydroxybenzoate, *p*-hydroxybenzoate and quinate, but not benzoate or *o*-hydroxybenzoate, by means of *meta* cleavage of the intermediate protocatechuate.

The mol% G + C of the DNA is: 46–50 (Bd).
Type strain: ATCC 27119.
GenBank accession number (16S rRNA): X67025.

Genus IV. **Marinospirillum** *Satomi, Kimura, Hayashi, Shouzen, Okuzumi and Fujii 1998, 1346*^{VP}

Masataka Satomi, Bon Kimura and Tateo Fujii

Ma.ri.no.spi.ril'lum. L. adj. *marinus* of the sea; Gr. n. *spira* a spiral; M.L. dim. neut. n. *spirillum* a small spiral; *Marinospirillum* a small spiral from the sea.

Helical cells. Motile by bipolar tufts of flagella. Thin-walled coccoid bodies are formed in aging cultures. Endospores are not formed. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. **Na^+ is required for growth.** Chemoheterotrophic. **Accumulate poly-β-hydroxybutyrate. Oxidase positive. Carbohydrates are neither oxidized nor fermented.** The major isoprenoid quinone type is Q-8. Belongs to the class *Gammaproteobacteria*. One species has been isolated from putrid infusions of marine mussels; another has been isolated from kusaya gravy.

The mol% G + C of the DNA is: 42–45.

Type species: **Marinospirillum minutulum** (Watanabe 1959) Satomi, Kimura, Hayashi, Shouzen, Okuzumi and Fujii 1998, 1346 (*Oceanospirillum minutulum* (Watanabe 1959) Hylemon, Wells, Krieg and Jannasch 1973, 373; *"Spirillum minutulum"* Watanabe 1959, 83.)

Further descriptive information

Because *Marinospirillum minutulum*—like most members of the genus *Oceanospirillum*—was isolated from putrid infusions of marine mussels, its source is most likely marine mud adherent to the mussels (Terasaki, 1970).

Marinospirillum megaterium was isolated from kusaya gravy (Fujii et al., 1990), which is used for producing Japanese traditional dried fish, and its true ecological niche is unknown. Under microscopic observation, this species is usually observed as the dominant microbial population in the gravy, characterized by large helical cells, but is unculturable on agar surfaces. The main chemical characteristics of kusaya gravy are as follows: salinity of approximately 3% NaCl concentration, low dissolved oxygen concentration, and large amounts of volatile basic nitrogen compounds (200–500 mg/100 g) (Satomi et al., 1997).

Enrichment and Isolation Procedures

Terasaki (1970) enriched and isolated *M. minutulum* using the following methods. Marine mussels were smashed with a hammer and placed in a Petri dish with a teaspoon of marine mud. Sterilized seawater was poured into the dish until the mussels sank completely in the solution. The infusion was incubated at 27–28°C and examined for the development of spirilla after 1, 2, and 7 d. Isolation was accomplished by streaking dilutions onto suitable agar media.

Fujii et al. (1990) enriched and isolated *M. megaterium* as follows. A loopful of kusaya gravy was used to inoculate the inlet tube of a horizontal glass tube, in which the inlet and outlet ends were bent upwards. After an appropriate time, the isolates accumulated predominantly in the outlet because of their high motility. By repeating this selective accumulation and purification process, the isolates could almost be purified (by microscopic observation). Isolation was accomplished by streaking a large amount of cells onto the suitable agar medium, because the ability of *M. megaterium* to form colonies on an agar surface was low. The ability to form colonies on the agar surface was lost after subsequent transfers of the culture.

Maintenance Procedures

Marinospirillum species may be maintained on stab cultures in TSSY semi-solid agar, which has the following composition (g/l): Trypticase peptone (BBL), 17.0; Phytone peptone (BBL), 3.0; Yeast nitrogen base (Difco), 1.0; NaCl, 30.0; and agar, 2.0; pH 8.0. Cultures are incubated at 25°C with biweekly transfer. Long-term preservation of *M. minutulum* by freeze-drying has been reported by Terasaki (1975).

Procedures for Testing Special Characters

Characterization methods for marinospirilla have been described in detail by Terasaki (1972, 1973) and Satomi et al. (1998). Media containing natural or artificial seawater or 2.5–3.0% sodium chloride must be used for all characterization tests. Media for *M. megaterium* must be supplemented with 0.1–0.3% agar because the organism requires semisolid media for growth.

Differentiation of the genus *Marinospirillum* from other genera

The genus *Marinospirillum* cannot be differentiated phenotypically from *Oceanospirillum*, but each *Marinospirillum* species can be differentiated from *Oceanospirillum*, by positive nitrate reduction (*M. minutulum*) and a prominent microaerophilic nature with no growth on agar surfaces (*M. megaterium*).

Taxonomic Comments

Phylogenetic analysis based on 16S rDNA gene sequences of the genus *Marinospirillum*, consisting of two species *M. minutulum* and *M. megaterium*, showed that this genus was closely related to the genera *Oceanospirillum* and *Halomonas* in the *Gammaproteobacteria* group (Fig. BXII.γ.109). Although members of the genera *Marinospirillum* and *Oceanospirillum* share helical cell morphology, there is a large phylogenetic distance between *Marinospirillum* and *Oceanospirillum*.

Differentiation of the species of the genus *Marinospirillum*

Table BXII.γ.90 lists the characteristics that differentiate *M. minutulum* from *M. megaterium*.

List of species of the genus Marinospirillum

1. **Marinospirillum minutulum** (Watanabe 1959) Satomi, Kimura, Hayashi, Shouzen, Okuzumi and Fujii 1998, 1346^{VP} (*Oceanospirillum minutulum* (Watanabe 1959) Hylemon, Wells, Krieg and Jannasch 1973, 373; *"Spirillum minutulum"* Watanabe 1959, 83.)

   mi.nu'tu.lum. L. dim. neut. adj. *minutulum* very little.

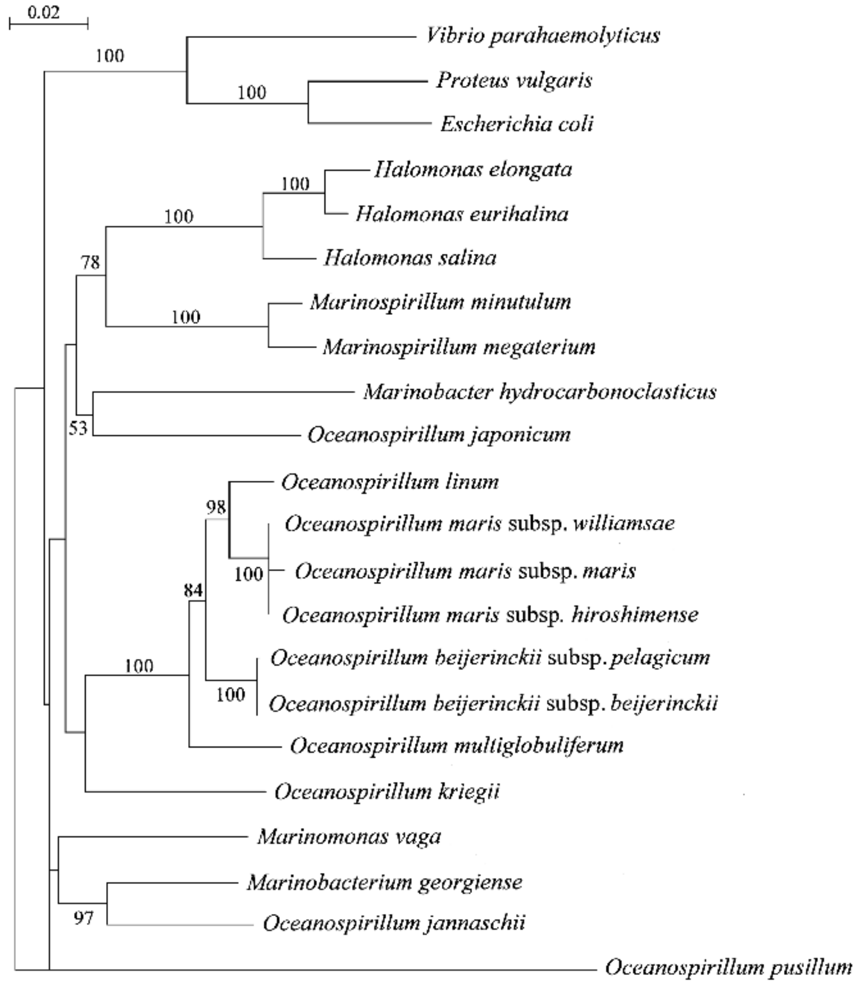

FIGURE BXII.γ.109. Phylogenetic trees of the genus *Marinospirillum* and related bacteria based on the nucleotide sequences of the 16S rRNA gene. The tree was constructed using the neighbor-joining method, and the nucleotide substitution rates (*K*nuc values) were computed by Kimura's 2-parameter model. The scale bar indicates the genetic distance of 0.02 *K*nuc. The numbers at the nodes indicate the percentages of occurrence in 1000 bootstrapped trees. Only values greater than 40% are shown. *Oceanospirillum pusillum* was used as an outgroup. Accession numbers for sequences used: *Marinospirillum minutulum* (AB006769), *M. megaterium* (AB006770), *Oceanospirillum linum* (M22365), *O. maris* subsp. *maris* (AB006771), *O. maris* subsp. *hiroshimense* (AB006762), *O. maris* subsp. *williamsae* (AB006763), *O. beijerinckii* subsp. *beijerinckii* (AB006760), *O. beijerinckii* subsp. *pelagicum* (AB006761), *O. multiglobuliferum* (AB006764), *O. japonicum* (AB006766), *O. kriegii* (AB006767), *O. jannaschii* (AB006765), *O. pusillum* (AB006768), *Halomonas elongata* (X67023), *Halomonas eurihalina* (X87218), *Halomonas salina* (X87217), *Marinomonas vaga* (X67025), *Marinobacter hydrocarbonoclasticus* (X67022), *Marinobacterium georgiense* (U58339), *Vibrio parahaemolyticus* (X56580), *Escherichia coli* (J01859), *Proteus vulgaris* (X07652).

TABLE BXII.γ.90. Characteristics differentiating the species of the genus *Marinospirillum*[a,b]

Characteristic	1. *M. minutulum*[c]	2. *M. megaterium*[d]

1% glycine	+	−

[a]Symbols: see standard definitions.

[b]Data from Satomi et al. (1998).

[c]ATCC 19193.

[d]Strains H7 and Sp5.

Rigid, helical cells with clockwise turns (Terasaki, 1973). Cell diameter, 0.3–0.4 μm; wavelength, 2.0–2.8 μm; helix diameter, 0.6–1.5 μm; length of helix, 3.0–8.0 μm. Coccoid bodies are predominant at 3–4 weeks but not after 24–48 h growth. NaCl is required for growth: optimum concentration, 2.5–3.0%; range 0.2–10%. Optimum temperature, 25–30°C; range, 4–30°C. Optimum pH, 8.0; range, 7.0–10.5. Aerobic. Grow in liquid media under static or aerobic conditions with shaking, or on plates. Catalase positive. Do not hydrolyze gelatin, hippurate, or starch. Reduce nitrate to nitrite. Do not produce DNase, RNase, urease, or phosphatase. The type strain was isolated from putrid infusions of marine mussels.

The mol% G + C of the DNA is: 42–44 (HPLC).
Type strain: ATCC 19193, DSM 6287.
GenBank accession number (16S rRNA): AB006769.

2. **Marinospirillum megaterium** Satomi, Kimura, Hayashi, Shouzen, Okuzumi and Fujii 1998, 1346[VP]
me.ga.te' ri.um. Gr. adj. *mega* large; Gr. n. *teras, teratis* monster, beast; M.L. n. *megaterium* big beast.

Rigid, helical cells, 0.8–1.2 × 5–15 μm, having clockwise turns; thin-walled coccoid bodies 2.0–2.5 μm in diameter. NaCl is required for growth: optimum concentration, 3%; range, 0.5–9.0%. Optimum temperature, 20–25°C; range, 4–25°C. Optimum pH, 8; range, 7.5–9.0. Microaerophilic: no growth occurs in liquid media under static or aerobic conditions with shaking, or on plates. Catalase weakly positive or negative. Do not hydrolyze gelatin, hippurate, or starch. Do not reduce nitrate. Do not produce DNase, RNase, urease, or phosphatase. The type strain was isolated from kusaya gravy.

The mol% G + C of the DNA is: 44–45 (HPLC).
Type strain: H7, JCM 10129.
GenBank accession number (16S rRNA): AB006770.

Genus V. **Neptunomonas** *Hedlund, Geiselbrecht, Bair and Staley 1999b, 1325[VP] (Effective publication: Hedlund, Geiselbrecht, Bair and Staley 1999a, 258)*

Brian P. Hedlund

Nep.tu.no.mo' nas. Rom. myth n. *Neptune* the Roman god of the sea; Gr. n. *monas* a unit, monad; M.L. n. *Neptunomonas* Neptune's monad.

Rod-shaped or slightly curved bacteria. Approximately 0.7–0.9 × 2.0–3.0 μm. (See Fig.BXII.γ.110). Cells may produce a capsule that is visible by India ink staining. Coccoid bodies may predominate in old cultures and are associated with a loss of viability. Poly-β-hydroxybutyrate is accumulated and may form small inclusions that are visible by phase-contrast microscopy. **Motile by a single polar flagellum. Aerobic; however, fermentation tests with some sugars and sugar alcohols are weakly positive. Acid is produced slowly from some carbohydrates. Na^+ is required for growth. Oxidase and catalase positive.** Phosphatase positive. **Utilize some carbohydrates, polycyclic aromatic hydrocarbons**, amino acids, organic acids, and sugar alcohols as sole carbon sources for chemoorganotrophic growth. Temperature range for known strains, ≤4–30°C. Indigenous to coastal marine sediments. Belong to the *Oceanospirillum* group of the class *Gammaproteobacteria* based on phylogenetic analyses of 16S rDNA gene sequences.

The mol% G + C of the DNA is: 46.

Type species: **Neptunomonas naphthovorans** Hedlund, Geiselbrecht, Bair and Staley 1999b, 1325 (Effective publication: Hedlund, Geiselbrecht, Bair and Staley 1999a, 258.)

Further descriptive information

Only one species of *Neptunomonas* is currently known, *N. naphthovorans*.

Polycyclic aromatic hydrocarbon (PAH) catabolism by *N. naphthovorans* strains NAG-2N-113 and NAG-2N-126 has been studied in some detail (Hedlund et al., 1999a). Both strains grow on naphthalene or 2-methylnaphthalene as a sole carbon and energy source. Only strain NAG-2N-113 grows weakly on phenanthrene. Both strains degrade 1-methylnaphthalene and acenaphthene under certain conditions; however, the degradation of these molecules is not coupled to growth. Colonies produce indigo when

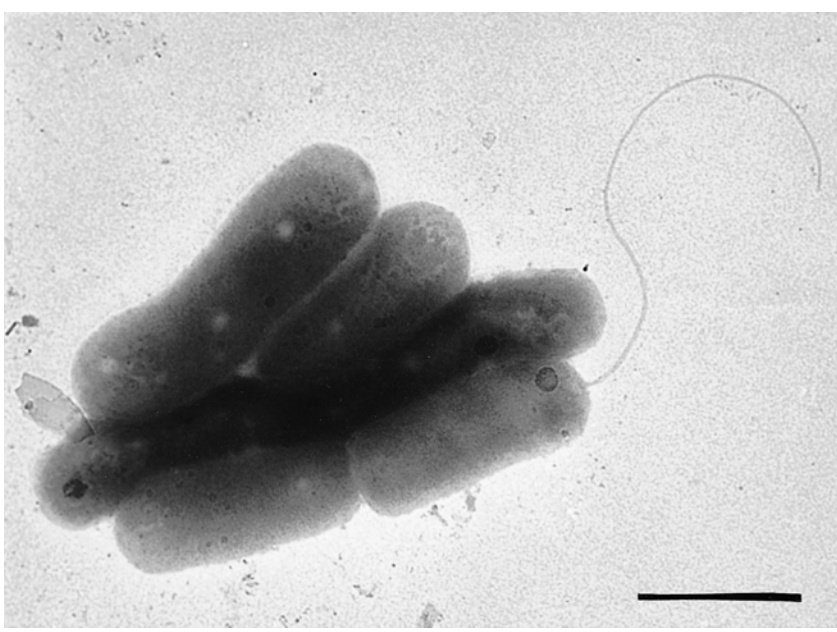

FIGURE BXII.γ.110. Electron micrograph of negatively stained *Neptunomonas naphthovorans* strain NAG-2N-126. Bar = 2 μm. (Reproduced with permission from B. Hedlund et al., Applied and Environmental Microbiology *65:* 251–259, 1999 ©American Society for Microbiology, Washington, D.C.)

naphthalene-induced cells are exposed to indole vapors, a characteristic *Neptunomonas* shares with naphthalene-degrading strains of *Pseudomonas*, *Burkholderia*, and *Marinobacter*, among others. This reaction is catalyzed by the naphthalene dioxygenase. A portion of the gene encoding the naphthalene dioxygenase large subunit has been sequenced from strains NAG-2N-113 and NAG-2N-126; they bear roughly 50–65% sequence identity to *Pseudomonas* and *Burkholderia* naphthalene dioxygenases. However, the low mol% G + C for the *Neptunomonas* dioxygenase gene indicates it is not newly acquired from organisms with a high mol% G + C by horizontal gene transfer. *Neptunomonas* does not produce colored intermediates characteristic of the *meta*-cleavage pathway when grown on naphthalene or other aromatic compounds.

A variety of carbon sources are used by *Neptunomonas* as sole carbon and energy sources, including naphthalene, 2-methylnaphthalene, *p*-hydroxybenzoate, D-fructose, D-glucose, citrate, DL-β-hydroxybutyrate, glutarate, succinate, DL-lactate, pyruvate, L-arginine, L-serine, L-glutamate, acetate, L-proline, DL-alanine, glycerol, mannitol, and D-arabitol.

All strains of this species have been isolated from a single area in Puget Sound near Seattle, WA USA.

Enrichment and Isolation Procedures

Neptunomonas strains have been isolated from coastal marine sediment contaminated with coal tar creosote, which consists mainly of polycyclic aromatic hydrocarbons. Two alternative methods have been used. The first method involves using a most probable number (MPN) approach to enumerate marine bacteria capable of growth on naphthalene and subsequently obtaining isolates from the positive MPN tubes. All manipulations have been done at 4°C with media that have been equilibrated to that temperature for several hours, but whether this is a necessary precaution is not yet known. Serial dilutions (10-fold) of the sediment are made into 5- or 10-ml portions of the artificial seawater solution ONR7a,[1] and naphthalene crystals are added as a sole carbon and energy source. The tubes are typically incubated near *in situ* temperature without shaking and monitored daily for turbidity. It should be noted that *Neptunomonas* strains do not remain viable for long periods in ONR7a with naphthalene; therefore, sampling the dilution tubes within days of the culture becoming turbid is recommended. Samples from positive tubes are diluted with ONR7a, and the dilutions are spread onto plates of ONR7a solidified with 0.8% agarose or onto a complex marine medium, such as Marine Broth 2216 solidified with 1.5% agar. Naphthalene crystals are added to the Petri dish lids, the plates are inverted, and the plates are sealed with Parafilm. If *Neptunomonas* is outnumbered by other naphthalene-degrading bacteria such as *Cycloclasticus*, *Neptunomonas* strains can be selected based on their ability to grow well in complex media such as Difco Marine Broth 2216.

A second isolation method employs a direct plating approach. Sediment is diluted into ONR7a and spread onto plates of ONR7a solidified with 0.8% agarose. Naphthalene crystals are added to the Petri dish lids, the plates are inverted, and then sealed.

Maintenance Procedures

Strains of *Neptunomonas* can be maintained for up to 1 month at 4°C on Parafilm-sealed plates of solidified Difco Marine Broth 2216. Additionally, freezer stocks containing glycerol or DMSO can be stored at −80°C for at least 2 years. Lyophilized cultures have also been revived; however, their long-term viability has not yet been evaluated.

Differentiation of the genus *Neptunomonas* from other genera

The characteristics that differentiate *Neptunomonas* from phylogenetically similar genera are listed in Table BXII.γ.91.

Several other genera of naphthalene-degrading marine bacteria exist, including *Cycloclasticus* (Dyksterhouse et al., 1995), *Marinobacter* (Gauthier et al., 1992), *Vibrio* (Geiselbrecht et al., 1996), *Pseudoalteromonas* (Hedlund et al. 1996a), and *Sphingomonas* (Zylstra, personal communication). Differential characteristics of these bacteria are shown in Table BXII.γ.92. However, it is generally recommended that 16S rRNA genes be sequenced in order to confidently identify new isolates of marine PAH-degraders.

Taxonomic Comments

Based on phylogenetic analyses using nearly complete 16S rRNA gene sequences, *Neptunomonas* is a member of the *Oceanospirillum* group of the class *Gammaproteobacteria*. However, the exact phylogenetic relationship among *Neptunomonas*, *Oceanospirillum*, *Marinomonas*, and *Marinobacterium* is uncertain, as evidenced by the low bootstrap value for the node connecting *Neptunomonas* to the tree (Fig. BXII.γ.111).

The phylogeny and taxonomy of the *Oceanospirillum* group is further complicated by nomenclatural problems associated with some members of the group. Four species, *O. linum*, *O. maris*, *O. beijerinckii*, and *O. multiglobuliferum* form a monophyletic cluster based on rRNA hybridization (Pot et al., 1989), multilocus enzyme electrophoresis (Pot et al., 1989), quinone analysis (Sakane and Yokota, 1994), fatty acid analysis (Sakane and Yokota, 1994), and 16S rRNA gene phylogenetic analysis (Hedlund et al., 1999a). Other taxa, such as *O. kriegii*, and *O. jannaschii*, are not as closely related by any measurement, and it is likely each will be assigned to a new genus. *O. japonicum* is phylogenetically distinct from the true members of the genus *Oceanospirillum*; however, it does share many phenotypic similarities with them. *O. pusillum* obviously should not be included in the genus *Oceanospirillum* since it belongs to the class *Alphaproteobacteria* (Satomi et al., 1998). Therefore, the taxonomy of the *Oceanospirillum* group will likely change dramatically in the near future.

Further Reading

Hedlund, B.P., A.D. Geiselbrecht, T.J. Bair and J.T. Staley. 1999. Polycyclic aromatic hydrocarbon degradation by a new marine bacterium, *Neptunomonas naphthovorans* gen. nov., sp. nov. Appl. Environ. Microbiol. *65*: 251–259.

1. ONR7a consists of several solutions that are prepared separately and mixed when cool. First, a 10× seawater salts solution is prepared, consisting of (g/l distilled water): NaCl, 228; Na_2SO_4, 40; KCl, 7.2; NaBr, 0.83, $NaHCO_3$, 0.31; H_3BO_3, 0.27; and NaF, 0.026. This 10× solution is diluted to 1×, and the following are added (g/l 1× solution): $Na_2HPO_4 \cdot 7H_2O$, 0.089; NH_4Cl, 0.27; and TAPSO buffer (3-[N-tris(hydroxymethyl)methylamino]-2-hydroxypropanesulfonic acid), 1.3. After the solution has been autoclaved and cooled to at least 50°C, 20.0 ml of a 50× divalent cation solution and 5.0 ml of a 200× Fe(II) solution are added per liter. The 50× divalent cations solution, which is prepared and autoclaved separately, contains (g/l): $MgCl_2 \cdot 6H_2O$, 559.1; $CaCl_2 \cdot 2H_2O$, 72.8; and $SrCl_2 \cdot 6H_2O$, 1.21. The 200× solution of Fe(II) is prepared by dissolving 0.04 g of $FeCl_2 \cdot 4H_2O$ with a few drops of concentrated HCl; water is then added to 100 ml, and the solution is sterilized by filtration. Long-term storage of the complete ONR7a solution is not recommended.

List of species of the genus Neptunomonas

1. **Neptunomonas naphthovorans** Hedlund, Geiselbrecht, Bair and Staley 1999b, 1325[VP] (Effective publication: Hedlund, Geiselbrecht, Bair and Staley 1999a, 258.)
naph.tho.vo′ rans. Chem. n. *naphtho-* combining form of *naphthalene*, a white, crystalline hydrocarbon; L. v. *voro* to devour; M.L. part. adj. *naphthovorans* naphthalene-devouring.

The characteristics are as described for the genus and as listed in Table BXII.γ.91. The type strain was isolated from Eagle Harbor, a creosote-contaminated EPA Superfund site in Puget Sound, Washington, USA.

The mol% G + C of the DNA is: 46.3 (T_m).

Type strain: NAG-2N-126, ATCC 700637.

GenBank accession number (16S rRNA): AF053734.

TABLE BXII.γ.91. Characteristics differentiating the genus *Neptunomonas* from related genera[a]

Characteristic	*Neptunomonas*	*Marinobacterium*	*Oceanospirillum*[b]	*O. japonicum*	*O. kriegii*
Cell shape:					
Curved rods	+				+
Straight rods	+	+			+
Spirilla			+	+	
Flagellar arrangement	single polar	single polar	bipolar tufts	bipolar or single tufts	single polar
Cell diameter, μm	0.7–0.9	0.5–0.7	0.3–1.2	0.8–1.4	0.8–1.2
Poly-β-hydroxybutyrate accumulation	+	−	+	+	+
NO_3^- reduced to NO_2^-	−	−	D	−	−
Catalase	+	+	D	w or −	NR
Amylase	−	−	−	−	NR
Gelatinase	−	−	D	d	NR
Lipase	−	+	NR	NR	+
Phosphatase	+	NR	D	w	NR
Acid from carbohydrates	+[c]	−	−	−	−
Carbohydrates fermented	+[c]	−	−	−	−
Temperature range, °C	≤4–30	4–41	2–43	10–43	20–35
Water-soluble, brown pigment	+	NR	D	−	NR
mol% G + C of DNA	46	54.9	45–50	45	54.8

[a]For symbols see standard definitions; NR, not reported; w, weakly positive.

[b]This includes the members of the genus *Oceanospirillum* as described in this book.

[c]Carbohydrate oxidation/fermentation tests were done in PSS media (Hylemon et al., 1973). Acidification took up to two weeks to occur.

TABLE BXII.γ.92. Differentiation of *Neptunomonas* from some other marine naphthalene-degrading bacteria[a,b]

Characteristic	*Neptunomonas*	*Cycloclasticus*	*Marinobacter*	*Pseudoalteromonas*	*Vibrio*
Indigo from indole[c]	+	−	+	d	−
Utilization of phenanthrene[c]	− or w	+	−[d]	d	+
Na^+ requirement	+	+	D	+	+[e]
Growth on marine broth 2216	+	− or w	+	+	+
Utilization of carbohydrates	+	−	−	+	+
D-glucose	+	−	−	+	+
D-fructose	+	−	−	d	D
Utilization of amino acids	+	+[f]	+[g]	+	+
Acid from D-glucose	+ or w	NG	−	−	+
mol% G + C	46	39	57.3–57.7[d]	37–50	38–51

[a]For symbols see standard definitions; NG, no growth in test medium; w, weakly positive.

[b]Marine bacteria are defined here as requiring Na^+ ions for growth. Taxa that have not been fully described are not considered here.

[c]The results for these phenotypes are only given for naphthalene-degrading strains. Otherwise, characteristics are generalized to encompass the whole genus.

[d]For these features we used the results of Spröer et al. (1998), which differ from those obtained previously (Gauthier et al., 1992).

[e]All *Vibrio* strains require Na^+ except *V. cholerae.*

[f]*Cycloclasticus* utilizes only L-glutamate.

[g]*Marinobacter* utilizes only L-proline and L-glutamate.

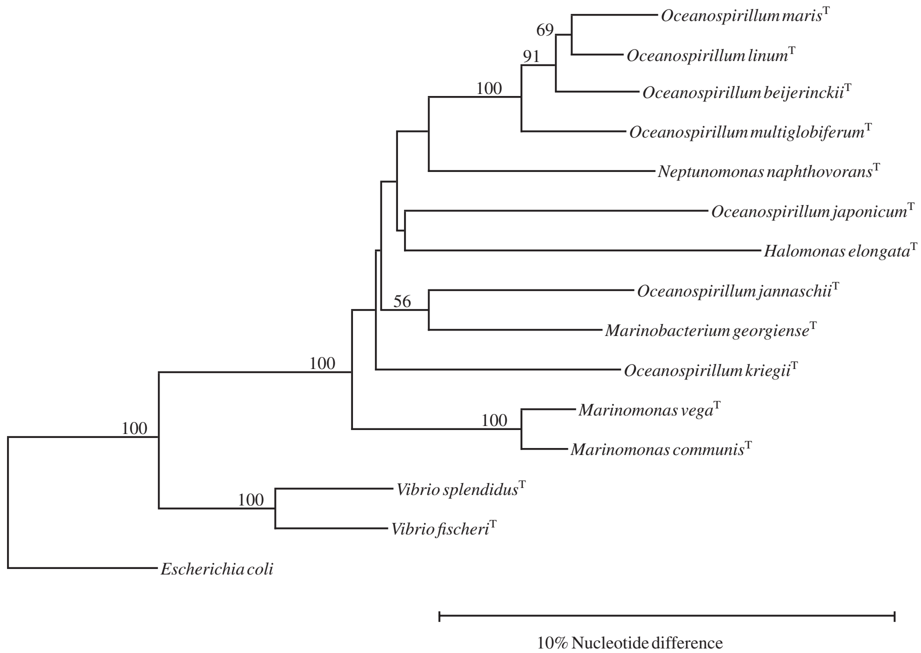

FIGURE BXII.γ.111. Dendrogram showing the relationship between *Neptunomonas* and its close relatives. The dendrogram was created in TreeCon using Jukes-Cantor distance with the Kimura 2–parameter correction. Numbers at branch nodes represent bootstrap values for 100 replications. Numbers below 50 are not shown. (Reproduced with permission from B. Hedlund et al., Applied and Environmental Microbiology *65:* 251–259, 1999 ©American Society for Microbiology, Washington, D.C.)

Family II. **Alcanivoraceae** *fam. nov.*

PETER N. GOLYSHIN, SHIGEAKI HARAYAMA, KENNETH N. TIMMIS AND MICHAIL M. YAKIMOV

Al.ca.ni.vo.ra'.ce.ae. M.L. masc. n. *Alcanivorax* type genus of the family; *-aceae* ending to denote family; M.L. masc. pl. n. *Alcanivoraceae* the *Alcanivorax* family.

Rods 0.6–0.8 × 1.6–2.5 µm in size, depending on the substrate used for growth. Some isolates are capable of anaerobic growth. Reduce nitrate to nitrite. **Principal carbon and energy sources are linear-chain alkanes and their derivatives**, with carbon chain length between 9 and 20. Only a few simple organic compounds are used as carbon and energy source (formate, acetate, propionate, methyl-pyruvate, and α-ketoglutarate). **Moderately halophilic**, NaCl content optimal for growth is between 3 and 10%. Strains of all recognized species and recent isolates are mesophilic, with the temperature optima about 25–30°C. Some isolates produce glucose lipid surfactants.

Type genus: **Alcanivorax** Yakimov, Golyshin, Lang, Moore, Abraham, Lünsdorf and Timmis 1998, 346.

Genus I. **Alcanivorax** *Yakimov, Golyshin, Lang, Moore, Abraham, Lünsdorf and Timmis 1998, 346[VP]*

PETER N. GOLYSHIN, SHIGEAKI HARAYAMA, KENNETH N. TIMMIS AND MICHAIL M. YAKIMOV

Al.ca.ni.vo'.rax. M.L. masc. n. *alcanum* alkane, aliphatic hydrocarbon; L. adj. *vorax* voracious, gluttonous; M.L. masc. n. *Alcanivorax* alkane-devouring.

Rods 0.6–0.8 × 1.6–2.5 µm when grown in pyruvate-supplemented medium and 0.6–0.8 × 1.0–1.5 µm when grown on *n*-alkanes. Nonmotile. Gram negative. Colonies 2–3 days old are circular, colorless, and transparent; in older cultures, they turn opaque and light yellow if grown on alkanes. **Aerobic and microaerophilic**, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Nitrate is reduced to nitrite, but anaerobic growth does not occur on nitrate. **Oxidase and catalase positive. Growth occurs on aliphatic hydrocarbons as sole or principal carbon sources.** Some strains produce glucose lipid surfactants that exist in two forms. **Moderately halophilic**; optimum NaCl concentration 3% (range 0.5–15%). Isolated from seawater and seawater sediments enriched with crude oil, petroleum hydrocarbons, or single aliphatic hydrocarbons.

The mol% G + C of the DNA is: 53–66.

Type species: **Alcanivorax borkumensis** Yakimov, Golyshin, Lang, Moore, Abraham, Lünsdorf and Timmis 1998, 347.

FURTHER DESCRIPTIVE INFORMATION

Some strains produce a glycine-containing biosurfactant precursor that is linked to the cell surface and increases the hydro-

phobicity of the cells and their affinity to oil droplets suspended in the water phase. Some strains produce another form—the mature extracellular glucose lipid biosurfactant, which lacks the terminal glycine residue, and which forms micelles with water-insoluble oil fractions, thereby increasing their bioavailability.

These organisms are distributed in natural marine environments around the world, and their predominance in microbial communities accidentally polluted, or experimentally spiked with oil, suggests on important role in natural petroleum biodegradation (Harayama et al., 1999).

Strains of *"Alcanivoraceae"* were isolated or detected in 16S rDNA clone libraries from different geographic locations (Table BXII.γ.93).

Genome format The genome size estimated for *Alcanivorax borkumensis* SK2T and AP1 is about 3 Mbp. Up to now, no plasmids have been detected in these bacteria.

Isolates of *Alcanivorax* are amenable to conjugative DNA transfer, and transposon mutagenesis (miniTn5-mutagenesis has been characterized by a random positioning of the inserts in the chromosome of *A. borkumensis* strain SK2T with an appropriate antibiotic marker (chloramphenicol, streptomycin/spectinomycin). Although isolates are sensitive to kanamycin, the relatively high salinity of common *Alcanivorax* growth media interferes with the use of this antibiotic marker for selection purposes.

The fluorescent *in situ* hybridization probe 5′-CCA AGA ATA CTA AGA TTC CC—complementary to rRNA between nucleotides 821-842 (*E. coli* numbering)—labeled with Cy3 to detect *"Alcanivoraceae"* in environmental samples has given satisfactory results under stringent conditions (35% (w/vol) formamide; hybridization at 46°C for 2 h). Probes that distinguish *Fundibacter* and *Alcanivorax* species hybridize to 16S rRNA between nucleotides 203 and 223 (*E. coli* numbering); these probes are 5′-GCG AGC TCA TCC ATC **T**GC A and 5′-GCG AGC TCA TCC ATC **A**GC A, respectively (mismatches are shown in boldface type).

Enrichment and Isolation Procedures

The principal sources of these organisms are seawater and seawater sediments, enriched with crude oil, petroleum hydrocarbons, or single aliphatic hydrocarbons. *n*-Hexadecane can serve as the sole carbon source for enrichment of the seawater/sediment samples; addition of nitrogen and phosphorus is required. The flat, colorless, transparent colonies of *Alcanivorax*-related strains develop on the agar surface within 3–5 d after plating. After incubation for longer than 1 week, colonies turn opaque and cream-colored.

Differentiation of the genus *Alcanivorax* from other genera

Characteristics that differentiate the genus from other related or phenotypically similar genera are given in Table BXII.γ.94.

Taxonomic Comments

The analysis of 16S rRNA gene sequencing data of both recognized and recently isolated strains belonging to the genera *Alcanivorax* and *Fundibacter* (Yakimov et al., 1998; Bruns and Berthe-Corti, 1999) suggest these bacteria belong to a distinct taxonomic group, presumably a new family, *"Alcanivoraceae"*, phylogenetically equidistant from the characterized lineages of the class *Gammaproteobacteria*, *"Alteromonadaceae"*, *Halomonas* spp., belonging to *Halomonadaceae* and members of family *Oceanospirillaceae* (Fig. BXII.γ.112).

A controversy exists regarding the taxonomic position of the

TABLE BXII.γ.93. List of strains relevant to the genus *Alcanivorax* and clones derived from 16S rRNA gene libraries from different geographic locations

Strain/clone designation	Origin	Notes
Alcanivorax borkumensis SK2, DSM 11573^T	Isle of Borkum, North Sea	Type and only species of *Alcanivorax*
Alcanivorax jadensis T9, DSM 12178^T	Jadebusen, North Sea	Formerly known as *Fundibacter jadensis* T9
Alcanivorax borkumensis AP1, SK, SK1, SK4A, SK7, MM1[a]	Isle of Borkum, North Sea	Isolates obtained from the enrichments along with the type strain SK2
Alcanivorax sp. ME104[a]	Mediterranean Sea, Harbor of Messina, Sicily	98% 16S rRNA gene similarity with the type strain
Alcanivorax borkumensis ME103, ME106, ME111[a]	Mediterranean Sea, Harbor of Messina, Sicily	100% 16S rRNA gene similarity with the type strain
Alcanivorax borkumensis LE4	Singapore shore	100% 16S rRNA gene similarity with the type strain
Alcanivorax sp. SCB54	California (E. Pacific)	Partially sequenced environmental clone
Alcanivorax sp. ME105, ME112[a]	Mediterranean Sea, Harbor of Messina, Sicily	95–98% 16S rRNA gene similarity with the type strain

[b] Modified from Yakimov et al. (1998).

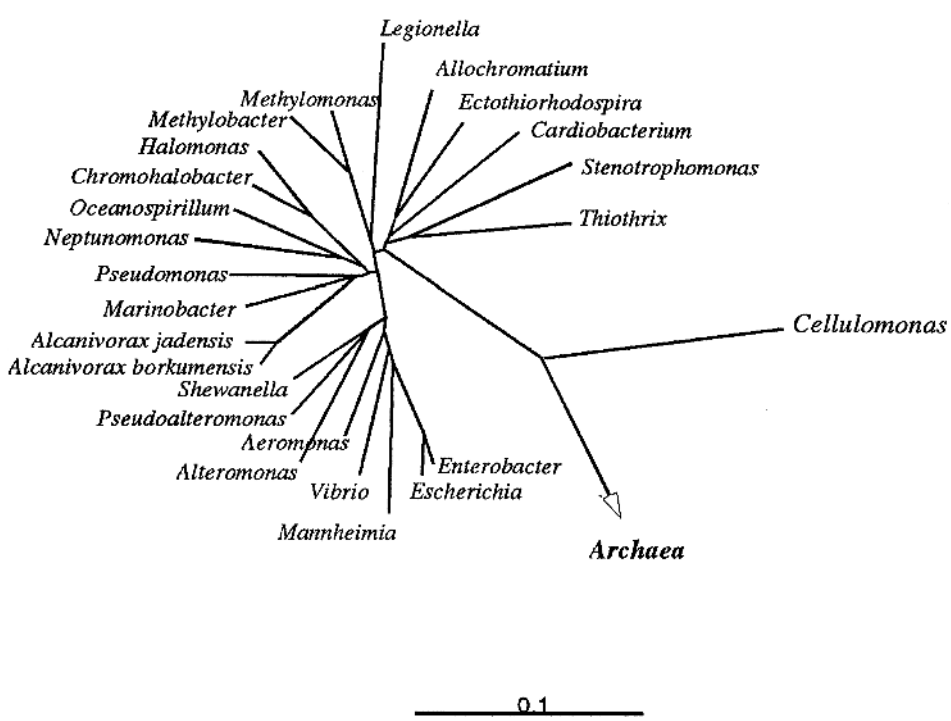

FIGURE BXII.γ.112. Phylogenetic position of species of genus *Alcanivorax* among principal genera within *Gammaproteobacteria*. Phylogenetic tree was rooted from an archaeon, *Pyrodictium occultum*, and *Cellulomonas* was used as an outgroup. The scale bar represents 0.1 fixed point mutation per sequence position. *Fundibacter jadensis* was transferred to the genus *Alcanivorax* as *Alcanivorax jadensis* (González and Whitman, 2002; Fernández-Martínez et al., 2003).

genus *Fundibacter* (see Other Organisms, below). Because two validly described genera—*Alcanivorax* (Yakimov, Golyshin, Lang, Moore, Abraham, Lünsdorf and Timmis, 1998) and *Fundibacter* (Bruns and Berthe-Corti, 1999)—share significant 16S rRNA homology (about 98%) and because no clear-cut phenotypic differentiation can be drawn between these genera, which were isolated from similar environmental sources (German North Sea, alkane-enriched aerobic pelagic sediments), it appears appropriate to assign the genus *Fundibacter* to the genus *Alcanivorax.* DNA/DNA hybridization studies between *A. borkumensis* and *F. jadensis* clearly indicate, however, that these two organisms do not belong to the same species (Steiner and Tindall, personal communication).

The sequencing of *gyrB* genes from above type cultures and a large number of recently isolated—but not validly published—*Alcanivorax* strains suggest existence of at least five genotypically distinct groups, presumably at the level of species (Fig. BXII.γ.113).

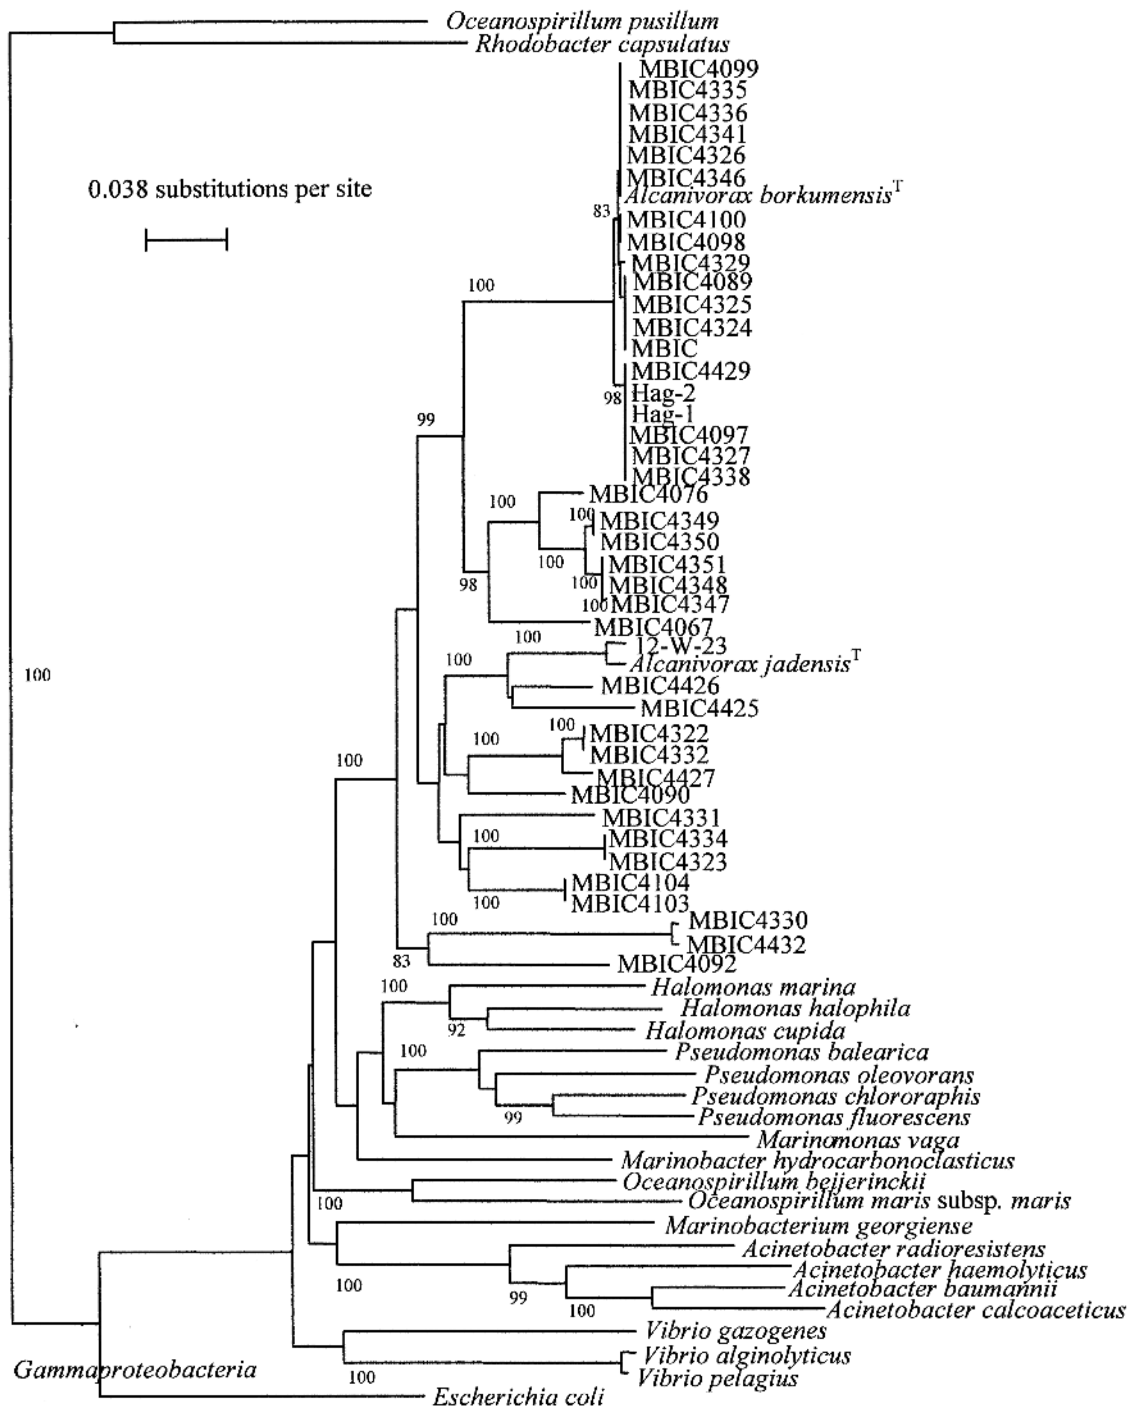

FIGURE BXII.γ.113. Phylogenetic tree derived from the similarities between the *gyrB* sequences. Bootstrap values over 80% are shown at the branch points. Strains are listed in Table BXII.γ.93. *Fundibacter jadensis* was transferred to the genus *Alcanivorax* as *Alcanivorax jadensis* (González and Whitman, 2002; Fernández-Martínez et al., 2003).

List of species of the genus Alcanivorax

1. **Alcanivorax borkumensis** Yakimov, Golyshin, Lang, Moore, Abraham, Lünsdorf and Timmis 1998, 347[VP]
bor.ku.me'n.sis. M.L. adj. *borkumensis* from the island of Borkum, a small island in Western-Elms harbor in the North Sea, located close to the German-Dutch border.

The characteristics are as described for the genus, with the following additional information. Optimum temperature 20–30°C; range, 10–35°C. Optimum NaCl concentration 3–10%; range, 1.0–12.5%. Reduce nitrate to nitrite, though no anaerobic growth occurs. Do not produce agarase, amylase, arginine dihydrolase, ornithine decarboxylase, lysine decarboxylase, gelatinase, or esculinase. Exhibit Tween 80 hydrolysis. Utilize aliphatic hydrocarbons (formate, acetate, propionate, methylpyruvate, α-ketoglutarate) and some short-chain fatty acids as sole or principal carbon source. Produce glucose lipids (Fig. BXII.γ.114) that exist in two forms: a glycine-containing biosurfactant precursor and the mature extracellular glucose lipid. Principal fatty acids are $C_{16:0}$, $C_{16:1}$, and $C_{18:1}$. Resistant to ampicillin, tetracycline, nalidixic acid; sensitive to streptomycin/spectinomycin, chloramphenicol, kanamycin.

The mol% G + C of the DNA is: 53.4 (HPLC).
Type strain: SK2, ATCC 700651, CIP 105606, DSM 11573.
GenBank accession number (16S rRNA): Y12579.

2. **Alcanivorax jadensis** Fernández-Martínez, Pujalte, García-Martínez, Mata, Garay, and Rodríguez-Valera 2003, 337[VP] (*Fundibacter jadensis* Bruns and Berthe-Corti 1999, 447.)
ja.den'sis. M. L. adj. *jadensis* referring to the region Jade, which forms part of the bay "Jadebusen", which belongs to the German North Sea coast.

Rods 0.3–0.7 µm wide and 0.8–1.8 µm long. Nonmotile. Pili are present. Gram negative. Colonies are circular, 0.25–1.25 mm in diameter and ivory-pigmented. The temperature spectrum ranges from 10–40°C, with optimal growth occurring at 30°C. Shows weak halotolerance and grows at NaCl concentrations ranging from 0.5–15% (w/v); optimum, 3%. It is able to grow both aerobically and anaerobically, and reduces nitrate. It grows with the carbon sources pyruvate and acetate if a synthetic medium is used and also with tetradecane, hexadecane, and pristane if the medium is supplemented with vitamins and mineral salts. The cells are resistant to ampicillin, cefazolin, cephalotin, erythromycin, linomycin, nalidixic acid, novobiocin, ofloxacin, oxacillin, penicillin, and tetracycline. Oxidase and catalase positive. Growth occurs on aliphatic hydrocarbons as the sole or principal carbon source (tetradecane, hexadecane, and pristane). Pyruvate and acetate can be used. The organisms emulsify alkanes, but do not produce glucose lipid.

The mol% G + C of the DNA is: 63.6 (T_m).
Type strain: T9, ATCC 700854, DSM 12178.
GenBank accession number (16S rRNA): AJ001150.

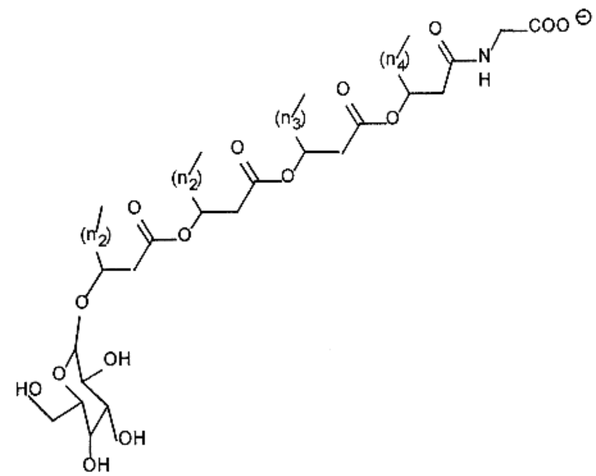

FIGURE BXII.γ.114. Cell-associated glucose lipid from *A. borkumensis* SK2[T].

Family III. **Hahellaceae** *fam. nov.*

George M. Garrity, Julia A. Bell and Timothy Lilburn

Ha. hel.la' ce.ae. M.L. fem. n. *Hahella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Hahellaceae* the *Hahella* family.

The family *Hahellaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the family contains the genera *Hahella* (type genus) and *Zooshikella*. *Zooshikella* was proposed after the cut-off date for inclusion in this volume (June 30, 2001) and is not described here (see Yi et al. (2003)).

Aerobic or facultatively anaerobic chemoorganotrophs. Require NaCl for growth.

Type genus: **Hahella** Lee, Chun, Moon, Ko, Lee, Lee and Bae 2001a, 664[VP].

Genus I. **Hahella** *Lee, Chun, Moon, Ko, Lee, Lee and Bae 2001a, 664*[VP]

THE EDITORIAL BOARD

Ha. hel' la. M.L. fem. n. named after Yung Chil Hah, a Korean bacteriologist who pioneered microbiological research in Korea.

Gram-negative motile rod. Facultatively anaerobic; produces acid from sugars. Reduces nitrate to nitrite. Hydrolyzes esculin and gelatin. **Produces extracellular polysaccharides and red pigment. Requires NaCl.**

The mol% G + C of the DNA is: 55.

Type species: **Hahella chejuensis** Lee, Chun, Moon, Ko, Lee, Lee and Bae 2001a, 665.

FURTHER DESCRIPTIVE INFORMATION

Analysis of 16S rDNA sequences showed that *Hahella chejuensis* is a member of the *Gammaproteobacteria* but is not closely related to any known genera (Lee et al., 2001a).

ENRICHMENT AND ISOLATION PROCEDURES

The strain was isolated directly from diluted marine sediment spread on ZoBell's medium (Lee et al., 2001a).

MAINTENANCE PROCEDURES

The strain was stored at −80° in 20% (w/v) glycerol (Lee et al., 2001a).

DIFFERENTIATION OF THE GENUS *HAHELLA* FROM OTHER GENERA

Lee et al. (2001a) provide a table of characteristics that differentiate *Hahella chejuensis* from other marine/halophilic bacteria in the *Gammaproteobacteria*.

List of species of the genus Hahella

1. **Hahella chejuensis** Lee, Chun, Moon, Ko, Lee, Lee and Bae 2001a, 665[VP]

   che.ju.en' sis. M.L. adj. *chejuensis* pertaining to Cheju Island, Republic of Korea, geographical origin of the type strain of the species.

   Young cells 0.5–0.7 × 1.6–9.0 µm; older cells 0.7–0.8 × 1.4–1.7 µm. Halophilic; produces red pigment soluble in methanol. Growth at 1–8% NaCl (optimum 2% NaCl), 10–45°C, and pH 6–10 (optimum pH 7). Grows on and produces acid from adonitol, D(+)-fructose, D(+)-glucose, inositol, D(+)-maltose, D(−)-mannitol, D(+)-mannose, D(−)-sorbitol, sucrose, and D(+)-trehalose. Does not grow on L(+)-arabinose, citrate, D(+)-galactose, D(+)-lactose, malate, malonate, D(+)-melibiose, D(+)-raffinose, L(+)-rhamnose, and D(+)-xylose. Major fatty acids octadecenoic, *cis*-9-hexadecenoic/*iso*-2-hydroxypentadecanoic, hexadecanoic, and 3-hydroxydodecanoic.

   The mol% G + C of the DNA is: 55 (T_m).

   Type strain: 96CJ10356, KCTC 2396, IMSNU 11157.

   GenBank accession number (16S rRNA): AF195410.

Family IV. **Halomonadaceae** Franzmann, Wehmeyer and Stackebrandt 1989, 205[VP] emend. Dobson and Franzmann 1996, 558

GEORGE M. GARRITY, JULIA A. BELL AND TIMOTHY LILBURN

Ha.lo.mo.na.da' ce.ae. M.L. fem. n. *Halomonas* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Halomonadaceae* the *Halomonas* family.

The family *Halomonadaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rDNA sequences; the family contains the genera *Halomonas* (type genus), *Carnimonas*, *Chromohalobacter*, *Cobetia*, *Deleya*, and *Zymobacter*. *Cobetia* was proposed after the cut-off date for inclusion in this volume (June 30, 2001) and is not described here (see Arahal et al. (2002a)).

Halotolerant or halophilic, except for *Zymomonas*. Motile by means of flagella. Aerobic or facultatively anaerobic chemoorganotrophs.

Type genus: **Halomonas** Vreeland, Litchfield, Martin, and Elliot 1980, 494[VP] emend. Dobson and Franzmann 1996, 557.

Genus I. **Halomonas** *Vreeland, Litchfield, Martin, and Elliot 1980, 494*[VP] *emend. Dobson and Franzmann 1996, 557*

RUSSELL H. VREELAND

Ha.lo.mo' nas. Gr. n. *hals, halos* salt of the sea; Gr. n. *monas* a unit, monad; M.L. fem. n. *Halomonas* salt(-tolerant) monad.

Straight or curved rod shaped cells, generally 0.6–0.8 × 1.6–1.9 µm. One species (*H. halodenitrificans*) presents coccoid cells. Species may form elongated, flexuous filaments under certain conditions. Endospores are not formed. **Gram negative. Rod shaped species are motile** by lateral, polar, or peritrichous flagella. Colonies are white or yellow, turning light brown with age. **Possess a mainly respiratory type of metabolism with oxygen as the terminal electron acceptor.** Some species are also capable of anaerobic growth in the presence of nitrate. Some species have been reported to grow under anaerobic conditions in the absence of nitrate if supplied with glucose (but not other carbohydrates or amino acids). Nitrate is reduced to nitrite; nitrogen

gas is not formed. All species tested are catalase positive; 17 of the 21 known species are also oxidase positive. Chemoorganotrophic. Carbohydrates, amino acids, polyols, and hydrocarbons can serve as sole carbon sources in mineral media. Ammonium sulfate can serve as a sole nitrogen source. **Intracellular granules are not produced. Halotolerant** (also described as slight to moderate halophiles), **able to grow in NaCl concentrations ranging from 0.1–32.5% (w/v).** The major respiratory quinone is ubiquinone 9. The major fatty acids are $C_{16:1}$, $C_{17:0\ cyc}$, $C_{16:0}$, $C_{18:1}$, and $C_{19:0\ cyc}$. In addition to having the signature sequences found in the *Halomonadaceae*, *Halomonas* species contain the following four signature bases (by *E. coli* numbering): C at position 1424, U at position 1439, A at position 1462, and C at position 1464. **Isolated from saline environments around the world**, including solar salt facilities, intertidal estuaries, the open ocean, and hypersaline lakes (Dead Sea, Israel; Organic Lake, Antarctica).

The mol% G + C of the DNA is: 52–68.

Type species: **Halomonas elongata** Vreeland, Litchfield, Martin and Elliot 1980, 495.

Further descriptive information

During exponential growth, 20 of the 21 *Halomonas* species consist of mixtures of straight and curved rods. Upon entry into stationary phase, several *Halomonas* species also form elongated, flexuous filaments of various lengths. The percentage and length of these elongated cells depends upon the type of growth medium. In complex Casamino acids medium (CAS)[1] with 8% NaCl, all of the cells may be elongated, with many filaments containing irregular loops and bends. In a chemically defined mineral salts medium (MS)[2] containing 8% NaCl, as few as 25% of the cells may be elongated, and the filaments seldom produce irregular looping or extensive bending.

Electron microscopy of thin sections from optimum growth conditions reveals a typical Gram-negative type of cell wall (Vreeland and Martin, 1980).

The number and arrangement of flagella on short cells depends upon the species examined. Cells generally possess 4–7 flagella. In some strains, the flagella are arranged laterally, while others possess only polar flagella. One biovar of this genus has both lateral and polar flagellation. Motile *Halomonas* cells describe a helix when viewed by light microscopy. Motility is generally lost rapidly under low oxygen concentrations. Flagella have not been observed on elongated cells or on cells grown in low NaCl concentrations (<0.2%).

On solid CAS or MS medium containing 8% NaCl, most *Halomonas* colonies are white to cream-colored, smooth, glistening, opaque, and ~2 mm in diameter after 24 h at 30°C. The colonies generally become yellow to light brown and spread following prolonged incubation.

Halomonas species require Na^+ for growth—at least 0.1% w/v NaCl added to CAS medium or 0.3% w/v NaCl added to MS medium—and will grow in a wide range of NaCl concentrations (0.1–32% NaCl w/v). When subjected to osmotic shock from either rapid dilution or increased NaCl concentration, *Halomonas* cells respond as osmometers and exhibit swelling or plasmolysis. Osmotically shocked *Halomonas* cells do not lose viability and soon reestablish osmotic balance and resume growth. This reestablishment of osmotic balance is mediated by an increased concentration of ectoine, which is the primary compatible solute found in *H. elongata*. The optimum NaCl concentration is 2.2–8.0% at 30°C. The Na^+ requirement of the type species can be satisfied by NaCl, $NaNO_3$, or NaBr (Vreeland and Martin, 1980). The NaCl requirement of the other species has not been tested in detail. NaCl tolerance is affected by growth temperature, but apparently not by the carbon source being used (Vreeland and Martin, 1980). In terms of the ability to promote salt tolerance, temperatures can be arranged from greatest degree of promotion to least as follows: 30°C, 23°C, 37°C, 15°C, 45°C, 4°C (Vreeland et al., 1980).

In CAS medium containing 8% NaCl, the *Halomonas* species that have been tested grow at pH values from 5.0–9.0. Alkaliphilic strains generally grow from pH 7.0–11.0 with an optimum at 9.5. The pH tolerance has not been tested on MS medium and has not been tested at different temperatures.

The physiological characteristics of all properly recognized *Halomonas* species are listed in Tables BXII.γ.95 and BXII.γ.96. Although considered mainly aerobic, some *Halomonas* species have been reported to grow on glucose under anaerobic conditions in the absence of nitrate or other terminal electron acceptors. If the glucose is replaced by other carbohydrates or an amino acid, nitrate is required for anaerobic growth.

Members of the genus are nutritionally versatile. The following compounds often serve as sole carbon sources for growth: glucose, gluconate, glycerol, fructose, mannose, sucrose, cellobiose, succinate, mannitol, alanine, glutamine, glutamate, asparagine, aspartate, lysine, histidine, phenylalanine, tyrosine, tryptophan, proline, arginine, leucine, isoleucine, valine, methionine, cysteine, serine, and threonine.

Halomonas species have been isolated from a solar salt facility on the island of Bonaire, Netherlands Antilles (Vreeland et al., 1980) from the Dead Sea and Canada (Huval et al., 1995), the Antarctic (Franzmann et al., 1987; James et al., 1990a), Great Salt Lake, Utah (Fendrich, 1988), estuaries (Hebert and Vreeland, 1987), and the Pacific Ocean (Baumann et al., 1983a). Representatives of the genus may be even more widespread in nature.

Enrichment and Isolation Procedures

Halomonas species may be isolated using a wide variety of media. Brine samples can be spread onto the surface of the medium and incubated at close to the environmental temperature and under high humidity for 2–7 d. *Halomonas* colonies are white to cream colored and easily distinguished from red-pigmented halophiles. Alternatively, the brine samples can be added directly to filter pads saturated with medium. This method has the advantage of allowing the use of small (9 mm) Petri plates, facilitating shipment to distant field areas. A disadvantage of the technique is that the white *Halomonas* colonies can be difficult to see

1. CAS medium is a modification of the medium of Abram and Gibbons, as described by Gibbons (1969), and contains (g/l of distilled water): yeast extract, 1.0; casamino acids (Difco) (not "vitamin-free"), 7.5; Proteose peptone No. 3 (Difco), 5.0; sodium citrate, 3.0; $MgSO_4 \cdot 7H_2O$, 20.0; K_2HPO_4, 7.5; and NaCl (or solar salt), 80.0. The pH is adjusted to 8.0 ± 0.1 with NaOH prior to sterilization and is 7.5 ± 0.1 after autoclaving at 121°C for 20 minutes (Vreeland et al., 1980, 1984). CAS medium is stable for several weeks when stored in the dark. It should be discarded if any crystal formation is seen.

2. MS medium is similar to that described by Vreeland and Martin (1980). It contains (g/l): $MgCl_2 \cdot 6H_2O$, 5.3; KCl 0.75; and $(NH_4)_2SO_4$, 4.1. It is supplemented with a carbon source (10–50 mM) and NaCl (2.92–198.7 g/l). Phosphate ($K_2HPO_4 \cdot 3H_2O$) is added as a sterile 10× concentrate after the medium has been autoclaved to give a final concentration of 0.5 g/l. The medium may also be supplemented with $CaCl_2$ (0.11 g/l) to enhance growth. The pH of the medium is adjusted to 7.2 with 1 N KOH prior to autoclaving and is 7.0 after sterilization.

on white filter pads; also, the pad fiber makes colonial isolation tedious.

A more direct isolation technique is to take advantage of the halotolerance of all of the species by setting up a salt-mediated selection medium. High salt brines can be mixed with low salt or distilled water, then spread onto a low salt medium. Alternatively, low salt samples can be added to high salt media to select for salt-tolerant organisms.

Maintenance Procedures

Halomonas strains can be maintained on agar slants containing 8% (w/v) NaCl. Stock cultures are transferred every 6 months, allowed to grow at 30°C for 1–7 d, and then stored in the dark at 4°C (Vreeland et al., 1980). Some media that have proven useful for growing Halomonas are HSC medium[3], MH medium[4], and AOL medium[5].

Most species of *Halomonas* have been lyophilized, but survival rates may vary with the strain and species. *Halomonas elongata* strains ATCC 33173 and 33174 have survived for up to 2 years. The growth from a fresh CAS slant or broth is suspended in 0.5 ml of a solution containing Proteose peptone No. 3 (Difco) (0.5%), yeast extract (1.0%), and NaCl (0.2%). A small amount of the suspension (0.1–0.2 ml) is transferred to a lyophilization vial, dipped into liquid N_2 for 5–10 min, and lyophilized. Preserved cultures are reconstituted by suspending the cells in a small amount of CAS lacking salt. After 15–30 min, the cells are transferred to CAS broth containing NaCl and incubated at 30°C.

Halomonas strains may also be stored frozen on ceramic Protec® or Microbank® beads at −80°C. When using ceramic beads, it is best to grow the cultures under optimum growth conditions and then add the culture to fresh medium and place it onto the pre-sterilized beads. The cultures may then be reincubated at 37°C for several hours to overnight to allow time for the cells to attach to the beads. After this incubation, the fluid may be drawn off and the culture frozen. *Halomonas* cultures have been preserved for up to 10 years using this technique; however, the quality of the culture has been found to deteriorate slowly under these conditions (R. Vreeland, unpublished observations).

Halomonas may also be stored frozen on ceramic beads under liquid N_2. Due to the variation in survival rates for other storage methods, liquid N_2 storage is the method of choice for long-term preservation.

Procedures for Testing Special Characters

A common characteristic of all *Halomonas* species is their ability to grow at a wide variety of salt concentrations. Huval and Vreeland (unpublished studies) have determined that the phenotypic characteristics of these bacteria are often affected by the salt concentration of the growth and testing medium. These effects are particularly noticeable at the low and high salt extremes. This aspect has also been encountered by Hebert and Vreeland (1987) during their characterization of *Halomonas halodurans*. Consequently, prior to conducting any taxonomic analysis on isolates suspected of belonging to *Halomonas*, the optimum growth conditions with respect to NaCl concentration, temperature, and pH must be determined. These characteristics are best tested by use of complex media, each containing 0, 3.5, 8.0, 15.0, 20.0, or 32.0% (w/v) NaCl or solar salt. Temperature tolerance and qualitative effects of temperature on salt tolerance can be tested by incubating tubes of each salt concentration at temperatures from 4–45°C. After 2–3 weeks, all tubes without visible growth should be incubated for an additional 2–3 weeks at the optimum temperature to determine whether any apparent inhibitory conditions have actually been lethal (Vreeland, 1993).

DNA may be extracted from *Halomonas* by the method of Marmur (1961) with some modification. *Halomonas* suspensions and the sodium dodecyl sulfate (SDS) used for lysis must be heated to 50°C. Following SDS addition (2% final concentration), the lysate is held at 50°C for 15 min. Pronase is not added to the suspension. Water-saturated phenol (also at 50°C) is then added to fully denature the protein. The preparation may then be cooled to room temperature and the rest of the Marmur procedure followed. This modification is necessary since some *Halomonas* strains possess a nuclease, which, unless inactivated by heating, causes rapid breakdown of DNA following cell lysis.

All other characterization tests may be performed using conventional techniques (Holding and Collee, 1971; Vreeland, 1993). All media are supplemented with NaCl at the optimum concentration, as determined above. Uninoculated controls are necessary to ensure that any reactions detected are not artifacts caused by the NaCl.

Differentiation of the genus *Halomonas* from other genera

Halomonas is easily differentiated from such genera as *Zymomonas*, *Cellvibrio*, *Oceanospirillum*, or *Serpens* on the basis of salt tolerance, fermentative ability, flexibility, high mol% G + C value, and the ability to catabolize several carbohydrates. *Halomonas* can be quickly differentiated from other genera by its ability to survive exposure to, and to grow in, very high (20%) NaCl concentrations.

Taxonomic Comments

The genus *Halomonas* currently contains 23 recognized, validly named species, which have been included because of the simi-

3. HSC medium is prepared as two separate solutions (A and B). Solution A contains NaCl or solar salt (25%, w/v); the pH is adjusted to 11 with 1 N NaOH, and "vitamin-free" casein (Difco) is added to a concentration of 15 g/l. This mixture is incubated at 30°C overnight to allow protein acidic groups to be exposed. The pH is then adjusted to 7.9 ± 0.1 with sterile NaOH or HCl. Solution B also contains 25% (w/v) solar salt or NaCl and is supplemented with yeast extract (0.2%), sodium citrate (0.6%), $MgSO_4 \cdot 7H_2O$ (4.0%), and ferric ammonium sulfate (0.01%). This solution is adjusted to pH 7.9 with 1 N NaOH and sterilized by autoclaving. Just before use, solutions A and B are mixed 1:1 (v/v). If a solid medium is to be used, agar (4.0%) is added to solution B prior to autoclaving.

4. MH medium contains 1% yeast extract, 0.5% Proteose Peptone no. 3 (Difco), and 0.1% glucose. It may be supplemented with synthetic sea salts. The concentrations of sea salts that have been used include: 0.5, 5.0, 10, 20, and 25% (w/v). The pH of this medium is usually adjusted to 7.2 prior to sterilization. Note that the salt concentrations listed for this medium do not represent the concentration of individual salts, such as NaCl, KCl, and $MgCl_2$; consequently, media made with sea salts obtained from different suppliers may differ in terms of the actual ion contents. Given the tolerance of the various *Halomonas* species, however, this should not be a problem.

5. AOL medium (Franzmann et al., 1987) is a synthetic medium that mimics the Antarctic hypersaline lake from which several species of *Halomonas* have been isolated. It consists of NaCl, 80.0 g; $MgSO_4 \cdot 7H_2O$, 9.5 g; KCl, 5.0 g; $CaCl_2 \cdot 2H_2O$, 0.2 g; $(NH_4)_2SO_4$, 0.1 g; KNO_3, 0.1 g; and yeast extract, 1.0 g; suspended in 960 ml of distilled water. The pH is adjusted to 7.0 and the medium is sterilized by autoclaving. When the solution cools to 60°C, 20 ml of Huntner mineral base solution (Atlas, 1997) is added, followed by 1.0 ml of a filter-sterilized vitamin solution containing (mg/100 ml): cyanocobalamin, 10.0; biotin, 2.0; thiamine hydrochloride, 10.0; calcium pantothenate, 5.0; folic acid, 2.0; nicotinamide, 5.0; and pyridoxine hydrochloride, 10.0. The medium is then completed by adding 20.0 ml of a sterile phosphate solution containing 0.25 g K_2HPO_4 and 0.25 g KH_2PO_4 per 100 ml of distilled water. The medium may be solidified with 15 g/l agar. An AOL-peptone medium may also be made by adding 5.0 g/l peptone to AOL medium.

[a]For symbols see standard definitions.

larity of their 16S rDNA sequences and the presence of respiratory ubiquinone-9. Although the genus is currently claimed to constitute a monophyletic group of organisms, it contains at least three main evolutionary branches. Subgroup 1 is composed of *H. halmophila*, *H. elongata* (the type species), *H. eurihalina*, *H. salina*, *H. halophila*, *H. pacifica*, *H. cupida*, and *H. halodenitrificans*. The 16S rDNA sequence similarities between pairs of these species range from 93.1 to 99.2%. The second subgroup contains both biovars of *H. subglaciescola* (ACAM 21 and ACAM 12), *H. halodurans*, *H. venusta*, *H. aquamarina*, *H. meridiana*, and *H. variabilis*, and the 16S rDNA sequence similarities among these species range from 94.4 to 100%. The third subgroup is composed of a single species, *H. marina*. When 16S rDNA sequences are used to distinguish the various phylogenetic subgroups within the genus, the situation improves only marginally. At the most restrictive similarity levels (98% and above), the genus seems to contain at least 10 individual phylogenetic groups (Fig. BXII.γ.115). Unfortunately, resolution of these subgroups deteriorates rapidly below this level. In fact, sequence homology levels existing between some members of the current genus are lower than those between members of the *Halomonas* and species currently listed in a different genus (Dobson and Franzmann, 1996).

Confusion about the current taxonomy of this group has arisen because the data that have been used to describe some of these individual species have been inconsistent. For instance, in the initial descriptions of *Halomonas subglaciescola* (Franzmann et al., 1987) and *Halomonas meridiana* (James et al., 1990a), data were used to compare these species to the type species *H. elongata*. Unfortunately, these two reports had only 55 kinds of characteristics in common, and within these common tests, 15 (27%) gave different results for *H. elongata*. Moreover, 17 of the 55 (31%) test results reported by James et al. (1990a) differed from those reported by Franzmann et al. (1987) for the type strain of *H. subglaciescola*. There is presently no information on the degree to which such discrepancies would affect the taxonomic placement of the species involved.

A similar situation exists with the organisms that were originally part of genera such as *Deleya* and *Halovibrio*, and with the species *"Paracoccus halodenitrificans"*, all of which were merged with the *Halomonas* based entirely upon 16S rDNA sequence similarities and a single chemotaxonomic feature. Very few of the phenetic characters originally used to describe these taxa are equivalent to those used to describe the rest of the *Halomonas* species. In fact, over 80 of the nearly 100 phenotypic descriptors for *Deleya* involve utilization of sole carbon sources, with virtually no information about the presence or absence of specific enzyme systems or abilities. Thus, it is difficult to provide a coherent and useable phenotypic description of the genus *Halomonas* and to provide reliable identifying features for the individual species.

At the chemotaxonomic level, the genus *Halomonas* represents a reasonably coherent group of bacteria; however, they do not possess specific or unique cell components that can be considered to be taxonomically distinct markers. All of the species possess ubiquinone-9 as their major respiratory quinone. When cells are grown on AOL with peptone, the major fatty acids of the *Halomonas* species that have been examined are $C_{16:1\ \omega7c}$, $C_{16:0}$, $C_{17:0\ cyclo}$, $C_{18:1}$, and $C_{19:0\ cyclo\ 11\text{-}12}$. The major polar lipids are phosphatidylethanolamine, phosphatidylglycerol, and an unidentified periodate–Schiff positive phospholipid (Franzmann and Tindall, 1990). Vreeland et al. (1984) have shown that the type strain *H. elongata* also contains cardiolipin. This particular lipid may be detected in increased concentration in cells grown in higher salt concentration.

Common molecular features among the species include the

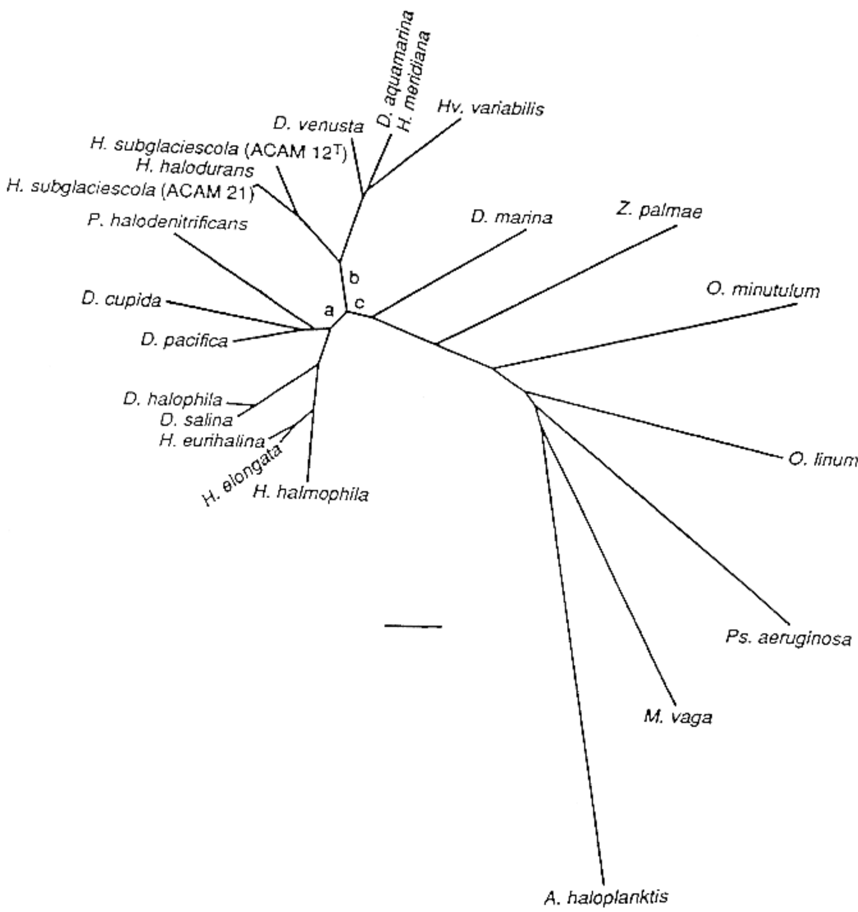

FIGURE BXII.γ.115. Distance tree containing the members of the genus *Halomonas* and other members of the class *Gammaproteobacteria*. Bar = 0.01 distance calculated by the Jukes–Cantor equation. Lower case letters a, b, and c refer to short internodes connecting the main branches of the monophyletic *Halomonas*. Abbreviations: *H.*, *Halomonas*; *O.*, *Oceanospirillum*; *Z.*, *Zymobacter*; *M.*, *Marinomonas*; *Ps.*, *Pseudomonas*; *A.*, *Alteromonas*. Redrawn and reprinted with permission from S. Dobson and P.D. Franzmann, International Journal of Systematic Bacteriology *46:* 550–558, 1996 ©International Union of Microbiological Societies.

presence of specific bases at 16 specific sites along the 16S rRNA molecule (Table BXII.γ.97). A taxonomic study of six species of *Halomonas* has recently been conducted by Huval et al. (1995). The DNA–DNA reassociation data presented in that article shows *Chromohalobacter israelensis* and *Chromohalobacter canadensis* possess 49% and 55% similarity, respectively, with the type species *Halomonas elongata*. *Halomonas halodurans* demonstrates DNA similarity of 28% with *H. elongata*. In contrast, *H. halophila* shows no detectable similarity with the type species of this genus (Table BXII.γ.98). Dobson et al. (1993) have shown that *H. aquamarina* shares a 41% DNA similarity with *H. venusta*, 16% similarity with *H. cupida*, and only 12% similarity with *H. pacifica* and *H. marina*. DNA–DNA hybridizations have not yet been conducted using any other species in the genus.

Acknowledgments

The author wishes to express his appreciation to Drs. C.D. Litchfield and E.L. Martin for their continued support and assistance in the preparation of this manuscript. This review was prepared with the support of National Science Foundation grants EAR 9714203 and EAR0085371.

Differentiation of the species of the genus *Halomonas*

Characteristics differentiating the species of the genus *Halomonas* are listed in Table BXII.γ.96.

List of species of the genus Halomonas

1. **Halomonas elongata** Vreeland, Litchfield, Martin and Elliot 1980, 495[VP]

e.lon′ga.ta. L. fem. part. adj. *elongata* elongated, stretched out.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Morphological features are shown in Figs. BXII.γ.116 and BXII.γ.117. Additional characteristics of the species include the ability to grow at 0.5% and 30% NaCl. Grows at pH 5.0–9.0 in complex medium with 8% NaCl at 30–37°C. Grows at 15°C. Catalase, phosphatase, lysine decarboxylase, β-galactoside, and indole are produced. Some strains may be positive for esculin hydrolysis. Hydrogen sulfide negative. Does not possess DNase or phenylalanine deaminase. Hydrolyzes Tween 20, but not Tween 80. This species has been reported to produce acid from fructose, D-glucose, lactose, D-maltose, and sucrose, but not from D-galactose, inulin, or D-mannitol. In addition to those listed in Table BXII.γ.95, the following compounds serve as sole carbon sources: esculin, D-galactose, L-rhamnose, D-salicin, D-xylose, fumarate, pyruvate, β-hydroxybutyrate, L-aspartic acid, L-glutamic acid, L-ornithine, L-valine, proline, L-asparagine, and tyrosine. The species does not utilize inulin, raffinose, trehalose, malonate, L-tryptophan, L-threonine, or methionine as sole carbon sources. Sensitive to gentamicin (10 μg), mercuric chloride (1:5000), neomycin (30 μg), streptomycin (10 μg), and

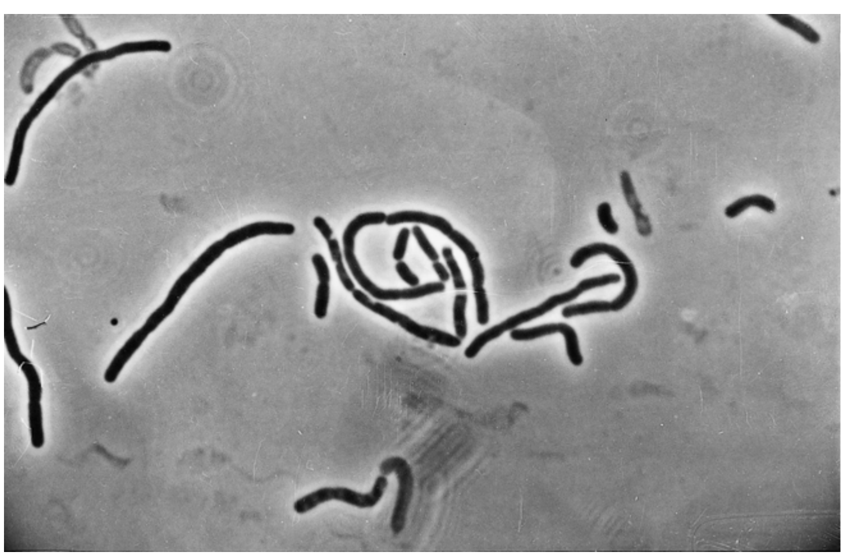

FIGURE BXII.γ.116. Phase contrast micrograph of *Halomonas elongata* strain 1H9 (ATCC 33173), showing both long and short cell forms (× 2000).

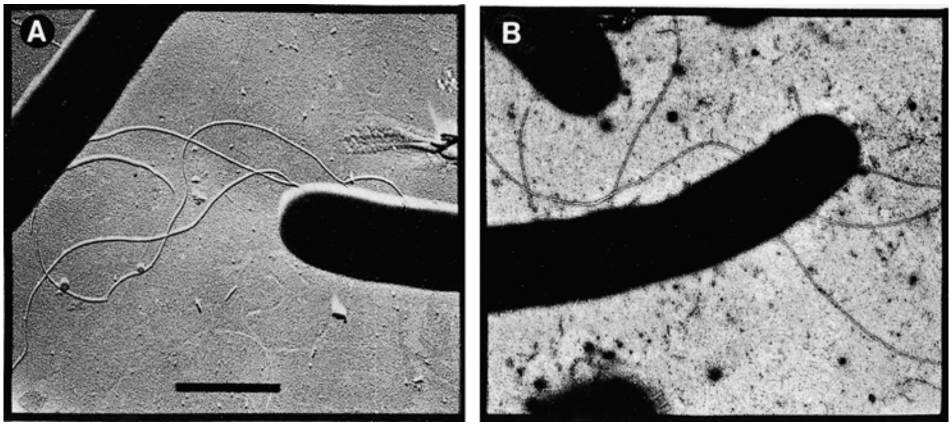

FIGURE BXII.γ.117. Electron micrographs of *Halomonas elongata*, showing flagellar arrangement. *A*, strain 1H9 (ATCC 33173); carbon shadowed. *B*, strain 1H15 (ATCC 33174); negatively stained (Bar = 1.0 μm).

chloramphenicol (30 μg). Resistant to ampicillin (10 μg), bacitracin (10 i.u.), cephalothin (30 μg), erythromycin (15 μg), nalidixic acid (30 μg), novobiocin (20 μg), vibriostat O/129 (10 μg), penicillin G (10 i.u.), and tetracycline (30 μg).

Sodium salts, such as sodium glutamate, $NaNO_3^-$, and NaBr, can substitute for NaCl. Na_2SO_3 and NaI cannot. The chloride salts of magnesium, lithium, potassium, and ammonia cannot substitute for NaCl in growth media. Possesses peptidoglycan. Based upon amino acid analyses, the peptidoglycan contains leucine in a crossbridge (Vreeland et al., 1984). Present in solar salterns, estuaries, salt marshes, and other environments containing NaCl. This species originally contained two biovars (ATCC 33174 = 1H15 [Vreeland et al., 1980] and DSM 3043 = 1H11 [Vreeland et al., 1980]). Both biovars have now been reclassified as *Chromohalobacter salexigens* (Arahal et al., 2001a).

The mol% G + C of the DNA is: 60.5 ± 0.5 (Bd, T_m).

Type strain: 1H9 of Vreeland et al., 1980, ATCC 33173, DSM 2581.

GenBank accession number (16S rRNA): M93355, X67023.

2. **Halomonas aquamarina** (ZoBell and Upham 1944) Dobson and Franzmann 1996, 556[VP] (*Alcaligenes aquamarinus* (ZoBell and Upham 1944) Hendrie, Holding and Shewan 1974, 537; *Deleya aquamarina* (ZoBell and Upham 1944) Akagawa and Yamasato 1989, 466; *"Achromobacter aquamarinus"* ZoBell and Upham 1944, 264.)
a.qua.ma.ri'na. L. n. *aqua* water; L. adj. *marina* of the sea; L.adj. *aquamarina* pertaining to seawater.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. This species may or may not produce H_2S and phenylalanine deaminase. The species does not hydrolyze esculin or produce DNase or β-galactosidase. This species utilizes malate, pyruvate, β-hydroxybutyrate, caprylate, L-aspartic acid, L-glutamic acid, and proline as sole sources of carbon. The species also utilizes butyrate, isobutyrate, valerate, isovalerate, caproate, heptanoate, adipate, pimelate, azelate, sebacate, levulinate, erythritol, *meso*-inositol, *n*-propanol, *n*-butanol, isobutanol, cytosine, and uracil. This is the only *Halomonas* species known to hydrolyze starch (Table BXII.γ.96) and utilize suberate. Accumulates polyhydroxyalkanoates. Some strains of the species may utilize D-galactose, trehalose, L-ornithine, and L-valine. The species does not grow on inulin, L-rhamnose, D-salicin, D-xylose, formate, malonate, oxalacetate, D-tartrate, benzoate, L-threonine, or tyrosine as the sole carbon source. There are no data available about the sensitivity of this species to antimicrobials. Isolated from the Pacific Ocean. The similarity of the 16S rRNA sequence of this species to the other *Halomonas* species ranges from 93.6–100%.

The mol% G + C of the DNA is: 60.5 ± 0.5 (Bd, T_m).

Type strain: ATCC 14400, DSM 30161, IAM 12550, NCMB 557.

GenBank accession number (16S rRNA): M93352.

3. **Halomonas campisalis** Mormile, Romine, Garcia, Ventosa, Bailey and Peyton 2000, 949[VP] (Effective publication: Mormile, Romine, Garcia, Ventosa, Bailey and Peyton 1999, 556.)
cam.pi.sa'lis. L. masc. n. *campus* plain, field; L. masc. n. *sal*- salt; gen. *salis* of salt; L. masc. n. *campisalis* of the plain of salt, of the salt plain.

General characteristics are as described for the genus and are presented in Tables BXII.γ.95 and BXII.γ.96. Additional characteristics include the ability to grow at temperatures from 4°C to 50°C. Optimal growth occurs at 30°C. This species reproduces at pH between 6.0 and 11.0 with optimal growth at pH 9.5. The optimal salt concentration is 1.5 M with a growth range from 0.2 to 4.5 M. In addition to those listed in Table BXII.γ.95, the species utilizes *n*-acetyl-glucosamine, ethanol, D(−)-fructose, D(+)-glucosamine, glycerol, pyruvate, and yeast extract. The species does not utilize benzoic acid, D(+)-galactose, D(+)-mannose, methanol, pectin, D(−)-ribose, L-rhamnose, L(−)-sorbose, whey, and D(+)-xylose. The organism does not grow fermentatively. The species gives negative tests for arginine dihydrolase, phenylalanine deaminase, indole production, and Voges–Proskauer.

This species is susceptible to ampicillin, chloramphenicol, and rifampin. It is resistant to kanamycin, neomycin, and streptomycin. The concentrations of antibiotics used were not provided in the original description.

The species was isolated from a soil sample just below the crystalline salt surface of a salt flat south of Alkali Lake in eastern Washington State, USA.

The mol% G + C of the DNA is: 66 (T_m).
Type strain: 4A, ATCC 700597.
GenBank accession number (16S rRNA): AFO54286.

4. **Halomonas cupida** (Baumann, Baumann, Mandel and Allen 1972) Dobson and Franzmann 1996, 556^VP (*Deleya cupida* (Baumann, Baumann, Mandel and Allen 1972) Baumann, Bowditch and Baumann 1983a, 801; *Alcaligenes cupidus* Baumann, Baumann, Mandel and Allen 1972, 426.)
cu'pi.da. L. adj. *cupidus* desiring.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. This species possesses peritrichous flagella; it has been described as utilizing 69–85 organic compounds, possibly more than any other *Halomonas* species. In addition to those listed, the species also utilizes D-galactose, D-xylose, fumarate, malate, pyruvate, β-hydroxybutyrate, benzoate, caprylate, L-aspartic acid, L-glutamic acid, proline, tyrosine, melibiose, saccharate, galacturonate, glucuronate, *N*-acetylglucosamine, butyrate, isobutyrate, valerate, isovalerate, caproate, heptanoate, pelargonate, caprate, glycolate, DL-glycerate, aconitate, erythritol, *meso*-inositol, *n*-propanol, isobutanol, benzoylformate, *p*-hydroxybenzoate (but not the *ortho* or *meta* isomers), putrescine, spermine, betaine, sarcosine, hippurate, and allantoin. The species may or may not grow on L-rhamnose, D-salicin, D-trehalose, malonate, and L-ornithine. This organism does not use formate, oxalate, D-tartrate, L-valine, or L-threonine as the sole source of carbon. The similarity of the 16S rDNA of this species to other *Halomonas* species ranges from 92.6–96.5%. Isolated from marine habitats.

The mol% G + C of the DNA is: 60–63 (Bd).
Type strain: ATCC 27124, DSM 4740.
GenBank accession number (16S rRNA): L42615.

5. **Halomonas desiderata** Berendes, Gottschalk, Heine-Dobbernack, Moore and Tindall 1997, 242^VP (Effective publication: Berendes, Gottschalk, Heine-Dobbernack, Moore and Tindall 1996,165.)
de.si.de.ra'ta. L. part. adj. *desiderata* wished for, the strain wished for.

Cells are motile with peritrichous flagella and are 0.4–0.6 × 1.0–2.6 μm. The colony type has not been described, but the species does not produce pigments. Requires sodium ions. Optimum pH is 9.7 and the optimum temperature for growth is 37–42°C. The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96.

Facultatively anaerobic in the presence of nitrate. Obligately alkaliphilic; optimum pH 9.5. Grows at 45°C. Denitrifying. Does not grow below pH 7 or above pH 11. Does not grow at 50°C. Supplemental vitamins or amino acids are not needed. Catalase positive and phenylalanine deaminase positive. Arginine dihydrolase negative. Does not hydrolyze starch, gelatin, casein, Tween 80, Tween 60, hippurate, or pullulan. Produces poly-β-hydroxybutyrate as a reserve material but does not produce levan from sucrose. Grows on MacConkey agar, *Salmonella–Shigella* agar, and Cetrimide agar. At pH 9.7, the species is resistant to up to 1% bile salts.

Utilizes D-xylose, ribose, trehalose, glycerol, DL-β-hydroxybutyrate, and benzoate as sole sources of carbon. Does not utilize inositol. Not fermentative; indole and Voges–Proskauer negative. The major respiratory quinone is ubiquinone-9. The major fatty acids are $C_{18:1}$ (52–65% depending on the strain), $C_{16:0}$ (13–23% depending on the strain), and $C_{16:1\ \omega7c}$. Other fatty acids detected in various strains include $C_{10:0}$, $C_{10:0\ 3OH}$, $C_{12:0}$, $C_{12:0\ 3OH}$, $C_{14:0}$, $C_{17:0\ cyclo}$, $C_{18:0}$, and $C_{19:0\ cyclo}$. The major phospholipids are phosphatidylglycerol, phosphatidylethanolamine, diphosphatidylglycerol, and an uncharacterized phosphoglycolipid. The similarity of the 16S rDNA of this species to other *Halomonas* species ranges from 89.7–94.8%. DNA–DNA hybridization data show similarities below 60–70%. Isolated from municipal sewage.

The mol% G + C of the DNA is: 66 (HPLC).
Type strain: DSM 9502.
GenBank accession number (16S rRNA): X92417.

6. **Halomonas eurihalina** (Quesada, Valderrama, Bejar, Ventosa, Gutierrez, Ruiz-Berraquero and Ramos-Cormenzana 1990) Mellado, Moore, Nieto and Ventosa 1995b, 715^VP (*Volcaniella eurihalina* Quesada, Valderrama, Bejar, Ventosa, Gutierrez, Ruiz-Berraquero and Ramos-Cormenzana 1990, 265.)
eu.ri.ha.li'na. Gr. adj. *euris* wide, broad; Gr. adj. *halinos* salted; M.L. adj. *eurihalina* growing at a wide range of salt concentrations.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Colonies grown on MH medium with 7.5% NaCl at 32°C for 72 h are 4–5 mm in diameter, circular, convex, smooth, opaque, cream-colored with entire margins, and very mucoid. This species requires Na^+ ions. Sodium can be supplied as NaCl, Na_2SO_4, or NaBr. Under optimum conditions, the species grows at pH 5.0–9.0. Catalase positive. Phosphatase, lysine decarboxylase, and β-galactosidase negative. Does not hydrolyze esculin. Produces acid from fructose and maltose. Some strains may also produce acid from D-galactose, D-glucose, lactose, mannitol, and sucrose. Utilizes fumarate, β-hydroxybutyrate, L-valine, L-threonine, proline, and tyrosine as sole carbon sources. Some strains also utilize D-galactose, raffinose, D-salicin, D-trehalose, L-ornithine, and methionine as sole carbon sources. This species hydrolyzes gelatin and grows on KCN, MacConkey, and Cetrimide agar. Some strains of this species produce H_2S and hydrolyze Tween 20. Sensitive to chloramphenicol (30 μg). Some strains may be sensitive to gentamicin (10 μg) and neomycin (30 μg). Resistant to most other antimicrobials. Isolated from hypersaline habitats (soils and salterns) and from ocean water.

The mol% G + C of the DNA is: 59.1–65.7 (T_m).
Type strain: ATCC 49336, DSM 5720.
GenBank accession number (16S rRNA): L42620, X87218.

7. **Halomonas halmophila** (Elazari-Volcani 1940) Franzmann, Wehmeyer and Stackebrandt 1989, 205^VP (Effective publication: Franzmann, Wehmeyer and Stackebrandt 1988, 19) emend. Dobson, James, Franzmann and McMeekin 1990, 462 (*Flavobacterium halmophilum* Elazari-Volcani 1940, 85.)
hal.mo.phi'lum. Gr. n. *halme* brine, seawater; Gr. adj. *philos*-loving; M.L. n. adj. *halmophilum* seawater loving.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Does not produce acid from sugars, D-mannitol, or inulin and does not produce indole. The species is sensitive to nalidixic acid

(30 μg) and resistant to ampicillin (10 μg), gentamicin (10 μg), neomycin (30 μg), streptomycin (10 μg), and tetracycline (30 μg). This species was transferred into the genus *Halomonas* when 16S rRNA cataloging showed an S_{AB} value of 0.66 to the type species of the genus *Halomonas*. The similarity of the 16S rDNA of this species to other *Halomonas* species ranges from 92.2–97.9%. The mol% G + C content of the DNA has been reported to be 49.7. The exact site from which this bacterium was isolated is not known, but was probably somewhere in the Dead Sea.

The mol% G + C of the DNA is: 49.7 (method unknown).

Type strain: ATCC 19717, DSM 5349.

GenBank accession number (16S rRNA): M59153.

The name of this species has been incorrectly spelled as *Flavobacterium halmephilum* (Weeks, 1974) and as *Flavobacterium halmephilium* (Weeks, 1974).

8. **Halomonas halodenitrificans** (Robinson and Gibbons 1952) Dobson and Franzmann 1996, 556^VP (*Paracoccus halodenitrificans* (Robinson and Gibbons 1952); *Micrococcus halodenitrificans* Robinson and Gibbons 1952, 154.)
ha.lo.de.ni.tri′fi.cans. Gr. n. *hals, halis* salt; M.L. v. *denitrifico* to denitrify; M.L. part. adj. *halodenitrificans* salt (requiring) denitrifying.

This is the only member of this genus that has a coccoid morphology. The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Most of the characteristics have been taken from the description of Kocur (1984). When grown on nutrient agar containing 6% NaCl, the colonies of this species are described as circular, entire, convex, butyrous, glistening, cream-colored, and opaque. The optimum growth temperature is 25–30°C; the growth range is 5–32°C. The species cannot grow in media containing less than 3% NaCl. Optimum growth occurs with 4.4–8.8% NaCl; slow growth occurs with up to 20% NaCl in media. Catalase positive; phosphatase is present. Hydrogen sulfide is not produced. Esculin is not hydrolyzed. Lysine decarboxylase, phenylalanine deaminase, and β-galactosidase negative. Indole and Voges–Proskauer negative. Does not hydrolyze Tween 80. Acid is not produced from either D-glucose or sorbitol. Acid production from other sugars or polyols has not been tested. L-valine, L-threonine, proline, and L-asparagine serve as sole carbon sources. Does not utilize L-aspartic acid, L-glutamic acid, or methionine as sole carbon sources. Sensitive to mercuric chloride and polymyxin B, although no concentrations have been specified. Resistant to gentamicin (10 μg), vibriostat O/129 (10 μg), penicillin G (10 i.u.), streptomycin (10 μg), tetracycline (30 μg), and chloramphenicol (30 μg). The similarity of the 16S rDNA of this species to each member of the genus *Halomonas* ranges from 91.5–95.6%. Isolated from meat-curing brines.

The mol% G + C of the DNA is: 64–66 (T_m, Bd).

Type strain: ATCC 13511, CCM 286, DSM 735, NCMB 700.

GenBank accession number (16S rRNA): L04942.

9. **Halomonas halodurans** Hebert and Vreeland 1987, 350^VP
ha.lo.du′rans. Gr. n. *hals, halos;* the sea, salt; L. v. *durare* to last endure; M.L. masc. adj. *Halodurans* salt tolerating.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. The original description of this species was based on tests using media supplemented with 2.6% NaCl. Later descriptions of this species by Hebert and Vreeland (1987) were performed at the optimum NaCl concentration for growth of the species (8.0%). Hebert and Vreeland (1987) noted several differences in the results of the phenotypic testing and attributed them to the differences in the salt content of the media. The biochemical properties listed in Tables BXII.γ.95 and BXII.γ.96 for this species are those corresponding to tests conducted with media containing 8% NaCl.

The cells are motile by single polar flagellum that is 8–10 μm in length and 12–14 nm wide. Colonies are circular, convex, smooth, entire, 2–3 mm in diameter, and nonpigmented following 48 h of growth at 20–35°C. This species does not grow in 30% NaCl. Grows at pH 6.0–8.0 in 8% NaCl.

Catalase positive; phosphatase, and lysine decarboxylase are present. Phenylalanine deaminase and β-galactosidase are absent. Hydrolyzes esculin. Tolerant to KCN. Hydrolyzes Tween 80. Hydrogen sulfide, indole, and acetyl-methyl carbinol (Voges–Proskauer) are not produced. Produces acid from D-fructose, D-galactose, D-glucose, lactose, salicin, sucrose, and D-xylose. Does not produce acid from D-mannitol, D-mannose, or L-rhamnose. Utilizes D-galactose, inulin, ribose, malonate, pyruvate, benzoate, L-ornithine, L-threonine, proline, and L-asparagine as sole sources of carbon. The species cannot use L-rhamnose, malate, β-hydroxybutyrate, or methionine as sole carbon sources. Sensitive to erythromycin (15 μg), nalidixic acid, (30 μg), streptomycin (10 μg), tetracycline (30 μg), and polymixin B (concentration unknown). The species is resistant to vibriostat O/129 (10 μg), penicillin G (10 i.u.), and chloramphenicol (30 μg). The similarity of the 16S rDNA of this species to other species of *Halomonas* ranges from 93.7–99.9%. The level of DNA–DNA homology between this species *H. elongata* and *H. canadensis* is shown in Table BXII.γ.98. Isolated from Great Bay Estuary (New Hampshire, USA).

The mol% G + C of the DNA is: 63.2 ± 1.1 (T_m, Bd).

Type strain: ATCC 29686, DSM 5160.

GenBank accession number (16S rRNA): L42619.

10. **Halomonas halophila** (Quesada, Ventosa, Ruiz-Berraquero and Ramos-Cormenzana 1984) Dobson and Franzmann 1996, 556^VP (*Deleya halophila* Quesada, Ventosa, Ruiz-Berraquero and Ramos-Cormenzana 1984, 290.)
ha.lo.phi′la. Gr. n. *halos* salt; Gr. adj. *philus* loving; M.L. adj.*halophila* salt loving.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. When grown with 7.5% sea salt for 4 days at 32°C, the colonies are circular, low convex, smooth, opaque, and cream-colored. Grows in 30% NaCl and at pH 5.0–9.0. Tests positive for catalase and phosphatase. DNase and phenylalanine deaminase negative. Produces hydrogen sulfide and hydrolyzes esculin, but does not hydrolyze Tween 80. Indole and Voges–Proskauer negative. Produces acid from D-galactose, D-glucose, and D-maltose. Some strains may also produce acid from sucrose, D-trehalose, and D-xylose. Acid is not produced from lactose and mannitol. In addition to the carbon sources listed in Table BXII.γ.95, this species also utilizes D-galactose, D-salicin, D-trehalose, D-xylose, fumarate, malate, pyruvate, L-aspartic acid, and L-glutamic acid as sole carbon sources. Some strains may also use L-orni-

thine. The species does not utilize L-rhamnose, hippurate, D-tartrate, benzoate, caprylate, or L-valine as sole carbon sources. The species is sensitive to ampicillin (10 μg), cephalothin (30 μg), erythromycin (15 μg), chloramphenicol (30 μg), polymyxin B, and rifampin A (no concentrations have been specified for the latter two anti-microbials). Resistant to bacitracin (10 i.u.) and lincomycin (concentration unknown). The similarity of the 16S rDNA of this species to each member of the *Halomonas* ranges from 93.8–99.2%. Isolated from saline soils.

The mol% G + C of the DNA is: 66.7 (T_m).

Type strain: CCM3662, DSM 4770.

GenBank accession number (16S rRNA): L42619 and M93353.

11. **Halomonas magadii** Duckworth, Grant, Jones, Meijer, Márquez and Ventosa 2000b, 1415[VP] (Effective publication: Duckworth, Grant, Jones, Meijer, Márquez and Ventosa 2000a, 59.)
ma.ga′di.i. M.L. gen. n. *magadi* of Magadi, named for lake Magadi, a saline soda lake in Kenya.

The characteristics are as described for the genus and are listed in Tables BXII.γ.95 and BXII.γ.96. Other descriptive characters are listed below. Rods 4.0–6.0 × 0.6–0.8 μm. Catalase positive, produces circular, low convex opaque cream-colored colonies. Alkaliphilic, growth occurs between pH 7.0 and 11.0 with an optimum around 9.5. Grows at salt concentrations from 0% to 20% between 25°C and 40°C with an optimum at 37°C. Phosphatase and phenylalanine deaminase negative. Does not hydrolyze gelatin or casein. Indole negative. No anaerobic growth in the presence or absence of nitrate. Produces H_2S from cysteine. When grown in alkaline medium, the species utilizes amygdalin, esculin, D-fructose, D-fucose, D-galactose, D-melibiose, L-raffinose, D-ribose, salicin, starch, trehalose, D-xylose, adonitol, D-glucuronolctone, D-glucosamine, dulcitol, erythritol, ethanol, glycerol, D-mannitol, *m*-inositol, propanol, D-sorbitol, *N*-acetylglucosamine, propionide, quinate, D-saccharate, salicylate, suberate, tartrate, L-asparagine, DL-aspartic acid, DL-phenylalanine, L-glutamine, α-aminovalerate, aconitate, α-ketoglutarate, butyrate, caprylate, fumarate, DL-glycerate, D-glucuronate, glutamate, *p*-hydroxybenzoate, hippurate, DL-malate, malonate, oxalate, L-ornithine, L-leucine, L-methionine, L-proline, L-threonine, L-valine, and pyruvate. Sarcosine, ethionine, creatine, DL-aminobutyrate, Tween 80, inulin, and L-rhamnose are not used. Sensitive to erythromycin (5 mg), streptomycin (10 mg), polymyxin (300 IU), sulphafurazole (100 mg), chloramphenicol (25 mg), and oleandomycin (5 mg). Not sensitive to gentamicin (10 mg), kanamycin (30 mg), fusidic acid (10 mg), tetracycline (25 mg), rifampicin (2 mg), bacitracin (10 IU), neomycin (30 mg), novobiocin (5 mg), and vancomycin (30 mg). Listed as insensitive to sulphamethoxazole, nitrofurantoin, trimethoprim, ampicillin, penicillin G, and methicillin, but no concentrations were specified.

The major polar lipids are phosphatidylglycerol, phosphatidyl glycerol phosphate, diphosphatidylglycerol, phosphatidylethanolamine, and a small amount of an unidentified glycolipid. Cells also contain ubiquinones 6 and 9.

The mol% G + C of the DNA is: 62 (T_m).

Type strain: 21M1, NCIMB 13595.

GenBank accession number (16S rRNA): X92150.

12. **Halomonas marina** (Cobet, Wirsen and Jones 1970) Dobson and Franzmann 1996, 556[VP] (*Deleya marina* (Cobet, Wirsen and Jones 1970) Baumann, Bowditch and Baumann 1983a,801; *Pseudomonas marina* (Cobet, Wirsen and Jones 1970) Baumann, Baumann, Mandel and Allen 1972, 423; *"Arthrobacter marinus"* Cobet, Wirsen and Jones 1970, 159.)
ma.ri′na. L. adj. *marina* of the sea.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. The cells possesses polar flagella. Baumann et al. (1983a) note that this species has flagella that tend to bend back toward the cell, giving arrangements that appear to be lateral or peritrichous. The species has been described as utilizing 35–47 organic compounds as sole sources of carbon. In addition to those listed in Table BXII.γ.95, this species utilizes D-galactose, fumarate, malate, pyruvate, β-hydroxybutyrate, L-aspartic acid, L-glutamic acid, L-proline, butyrate, valerate, isovalerate, caproate, heptanoate, pelargonate, caprate, DL-glycerate, α-ketoglutarate, aconitate, *n*-butanol, sarcosine, and creatine. Some strains may also utilize malonate and L-ornithine as sole carbon sources. The species does not use L-rhamnose, ribose, D-salicin, D-trehalose, D-xylose, hippurate, D-tartrate, benzoate, L-valine, or L-threonine. The similarity of the 16S rDNA of this species to other *Halomonas* species is only 92.3–94.8%. Isolated from marine habitats.

The mol% G + C of the DNA is: 63 (Bd).

Type strain: C 25374, DSM 4741.

GenBank accession number (16S rRNA): M93354.

13. **Halomonas marisflavae** Yoon, Choi, Lee, Kho, Kang, and Park 2001a, 1176[VP]
ma.ris.fla′vae. L. gen. neut. n. *maris* of the sea; L. neut. adj. *flavum* yellow; L. gen. neut. n. *marisflavae* of the Yellow Sea, Korea.

The characteristics are as described for the genus and are listed in Tables BXII.γ.95 and BXII.γ.96 The species produces rod or oval shaped cells that are 0.9–1.3 × 1.7–2.3 μm following 3 days growth at 28°C. Cells are motile with a single polar flagellum. Colonies are yellow-orange, smooth, glistening, circular, and slightly irregular on Tryptic Soy Agar (TSA) and on Marine Agar (MA). The colonies are described as being convex on TSA and concave on MA. Optimal growth occurs between 0.5% and 12% NaCl (w/v) and at 25–30°C. The optimal pH for growth is 7.0–8.0. Grows anaerobically on MA medium although the exact conditions for this characteristic were not specified. Catalase positive. Hydrolyzes esculin and gelatin, but not casein, hypoxanthine, Tween 80, tyrosine, or xanthine. Indole and arginine deaminase negative. Assimilates and produces acid from D-glucose, arabinose, mannose, mannitol, gluconate, malate, and citrate. The species is also described as producing acid from glycerol, erythritol, ribose, D-xylose, galactose, D-fructose, arbutin, salicin, maltose, melibiose, trehalose, gentiobiose, D-turanose, D-lyxose, and D-furanose. Also produces a weak acid reaction from adonitol, mannitol, and xylitol.

The predominant respiratory quinone is ubiquinone-9. The major fatty acids are $C_{18:1}$, $C_{16:0}$, $C_{16:1\ \omega7c}$ and/or $C_{15:0\ iso\ 2OH}$.

Isolated from the Yellow Sea, Korea.

The mol% G + C of the DNA is: 59 (HPLC).

Type strain: SW32, JCM 10873, KCCM 80003.

GenBank accession number (16S rRNA): AF251143.

14. **Halomonas maura** Bouchotroch, Quesada, Del Moral, Llamas and Bejar 2001, 1630[VP]
mau'ra. L. adj. *maurus* northwest African.

The characteristics are as described for the genus and are listed in Tables BXII.γ.95 and BXII.γ.96. This species produces one of the longest rods (6.0–9.0 × 0.5–0.7 μm) in the genus. It and *Halomonas eurihalina* are the only species known to produce large amounts of exopolysaccharide. Colonies are circular, convex, mucoid, cream-colored, and 2–3 mm in diameter after 24 hours growth at 32°C. Colonies expand to over 5 mm in diameter after 72 hours. Grows in salt concentrations between 1% and 15% with optimal growth occurring between 7.5 and 10% (w/v). The salt concentrations given actually reflect the percentage of total sea salts and not specifically NaCl. However, the original description of this species states that the organism is able to grow optimally in medium containing 1.2M NaCl (7.0% w/v) and 0.2M $MgSO_4 \cdot 7H_2O$ (4.5%). The description also states that $MgCl_2 \cdot 6H_2O$ may be substituted for magnesium sulfate. The species is capable of anaerobic growth in the presence of nitrate but not fumarate. Catalase positive. Does not produce acids from sugars. Reduces selenite and oxidizes gluconate. The species produces H_2S from peptones and hydrolyzes Tween 20. Indole, methyl-red, and Voges–Proskauer tests are negative. The species does not utilize esculin, tyrosine, DNA, gelatin, casein, lecithin, and Tween 80, nor does it hydrolyze blood, produce phenylalanine deaminase, grow on cetrimide agar or under anaerobic conditions on normal medium. In addition, the type strain of the species produces phosphatase and grows on MacConkey and KCN agars and is ONPG negative.

In addition to the compounds listed in Table BXII.γ.95, the species utilizes D-galactose, *myo*-inositol, and D-sorbitol as sole sources of carbon and energy. The species does not utilize formate, D-salicin, or L-sorbose. The type strain differs somewhat in these characters in that it also utilizes citrate, ethanol, fumarate, D-fructose, glycerol, D-rhamnose, and D-ribose. The type strain also does not utilize lactose or D-trehalose. The species also utilizes the amino acids listed in Table BXII.γ.95, as well as L-ornithine and L-valine, as sole sources of carbon and nitrogen. The organism does not utilize cysteine or L-tryptophan in this manner. As a whole, the species is susceptible to amoxycillin, ampicillin, cephalothin, cefoxitin, chloramphenicol, nalidixic acid, nitrofurantoin, polymixin, rifampicin, and trimethoprim-sulfamethoxazole. The species is resistant to tetracycline and Vibriostat O/129. The type strain is also sensitive to gentamicin, penicillin, sulfonamide, and tobramycin while being resistant to erythromycin. Unfortunately, no antibiotic concentrations were provided in the original species description. These data may be provided by Bouchotroch et al. (1999) which was cited by Bouchotroch et al. (2001).

The major fatty acids (up to 81% total) of the type strain are $C_{18:1\ \omega7c}$, $C_{16:1\ \omega7c}/C_{15:0\ iso\ 2OH}$, and $C_{16:0}$. The bacterium produces exo-polysaccharide designated EPS S-31 which is composed of neutral sugars glucose, mannose, and galactose in a ratio of 1:4:2.5. EPS S-31 emulsifies crude oil.

The species was isolated from a solar saltern in Asilah Morocco.

The mol% G + C of the DNA is: 62.2–64.1 (T_m).

Type strain: S-31, CECT 5298, DSM13445.

GenBank accession number (16S rRNA): AJ271864.

15. **Halomonas meridiana** James, Dobson, Franzmann and McMeekin 1990b, 470[VP] (Effective publication: James, Dobson, Franzmann and McMeekin 1990a, 277.)
me.ri.di.a'na. L. adj. *meridiana* of the south.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. The colonies produced by this species are smooth, circular, convex, and white to off-white, with entire margins. Yellow colonies may be produced on media containing alanine or pyruvate. The cells may possess either lateral or polar flagella. The species grows in media of pH 6.0–9.0; some strains may grow at pH 5.0. Catalase positive. Test results for phosphatase, DNase, lysine decarboxylase, phenylalanine deaminase, and β-galactosidase are all negative. Most strains have been reported to hydrolyze Tween 80 and Tween 20. Produces acid from D-fructose, maltose, and sucrose. Some strains may produce acid from D-galactose, D-glucose, lactose, and mannitol. Utilizes D-xylose, fumarate, β-hydroxybutyrate, L-valine, proline, and L-asparagine as sole sources of carbon. Most strains also utilize D-galactose and D-rhamnose. Some strains may utilize raffinose, D-salicin, D-trehalose, L-ornithine, L-threonine, and methionine as sole carbon sources. Does not use malonate. Resistant to most antibiotics, including ampicillin (10 μg), bacitracin (10 i.u.), cephalothin (30 μg), erythromycin (10 μg), mercuric chloride 1:5000 (200 mg/l), nalidixic acid (30 μg), novobiocin (20 μg), vibriostat O/129 (10 μg), penicillin G (10 i.u.), streptomycin (10 μg), and tetracycline (30 μg). Some strains show sensitivity to gentamicin (10 μg), neomycin (30 μg), and chloramphenicol (30 μg). The similarity of the 16S rDNA of this species to each member of the *Halomonas* ranges from 93.6–100%. Isolated from Antarctic lakes.

The mol% G + C of the DNA is: 58.8–59.1 ± 0.8 (T_m).

Type strain: ACAM 246, ATCC 49692, DSM 5425, UQM 3352.

GenBank accession number (16S rRNA): M93356.

16. **Halomonas pacifica** (Baumann, Baumann, Mandel and Allen 1972) Dobson and Franzmann 1996, 556[VP] (*Deleya pacifica* (Baumann, Baumann, Mandel and Allen 1972) Baumann, Bowditch and Baumann 1983a, 801; *Alcaligenes pacificus* Baumann, Baumann, Mandel and Allen 1972, 426.)
pa.ci'fic.a. M.L. adj. *pacifica* pertaining to the Pacific ocean.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. In addition, the species has been shown to utilize fumarate, malate, pyruvate, β-hydroxybutyrate, benzoate, L-aspartic acid, L-glutamic acid, L-ornithine, proline, *N*-acetylglucosamine, butyrate, isobutyrate, valerate, isovalerate, caproate, heptanoate, glutarate, DL-glycerate, 2,3-butyleneglycol, benzoate, *p*-hydroxybenzoate (but not the *ortho* and *meta* isomers), phenylacetate, δ-aminovalerate, DL-kynurenine, kynurenate, anthranilate, benzylamine, putrescine, spermine, histamine, butylamine, betaine, sarcosine, and nicotinate as carbon sources. Some strains may use caprylate as well. The species does not use D-galactose, L-rhamnose, ribose, D-salicin, D-trehalose, D-xylose, malonate, D-tartrate, L-valine, or L-threonine as sole carbon sources. The similarity of the 16S rDNA of this species to each member of the *Halomonas* ranges from 93.2–96.6%. Isolated from marine habitats.

The mol% G + C of the DNA is: 67–68 (Bd).

Type strain: ATCC 27122, DSM 4742.

GenBank accession number (16S rRNA): L42616.

17. **Halomonas pantelleriensis** Romano, Nicolaus, Lama, Manca and Gambacorta 1997, 601[VP] (Effective publication: Romano, Nicolaus, Lama, Manca and Gambacorta 1996, 332.)
pan.tel.le.ri.en′sis. from the place of isolation, Pantelleria Island in the south of Sicily, Italy.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Colonies are cream to pink, making this the only species of the genus with pink colonies. Colonies are smooth, granulate, entire, circular, raised, and 0.11 mm in diameter. The species produces PHB. In defined medium, the species requires biotin or thiamine (50 μg/l) in addition to the carbon sources listed in Table BXII.γ.95. Optimum growth occurs in media containing 10% NaCl, 33–35°C, pH 9.0. The species is alkalophilic and grows at a pH range of 7.5–11.0. Catalase and α-glucosidase positive; β-galactosidase negative. Decomposes tyrosine. Hydrolyzes hippurate, but does not attack casein, gelatin or L- or D-*N*′-benzoylarginine-*p*-nitroanilide. The species gives a weak reaction for phenylalanine deaminase and is not sensitive to lysozyme. In addition to the substrates listed in Table BXII.γ.95, the species also utilizes fructose, D-xylose, galactose, trehalose, salicin, sorbitol, glycerol, pyruvate, heptanoate, and valine. The organism cannot utilize raffinose, ethanol, or valerate. The species is sensitive to chloramphenicol (30 μg) and erythromycin (30 μg). It is insensitive to lincomycin (15 μg), gentamicin (10 μg), ampicillin (25 μg), tetracycline (50 μg), penicillin (10 μg), neomycin (30 μg), bacitracin (10 μg), and novobiocin (30 μg). The similarity of the 16S rDNA of this species to other members of the *Halomonas* ranges from 93.1–95.8%. This species represents a distinct phylogenetic line within the larger genus, and is most closely related to *H. marina* and *H. halodenitrificans*. Isolated from hard sand on the island of Pantelleria, south of Sicily, Italy.

The mol% G + C of the DNA is: 65.02 (HPLC).

Type strain: ATCC 700273, DSM 9661.

GenBank accession number (16S rRNA): X93493.

18. **Halomonas salina** (Valderrama, Quesada, Bejar, Ventosa, Gutierrez, Ruiz-Berraquero and Ramos-Cormenzana 1991) Dobson and Franzmann 1996, 556[VP] (*Delaya salina* Valderrama, Quesada, Bejar, Ventosa, Gutierrez, Ruiz-Berraquero and Ramos-Cormanzana 1991, 382.)
sa.li′na. L. adj. *salina* salted, saline.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. Of all of the *Halomonas* species, *H. salina* is currently the easiest to distinguish at the phenotypic level. The species has several characteristics that are not shared by the other halomonads. It forms coccoid cells when grown in low salts, but produces typical elongated filaments when grown in optimum (7.5% total sea salts) and higher salts, but not in 30% salts. The cells are nonmotile, produce a capsule, and accumulate poly-β-hydroxybutyrate. The colonies produced after 48 h at 32°C on MH medium are small (1–2 mm in diameter), convex, smooth, glossy, and translucent yellow to cream and have entire margins. This is also the only *Halomonas* species known to reduce selenite and to require Mg^{2+}, in addition to Na^{+}. Unlike other *Halomonas* species, *H. salina* can only use cations supplied as either Cl^{-} or SO_4^{2-} salts. Members of the species grow at pH 6.0–9.0. Some strains also grow at pH 5.0. Catalase positive. Some strains also possess DNase, phenylalanine deaminase, and β-galactosidase. Some strains produce hydrogen sulfide, are KCN tolerant and hydrolyze Tween 80 and Tween 20. Some strains grow on MacConkey and cetrimide agars. Does not possess phosphatase, lysine decarboxylase, or lecithinase. Some strains may produce acid from D-mannitol and sucrose. Acid is not produced from other sugars or poly-alcohols. The members of this species utilize D-salicin, fumarate, malate, and L-aspartic acid as sole sources of carbon. Some strains may also utilize D-galactose, inulin, raffinose, L-rhamnose, sorbose, D-trehalose, D-xylose, formate, pyruvate, D-tartrate, β-hydroxybutyrate, and L-glutamic acid. The species does not utilize oxalate, benzoate, or caprylate as sole carbon sources. Sensitive to ampicillin (10 μg), cephalothin (30 μg), erythromycin (15 μg), nalidixic acid (15 μg), penicillin G (10 i.u.), and chloramphenicol (30 μg). Some strains are also sensitive to gentamicin (10 μg), streptomycin (10 μg), and tetracycline (30 μg). Isolated from hypersaline habitats such as soils, salt ponds, salt lakes, and from the sea.

The mol% G + C of the DNA is: 60.7–64 (T_m).

Type strain: ATCC 49509, DSM 5928.

GenBank accession number (16S rRNA): L42617, X87217.

19. **Halomonas subglaciescola** Franzmann, Burton and McMeekin 1987, 32[VP]
sub.gla′ci.es.co.la. L. pref. *sub* below; L. n. *glacies* ice; L. suff. *cola* to dwell; M.L. adj. *subglaciescola* dwelling below ice.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. When motile, the cells are peritrichously flagellated. On solid media, the colonies produced are white to cream. Yellow colonies may form on media enriched with alanine or hydroxy-L-proline. This species cannot be grown on simple media, such as CAS or MH. Grows at temperatures as low as −5°C. The species has two biovars. Biovar I is motile and produces long filamentous cells >10 μm long. Biovar II is nonmotile and produces cells <10 μm long. The type strain belongs to Biovar I. Some characteristics of the species are listed in Tables BXII.γ.95 and BXII.γ.96. The species grows at pH 5.0–9.0 and does not grow above 25°C. The species does not grow in the presence of 30% NaCl. Catalase and phenylalanine deaminase positive. Phosphatase, lysine decarboxylase, and β-galactosidase negative. Does not produce indole or hydrogen sulfide; does not hydrolyze esculin. The species does not produce acid from either adonitol or sorbitol. There is no data available for acid production from other compounds. This species has been reported to grow on L-threonine and proline as primary carbon sources. It does not utilize sucrose, L-aspartic acid, L-glutamic acid, methionine, or L-asparagine as sole carbon sources. Sensitive to mercuric chloride (200 mg/l). Some strains are sensitive to Vibriostat O/129 (10 μg), penicillin G (10 i.u.), and chloramphenicol (30 μg). Resistant to gentamicin (10 μg), neomycin (30 μg), streptomycin (10 μg), and tetracycline (30 μg). The similarity of the 16S rDNA of both biovars of this species to other *Halomonas* species ranges from 93.7–96.1% for Biovar I and from 93.6–99.9% for Biovar II. The 16S rDNA sequence of Biovar II shows only 98.2% similarity to that of Biovar I. However, Biovar II shows 99.9% sequence similarity to *Halomonas halodurans*, indicating that Biovar II is likely a variant of the later species. Isolated from Antarctic hypersaline lakes.

The mol% G + C of the DNA is: 60.9–62.9 ± 1.0 (method unknown).

Type strain: ATCC 43668, DSM 4683, UQM 2926.

GenBank accession number (16S rRNA): M93358.

20. **Halomonas variabilis** (Fendrich 1989) Dobson and Franzmann 1996, 556^{VP} (*Halovibrio variabilis* Fendrich 1989, 205.) *va.ri.a' bi.lis.* L. adj. *variabilis* changeable, variable; referring to variation of the cell diameter with changing salt concentrations.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. The cells are curved rods (described as vibrion shaped). Coccoid bodies may form in older cultures. Cells have monotrichous flagellation. Colonies are circular, entire, smooth, slimy, raised, and produce a light brown pigment. The cells grow in NaCl concentrations from 1.2–4.9 M, with an optimum salt concentration of 1.0 M. The optimum pH for growth is 7.5; minimum, 6.5; maximum, 8.4. Temperature range for growth: 15–37°C; optimum, 33°C. Minimum doubling time, 7.5 h. The similarity of the 16S rDNA of this species to other *Halomonas* species ranges from 91.5–96.8%. Isolated from the North Arm of the Great Salt Lake Utah (USA).

The mol% G + C of the DNA is: 57.0 (method unknown).

Type strain: DSM 3051.

GenBank accession number (16S rRNA): M93357, X90483.

21. **Halomonas venusta** (Baumann, Baumann, Mandel and Allen 1972) Dobson and Franzmann 1996, 556^{VP} (*Delaya venusta* (Baumann, Baumann, Mandel and Allen 1972) Baumann, Bowditch and Baumann 1983a, 801; *Alcaligenes venustus* Baumann, Baumann, Mandel and Allen 1972, 426.) *ve.nus' tus.* L. adj. *venustus* lovely, beautiful.

The characteristics are as described for the genus and as listed in Tables BXII.γ.95 and BXII.γ.96. The cells possess peritrichous flagella. The species utilizes 52–76 organic compounds. Also utilized, in addition to compounds listed in Table BXII.γ.95, are: galacturonate, glucuronate, *N*-acetylglucosamine, butyrate, isobutyrate, valerate, isovalerate, caproate, heptanoate, caprate, glutarate, glycolate, α-ketoglutarate, aconitate, *meso*-inositol, propyleneglycol, 2,3-butyleneglycol, *n*-propanol, *n*-butanol, isobutanol, L-mandelate, benzoylformate, benzoate, *o*-, *m*-, and *p*-hydroxybenzoate, phenylate, quinate, δ-aminovalerate, anthranilate, ethanolamine, putrescine, betaine, sarcosine, acetamide, and allantoin. The similarity of the 16S rDNA of this species to other *Halomonas* species ranges from 93.2–98%.

The mol% G + C of the DNA is: 58.7 (Bd).

Type strain: ATCC 27125, DSM 4743.

GenBank accession number (16S rRNA): L42618.

Genus II. **Carnimonas** *Garriga, Ehrmann, Arnau, Hugas and Vogel 1998, 684*^{VP}

Margarita Garriga, Matthias A. Ehrmann, Jacint Arnau, Marta Hugas and Rudi F. Vogel

Car.ni' mo.nas. L. gen. n. *carnis* of meat; Gr. n. *monas* a unit, monad; *Carnimonas* a monad of meat.

Straight or slightly curved rods, 0.5–0.6 × 1.0–1.7 µm, occurring singly or in pairs. Gram negative. Does not form spores. **Nonmotile. Oxidase and catalase positive. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Moderately halotolerant.** Optimum temperature for growth is 28–30°C. **No growth occurs at 5°C or 37°C.** Chemoorganotrophic. **Acid, but no gas, is produced from D-glucose, D-xylose, and various other carbohydrates. β-Galactosidase (ONPG) activity occurs.** The main respiratory quinone is ubiquinone-9. Main components in the polar lipid composition are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylethanolamine. Major fatty acids are $C_{16:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{19:0cyc}$. Belongs to the class *Gammaproteobacteria*. Forms dark spots on the surface of raw, cured meat products.

The mol% G + C of the DNA is: 56.

Type species: **Carnimonas nigrificans** Garriga, Ehrmann, Arnau, Hugas and Vogel 1998, 685.

Further descriptive information

On tryptone soy agar, colonies appear white, convex, shiny, and circular. No pigmentation is visible in any culture media. Optimum temperature for growth is 28–30°C. No growth occurs at 5°C or 37°C. Growth occurs in the presence of 8% NaCl, but not at higher levels.

Indole production, reduction of nitrate, and the Voges–Proskauer reaction are negative. All strains produce acid from glucose, xylose, melibiose, maltose, and saccharose. No gas is produced from glucose. Additional physiological data are provided in Table BXII.γ.99.

Garriga et al. (1998) have reported that the main polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylethanolamine. In addition, there are three unidentified components. The fatty acid profile contains major amounts of several saturated and unsaturated straight chain fatty acids and only minor fractions of 3-hydroxylated fatty acids. The main fatty acids are palmitic acid ($C_{16:0}$), which comprises 40% of total fatty acids, and the cyclopropanic acid $C_{19:0\ cyc}$, which comprises 21.07%. Oleic acid ($C_{18:1\ \omega 9t}$) comprises 7.45% and a $C_{18:1\ \omega 7c/\omega 9t/\omega 12t}$ group comprises 12.9%. Moreover, a $C_{16:1}$ fatty acid comprises 6.7%, whereas only minor amounts of $C_{12:1\ 3OH}$ (1.85%) and traces of $C_{16:0\ 3OH}$ (0.46%) are found. No match was found after comparison with the microbial ID, TSBA library (Newark, DE, USA).

No pathogenic effect on mice is detectable 8 d after intraperitoneal injection of up to 1.9 × 10^{10} CFU of *Carnimonas nigrificans*. Under similar conditions, the bacteria used as controls (*Escherichia coli* HM-42, *Pseudomonas aeruginosa* HS-116, *Staphylococcus aureus* HS-93) show a concentration-dependent lethality.

The presence of dark spots on the surface of raw, cured meat products was first described by Hugas and Arnau (1987). In 1993, Arnau and Garriga identified a Gram-negative bacterium (now *C. nigrificans*) as being responsible for this defect. The defect, a rust-like color turning to black within hours, can be reproduced on comminuted pork meat containing salt (40 g/kg) and dex-

trose (20 g/kg) after inoculation of an overnight culture and storage in an aerobic environment at 30°C. The browning effect is increased by some amino acids, i.e., glycine, L-arginine, L-glutamine, and L-monosodium glutamate, when added (20 g/kg) to a meat mixture containing salt and dextrose. *N*-Acetyl-L-cysteine, L-cysteine, potassium metabisulfite, and propyl-3,4,5-trihydroxybenzoate (5 g/kg) are useful in the prevention of this defect (Arnau and Garriga, 2000). The browning produced by *C. nigrificans* with dextrose and amino acids and the inhibitory properties of some of the substances studied show similarities to the Maillard reaction. However, important differences exist in the temperature pattern, the oxygen effect, and carbohydrates involved.

Enrichment and Isolation Procedures

The isolation of *C. nigrificans* from raw, cured meat products must be done at the beginning of browning; no recovery is possible later. The organism is capable of growing on Cetrimide agar and MacConkey agar; consequently, these selective media could be used for isolation procedures. Incubation should be performed under aerobic conditions at 30°C for 2–3 days. After isolation, *C. nigrificans* grows well on the usual nutrient media (e.g., tryptone soy broth, brain–heart infusion broth).

Maintenance Procedures

Cultures in routine use can be maintained in tryptone soy broth or agar at 4°C. Cultures may be preserved for long-term storage in tryptone soy broth with 20% glycerol at −80°C.

Procedures for Testing Special Characters

Comparative sequence analysis of 16S rRNA gene sequences has revealed a diagnostic sequence that can be used as a target site for specific amplification. The sequence of the oligonucleotide used as specific primer for *C. nigrificans* strain CTCBS1 is 5′-TAA CGT CCT TCA TGC CGG-3′ (binding position 469–486 in the *E. coli* numbering system). This primer (bs1) has been checked for its specificity against more than 10,000 16S rRNA sequences by using the probe-checking software provided by the Ribosomal Database Project (Maidak et al., 1996). PCR and cycle conditions for the species-specific reaction with primer bs1 and universal primer 616V are as follows: one initial cycle 94°C (120 s), followed by 32 cycles of 94°C (45 s), 50°C (90 s), and 72°C (120 s). Master mixes are prepared with reaction buffer containing 10 mM Tris-HCl, 1.5 mM $MgCl_2$, 50 mM KCl, pH 8.3, 200 nM dNTP, 0.5 pmol each primer, and Taq DNA polymerase (Boehringer, Mannheim, Germany).

Specific amplification of a 480 bp fragment using primer bs1 and 616V occurs only in *C. nigrificans* strains.

Differentiation of the genus *Carnimonas* from other genera

The closest relatives of *Carnimonas nigrificans* are *Zymobacter palmae* and the genus *Halomonas* (at least *Chromohalobacter*). Some physiological and morphological properties, e.g., relationship to oxygen, growth temperature, hydrolysis of starch, oxidase reaction, as well as flagellation and motility, are useful in differentiating *Carnimonas* from these organisms (Table BXII.γ.99 and Table BXII.γ.100).

The mol% G + C content of 56, the presence of ubiquinone 9 as the major respiratory lipoquinone, and the lack of $C_{19:0\ cyc}$ in the non-polar lipid profile are sufficient to exclude these organisms from *Oceanospirillum*. The mol% G + C content of *Carnimonas nigrificans* CTCBS1 differs by at least 4.2% from those of *Halomonas* and *Chromohalobacter*, and there are distinct differences in the fatty acid profiles of these organisms; the levels of $C_{16:0}$ in the profiles of members of the genus *Halomonas* range from 15.5 to 32%, whereas the level in *Carnimonas nigrificans* CTCBS1 is 40%. Additionally, in contrast to *Halomonas*, no $C_{17:0\ cyc}$ could be detected in *Carnimonas nigrificans* CTCBS1.

Taxonomic Comments

The phylogenetic tree, based on 16S rDNA sequences, is shown in Fig. BXII.γ.118. The topology of all organisms illustrated in the tree is based on maximum likelihood analysis of 16S rDNA sequences (Fig. BXII.γ.118) and is consistent with a tree previously published by Dobson and Franzmann (1996). The closest relatives of strain *Carnimonas nigrificans* are *Zymobacter palmae* with 93.3% sequence similarity and, to a lesser extent, species of the genus *Halomonas* (at least 91.9%) and *Chromohalobacter* (91.5%).

The phylogenetic tree shows that the closest relationship is

to *Zymobacter palmae* ATCC 51623^{T}. *Zymobacter palmae* is the single species of the genus *Zymobacter* and the closest phylogenetic relative to strain CTCBS1 (Okamoto et al., 1993). The G + C content of its DNA is 55.8 mol%, in the range of that determined for CTCBS1. The profiles of the major fatty acids of the two strains are similar; however, a significant amount (5%) of a $C_{12:0}$ fatty acid that might be unique to *Zymobacter palmae* is not detected in strain CTCBS1 or the other closely related genera.

Genus III. **Chromohalobacter** *Ventosa, Gutierrez, García and Ruiz-Berraquero 1989, 384[VP] emend. Arahal, García, Ludwig, Schleifer and Ventosa 2001a, 1446)*

ANTONIO VENTOSA

Chro.mo.ha'lo.bac'ter. Gr. n. *chroma* color; Gr. n. *halos* the sea, salt; M.L. n. *bacter* rod; M.L. masc. n.*Chromohalobacter* colored salt rod.

Gram-negative, straight or sometimes slightly curved, rods (0.6–1.2 × 1.5–4.2 μm). Motile by polar or peritrichous flagella. Cells occur singly, in pairs, and in short chains. Spores are not formed. **Moderately halophilic.** Salt is required for growth. **The optimum salt concentration for growth is between 8 and 10%.** May grow at salt concentrations up to 30%. The broader ranges of temperature and pH observed for growth are 5–45°C (optimal 30–37°C) and pH 5.0–10.0 (optimal pH 7.5), respectively. **Aerobic.** Chemoorganotrophic. Catalase positive. **Oxidase negative. Most strains reduce nitrates.** Phenylalanine deaminase test is negative. Gelatin, starch, Tween 80, esculin, DNA, and tyrosine are not hydrolyzed. Acid is produced aerobically from D-glucose and other sugars. Carbohydrates, amino acids, and some polyols can serve as sole carbon sources. Colonies are cream to brown-yellow pigmented.

The mol% G + C of the DNA is: 62–66.

Type species: **Chromohalobacter marismortui** (ex Elazari-Volcani 1940) Ventosa, Gutierrez, García and Ruiz-Berraquero 1989, 384.

FURTHER DESCRIPTIVE INFORMATION

The genus *Chromohalobacter* was created by Ventosa et al. (1989) to accommodate seven moderately halophilic isolates obtained during the course of an extensive taxonomic study of bacteria isolated from salterns in the Mediterranean coast (Ventosa et al., 1982). These isolates showed phenotypic and chemotaxonomic features very similar to those of *"Chromobacterium marismortui"*, a species originally described by Elazari-Volcani (1940) based on strains isolated from the Dead Sea. This species was described in the 7th edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957), and in the 8th edition it was included in the genus *Chromobacterium* as a species *incertae sedis* since it did not produce violacein and lacked the typical flagellar arrangement of the genus *Chromobacterium* (Buchanan and Gibbons, 1974). It was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980). Until recently, the genus *Chromohalobacter* was represented by a single species, *Chromohalobacter marismortui*, which was phylogenetically closely related to species of the genus *Halomonas* and included in the family *Halomonadaceae* (Mellado et al., 1995b). Very recent studies based on 16S rDNA gene sequence comparison and other phenotypic and molecular data supported the conclusion that two species previously described as members of the genus *Halomonas*, *Halomonas canadensis* and *Halomonas israelensis*, should be placed in the genus *Chromohalobacter*, as *Chromohalobacter canadensis* and *Chromohalobacter israelensis*, respectively (Arahal et al., 2001a). Finally, a study of two strains previously assigned to the species *Halomonas elongata*, strains DSM 3043 and ATCC 33174, showed that they represent a different species of the genus *Chromohalobacter*, and named them as *Chromohalobacter salexigens* (Arahal et al., 2001b).

All species currently described as members of the genus *Chromohalobacter* have a specific requirement for Na^+. They grow optimally in media containing 8–10% salt and are defined as moderately halophilic microorganisms (Ventosa et al., 1998). Few studies have been carried out with the type species *C. marismortui*; however, *C. canadensis* and *C. israelensis* have been extensively used for physiological studies. These species were formerly designated as strain Ba_1 (Rafaeli-Eshkol, 1968), isolated from the Dead Sea (*C. canadensis*) and strain NRCC 41277, isolated by Matheson et al. (1976) as a medium contaminant (*C. israelensis*). More detailed information about their physiological and biochemical features can be found in a recent review (Ventosa et al., 1998).

To cope with the high external salinity, halophilic bacteria need to balance their cytoplasm with the osmotic pressure exerted by the external medium. However, in *C. canadensis* and *C. israelensis*, as in many other moderate halophiles, the sum of the apparent intracellular concentration of Na^+ and K^+ ions is much lower than the external concentration (Matheson et al., 1976; Goldberg and Gilboa, 1978). They accumulate intracellular organic compounds, called compatible solutes, such as glycine betaine (Rafaeli-Eshkol and Avi-Dor, 1968; Shkedy-Vinkler and Avi-Dor, 1975). However, the most wide spread compatible solutes found in halophilic bacteria, and in *Chromohalobacter* in particular, are ectoine and its β-hydroxy derivative, hydroxyectoine (Ventosa et al., 1998). During recent years, several studies have focused on the osmoregulatory mechanisms of *C. salexigens* DSM 3043. It was selected as an excellent model organism because it displays one of the widest ranges of salt tolerance found in nature. In order to maintain its internal osmolarity and generate turgor in environments with high salinities, *C. salexigens* accumulates compounds such as glycine betaine, choline or choline-*O*-sulfate, when present externally. However, the main osmoadaptation mechanism is the *de novo* synthesis of ectoine and hydroxyectoine (Cánovas et al., 1996, 1997, 1998b, 1999; Nieto et al., 2000). Genes involved in the biosynthesis of ectoine and the oxidation of choline to betaine have been recently characterized (Cánovas et al., 1998a, 2000). The ectoine synthesis genes of *C. salexigens* and *Halomonas elongata* have lower sequence homology values than was expected from two closely related halophilic microorganisms (Nieto et al., 2000).

The genome size, determined by pulsed-field gel electrophoresis, of three strains of *C. marismortui* (including the type strain) ranged from 1770 to 2295 kb and that of *C. israelensis* was estimated to be 2490 kb (Mellado et al., 1998). Several plasmids have also been reported (Ventosa et al., 1994; Mellado et al., 1995a; Vargas et al., 1995a). The basic replicon of the narrow-host-range plasmid pCM1 from *C. marismortui* has been sequenced and characterized in detail (Mellado et al., 1995a). Cloning and shuttle vectors useful for the genetic manipulation of these bacteria have been reported (Mellado et al., 1995c; Vargas et al., 1995a). Conjugation is the only genetic transfer mechanism that has been described for this genus (Vargas et al., 1997).

ENRICHMENT AND ISOLATION PROCEDURES

Selective procedures for the enrichment and isolation of species of the genus *Chromohalobacter* have not been reported. They can be isolated from hypersaline environments by direct plating on complex media supplemented with a salt mixture and incubation at 30–37°C for 7–10 d. The isolation medium described by Ventosa et al. (1982) can be used.

Maintenance Procedures

For short-term storage, the species of the genus *Chromohalobacter* can be maintained on complex medium containing 10% salts. An appropriate medium is described by Ventosa et al. (1989). Long-term storage of members of this genus can be carried out by freeze-drying, storage at −80°C, or storage in liquid nitrogen.

Differentiation of the genus *Chromohalobacter* from other genera

The genus *Chromohalobacter* belongs to the family *Halomonadaceae* and is closely related to the genus *Halomonas* (Fig. BXII.γ.119), as well as to *Zymobacter* and *Carnimonas*. Since the genus *Halomonas* is taxonomically heterogeneous and contains greater than 20 species, it is very difficult to differentiate these two genera based on phenotypic or chemotaxonomic characteristics. Typical features of species of the genus *Chromohalobacter* are their optimal growth in media containing 8–10% salt and characteristic results for the biochemical tests reported in the genus description. Species of the genus *Chromohalobacter* can be phylogenetically differentiated from other related genera by comparison of 16S rRNA gene sequences.

Differential features of the four currently recognized species of the genus *Chromohalobacter* are given in Table BXII.γ.101.

Acknowledgments

I am grateful to Drs. R.H. Vreeland and J.T. Staley for the critical reading of this article and to Dr. D.R. Arahal for help with the phylogenetic analysis.

yellow rings. They produce a yellow pigment and a violet-blue pigment which is not violacein. Production of pigment is favored by suboptimal growth temperatures, glycerol, and a salt concentration of 10%. In liquid medium containing 10% salts, turbidity and a pellicle are produced; usually brown-to-yellow pigments are also produced.

Grows in media containing 1–30% salts, with an optimum at about 10% salts. Growth occurs at 5–45°C (optimum temperature is 37°C) and pH 5–10 (optimal growth at pH 7.5) on solid media containing 10% salts. Acid is produced without gas under aerobic conditions in marine oxidation–fermentation medium supplemented with 10% salts and D-glucose, D-galactose, maltose, lactose, D-arabinose, D-xylose, sucrose, trehalose, glycerol, and D-mannitol. Generally, nitrate is reduced to nitrite (except the type strain). Gelatin, casein, starch, esculin, tyrosine, Tween 80, and DNA are not hydrolyzed. Phosphatase, Voges–Proskauer, β-galactosidase, phenylalanine deaminase, and arginine dehydrolase tests are negative.

The following compounds are utilized as sole carbon and energy sources: dulcitol, D-fucose, D-galactose, D-gluconate, D-glucose, glutamate, *meso*-inositol, maltose, D-mannitol, D-mannose, pyruvate, D-ribose, sucrose, D-sorbitol, and D-xylose. The following compounds are not utilized as sole carbon and energy sources: *N*-acetylglucosamine, amygdalin, DL-α-aminobutyrate, butyrate, cellobiose, citrate, esculin, *p*-hydroxybenzoate, hippurate, inulin, malonate, melibiose, oxalate, raffinose, salicylate, salicin, and D-tartrate. The following compounds are utilized as sole carbon, nitrogen, and energy sources: L-alanine, DL-arginine, L-glutamine, L-ornithine, L-proline, putrescine, and L-serine. The following compounds are not utilized as sole carbon, nitrogen, and energy sources: L-allantoin, betaine, creatine, ethionine, L-isoleucine, L-leucine, phenylalanine, sarcosine, L-threonine, and L-valine.

Isolated from the Dead Sea and marine salterns.

The mol% G + C of the DNA is: 62.1–64.9 (T_m).

Type strain: ATCC 17056, CCM 3518, DSM 6770, NCIMB 8731.

GenBank accession number (16S rRNA): X87219.

Additional Remarks: Other sequences: strain A-65 (X87220), strain A-100 (X87221), strain A-492 (X87222), and strain T1093 (U78719).

2. **Chromohalobacter canadensis** (Huval, Latta, Wallace, Kushner and Vreeland 1996) Arahal, García, Ludwig, Schleifer and Ventosa 2001a, 1447[VP] (*Halomonas canadensis* Huval, Latta, Wallace, Kushner and Vreeland 1995, 1130.)
ca.na.den′sis. M.L. n. *canadensis* pertaining to Canada, the country where the type strain was isolated.

See Table BXII.γ.101 and generic description for many features. Cells are Gram negative, straight or curved rods with rounded ends, 0.6–1.2 × 2.0–3.8 μm; cells occur singly, in pairs, or in short chains. Pleomorphic cells are not present. Both culture age and salt concentration affect chain length. Motile by a single polar flagellum. Spores are not formed. On solid complex media with 8% salts, colonies are translucent and convex with a smooth glistening surface, produce a nondiffusible white pigment, and have a diameter of 2–6 mm after 7 days of growth at 30°C.

Grows in media containing 3–25% NaCl from 15 to 30°C; grows in media with 8–32% NaCl at 45°C. Optimal growth at 7.5% NaCl. Growth occurs at 5–45°C (optimum temperature is 30°C) and from pH 5 to 9 on solid media containing 8% NaCl. Acid is produced from mannose, lactose, glycerol, and cellobiose but not from sucrose. Nitrate is reduced to nitrite. Phenylalanine deaminase and Voges–Proskauer tests are negative. Gelatin, starch, DNA, esculin, and agar are not hydrolyzed.

The following compounds are utilized as sole carbon and energy sources: acetate, citrate, DL-malate, succinate, lactate, D-glucose, xylose, L-arabinose, D-fructose, D-mannitol, *meso*-inositol, ethanol, mannose, esculin, glycerol, and gluconic acid. The following compounds are not utilized as sole carbon and energy sources: butyrate, isobutyrate, propionate, tartrate, benzoate, maltose, melibiose, L-sorbose, D-ribose, D-sorbitol, *n*-propanol, *n*-butanol, ethylene glycol, *n*-hexadecane, pyridine-1-oxide, formaldehyde, formamide, *N,N*-dimethylacetamide, and ethylenediamine. Isolated as a contaminant on Sehgal and Gibbons medium containing 25% NaCl.

The mol% G + C of the DNA is: 62 (T_m).

Type strain: ATCC 43984, DSM 6769, CECT 5385, CCM 4919, CIP 105571, NCIMB 13767, NRCC 41227.

GenBank accession number (16S rRNA): AJ295143.

3. **Chromohalobacter israelensis** (Huval, Latta, Wallace, Kushner and Vreeland 1996) Arahal, García, Ludwig, Schleifer

and Ventosa 2001a, 1447[VP] (*Halomonas israelensis* Huval, Latta, Wallace, Kushner and Vreeland 1996, 1189.)
is.ra.el.en' sis. M.L. n. *israelensis* an inhabitant of Israel.

See Table BXII.γ.101 and generic description for many features. Gram negative. Cells are straight rods with rounded ends, 0.6–0.9 × 1.5–4.2 μm, occurring singly and occasionally in pairs or short chains. Pleomorphic cells are not present. On solid complex medium with 8% NaCl colonies are flat with entire margins, produce a nondiffusible cream pigment, and have 2–6 mm in diameter after 7 days.

Grows in media containing 3.5–20% NaCl (optimum at 8% NaCl). Growth occurs at 15–45°C (optimum temperature is 30°C) and from pH 5 to 9. Acid is produced without gas from mannose, lactose, glycerol, cellobiose, and sucrose. Nitrate is reduced to nitrite. Phenylalanine deaminase, Voges–Proskauer, and methyl red tests are negative. Gelatin, starch, esculin, and DNA are not hydrolyzed.

The following compounds are utilized as sole carbon and energy sources: cellobiose, lactose, mannose, esculin, glycerol, acetate, starch, gluconic acid, and sucrose.

The mol% G + C of the DNA is: 65 (T_m).

Type strain: ATCC 43985, DSM 6768, CECT 5287, CCM 4920, CIP 106853, NCIMB 13766.

GenBank accession number (16S rRNA): AJ295144.

4. **Chromohalobacter salexigens** Arahal, García, Vargas, Cánovas, Nieto and Ventosa 2001b, 1460[VP]
sal.ex' i.gens. L. n. *sal* salt; L. v. *exigo* to demand; M.L. part. adj. *salexigens* salt-demanding.

See Table BXII.γ.101 and generic description for many features. Cells are Gram-negative rods, 0.7–1.0 × 2.0–3.0 μm; cells occur singly or in pairs. Motile. Spores are not formed. On solid, complex media containing 10% salts, colonies are cream, opaque, and circular and less than 2 mm in diameter; spreading may occur after extended incubation. In liquid medium containing 10% salts, a homogeneous turbidity is produced.

Grows in media containing 0.9–25% salts, and optimal growth at 7.5–10% salts. Growth occurs at 15–45°C (optimum temperature is 37°C) and from pH 5 to 10 on liquid media containing 10% salts (optimal growth at pH 7.5). Acid is produced from L-arabinose, D-fructose, D-galactose, glycerol, D-glucose, lactose, maltose, D-mannose, sucrose, and D-xylose, but not from trehalose. Nitrate is reduced to nitrite but nitrite is not reduced. Gelatin, starch, esculin, DNA, and Tween 80 are not hydrolyzed. Methyl red positive. Indole and acetoin are not produced. Phenylalanine deaminase, lysine decarboxylase, and ornithine decarboxylase are not produced.

The following compounds are utilized as sole carbon and energy sources: L-arabinose, erythritol, D-fructose, D-galactose, D-glucose, maltose, D-mannitol, D-mannose, D-sorbitol, sucrose, D-trehalose, D-ribose, D-xylose, ethanol, glycerol, *meso*-inositol, dulcitol, acetate, α-aminovalerate, α-ketoglutarate, citrate, fumarate, DL-glycerate, glutamate, malate, malonate, propionate, D-saccharate, succinate, and D-tartrate. The following compounds are not utilized as sole carbon and energy sources: adonitol, cellobiose, L-fucose, α-lactose, D-melibiose, D-raffinose, L-rhamnose, galactosamine, gluconolactone, inulin, DL-α-aminobutyrate, butyrate, caprylate, lactate and oxalate. The following compounds are utilized as sole sources of carbon, nitrogen and energy: L-arginine, L-asparagine, betaine, glycine, L-glutamine, L-lysine, L-ornithine, L-proline, and L-serine. The following compounds are not utilized as sole sources of carbon, nitrogen and energy: L-alanine, creatine, L-methionine, putrescine, sarcosine, L-threonine, and L-valine.

Isolated from salterns.

The mol% G + C of the DNA is: 64.2–66.0 (T_m).

Type strain: ATCC BAA-138, CECT 5384, CCM 4921, CIP 106854, DSM 3043, NCIMB 13768.

GenBank accession number (16S rRNA): AJ295146.

Additional Remarks: Other sequence: AJ295147 (*C. salexigens* ATCC 33174).

Genus IV. **Zymobacter** *Okamoto, Taguchi, Nakamura, Ikenaga, Kuraishi and Yamasato 1995, 418*[VP] *(Effective publication: Okamoto, Taguchi, Nakamura, Ikenaga, Kuraishi and Yamasato 1993, 336)*

Tomoyuki Okamoto, Hiroshi Kuraishi and Kazuhide Yamasato

Zy.mo.bac' ter. Gr. n. *zyme* leaven, ferment; M.L. n. *bacter* masc. equivalent of Gr. neut. n. *bakterion* rod♂sc. n. *Zymobacter* the fermenting rod.

Rod-shaped cells with rounded ends, 1.3–2.4 × 0.7–0.9 μm; usually single. **Motile by peritrichous flagella** that are nonsheathed. Gram negative. **Facultatively anaerobic.** Chemoorganotrophic. **Grow on and ferment 1 mol of glucose or the hexose moiety of maltose to produce approximately 2 mol each of ethanol and CO_2, with trace amounts of acids.** Ferment hexoses, α-linked di- and trisaccharides, and sugar alcohols. Growth occurs at pH 4.7–8.1. Catalase positive. **The predominant cellular fatty acids are oleic acid, cyclopropanic acid of $C_{19:0}$, and palmitic acid. The hydroxylated acid is characteristically $C_{12:0\ 3OH}$. The quinone system is ubiquinone-9.**

The mol% G + C of the DNA is: 55.4–56.2 (HPLC).

Type species: **Zymobacter palmae** Okamoto, Taguchi, Nakamura, Ikenaga, Kuraishi and Yamasato 1995, 418 (Effective publication: Okamoto, Taguchi, Nakamura, Ikenaga, Kuraishi and Yamasato 1993, 336.)

Further descriptive information

The morphology of the cells is depicted in Fig. BXII.γ.120. The cells can possess as many as 20 peritrichous flagella.

When grown on MY agar[1], the colonies are round, entire, smooth, opaque, and milky white. Colonies of similar size develop under aerobic and anaerobic growth conditions. When the organism is grown in MY broth, the medium is slightly turbid, becoming cloudy with flocculent cells during the late log phase growth, then transparent due to sedimentation of cells during the stationary phase. No pellicle is formed. Growth is better in static cultures than in shaken cultures. *Zymobacter* requires nic-

1. MY agar (per liter): yeast extract (Difco), 10.0; maltose, 20.0; KH_2PO_4, 2.0; NaCl, 5.0; agar (Difco), 15.0; pH 6.0.

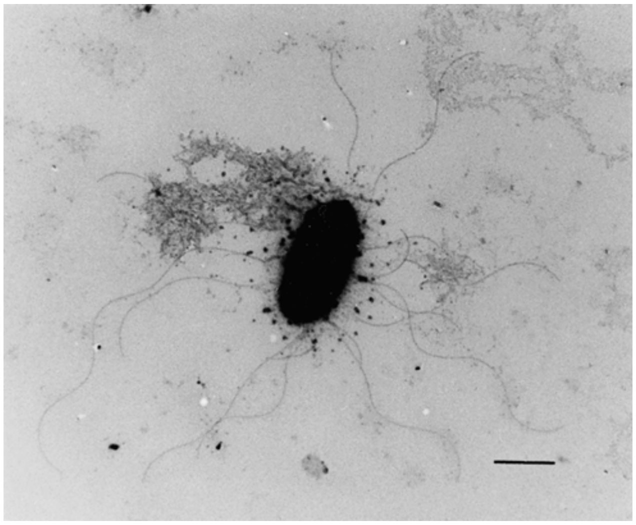

FIGURE BXII.γ.120. Electron micrograph of peritrichous flagella of *Zymobacter palmae* T109[T]. Bar = 1 μm.

otinic acid for growth. Growth does not occur in the absence of a sugar or sugar alcohol.

Growth occurs at 15–37°C (optimum, 30°C) and pH 4.7–8.1 (optimum, 6.0). The organisms are neither halophilic nor halotolerant, but they are considerably tolerant to ethanol and produce 5.8% ethanol from maltose after 6 d of fermentation.

The organism produces more than 0.5% (w/v) ethanol in the culture broth from glucose, fructose, maltose, sucrose, melibiose, raffinose, sorbitol, mannitol, and—depending on the strain—mannose and galactose. The specific growth rate on glucose is higher than that on maltose at sugar concentrations less than 7.5% (w/v). Growth is poor at glucose concentrations greater than 15% (w/v). The specific growth rate on maltose is substantially similar over a concentration range of 2.5–20% (w/v) (Table BXII.γ.102). Growth is initiated at 50% (w/v) maltose, but not at 25% (w/ v) glucose; this divergence may be due to the differing osmotic pressures exerted by these sugars.

The genera *Zymomonas*, *Saccharobacter*, and *Zymobacter* are unique among bacteria in terms of their energy-yielding metabolism, which produces ethanol, CO_2, and small amounts of other products. *Zymomonas* has been studied as a potential bacterium for the industrial production of ethanol, but its spectrum of fermentable sugars is limited to glucose, fructose, and sucrose (Ingram et al., 1998). *Zymobacter* (and *Saccharobacter*) may be preferable to *Zymomonas* in this regard, as it has a wider profile of fermentable sugars, especially maltose and raffinose.

Palmitic acid ($C_{16:0}$) comprises 46–54% of the whole cell fatty acids. Oleic acid ($C_{18:1\ \omega 9c}$) $C_{19:0\ cyc}$ account for 30–42% (Table BXII.γ.103).

Enrichment and Isolation Procedures

Okamoto et al. (1993) have used a two-step procedure to first isolate ethanol-tolerant bacteria and then select maltose-fermenting, ethanol-producing isolates to obtain *Zymobacter* strains. The composition of the isolation medium is (g/l): yeast extract (Difco), 10.0; glucose, 20.0; KH_2PO_4, 2.0; Bacto agar (Difco), 15.0 g; pH 6.0. Ethanol is added to a concentration of 5% (v/v). To prevent multiplication of fungi and yeasts, the antibiotic Kabicidine (Wako Pure Chemical Industries, Osaka, Japan) is added to a concentration of 100 mg/l. Diluted samples are plated onto the medium and incubated at 30°C for 4 d. Isolates are incubated at 30°C for 4 d in MY medium, and those that produce concentrations of ethanol in excess of 2% are selected. Four strains have been obtained from palm sap from among 500 samples of plant sap, fermented foods, and alcoholic beverages collected from tropical and subtropical regions of Brazil, Indonesia, Japan, Thailand, and other countries.

Maintenance Procedures

Zymobacter cultures can be maintained by serial transfer every 2 weeks on MY agar and stored at 4°C. *Zymobacter* can be preserved for many years by lyophilization, L-drying, or freezing with 50% glycerol at −80°C.

Procedures for Testing Special Characters

Characterization procedures for *Zymobacter* strains have been described by Okamoto et al. (1993). Conventional taxonomic features can be determined through standard methods. Test media that cannot support the growth must be supplemented with nicotinic acid (1 mg/l) and/or yeast extract (10.0 g/l), as well as with glucose or maltose. Flagellation is observed when cells are grown at 20°C for 12 h in brain–heart infusion broth (Difco) supplemented with nicotinic acid (1 mg /l), maltose (20.0 g/l), and liver infusion (10% (v/v); pH 6.0. The liver infusion is prepared by gently boiling 100 g of sliced cattle liver in 250 ml water for 30 min and filtering through cloth. Cells can be shadowed with platinum and visualized by transmission electron microscopy. The basal liquid medium for testing growth-factor requirement and fermentation of carbon compounds is composed of (g/l): K_2HPO_4, 7.0; KH_2PO_4, 2.0; $MgSO_4 \cdot 7H_2O$, 0.1; $(NH_4)_2SO_4$, 1.0; pH 6.0. Maltose is added when assessing growth-factor requirements, and nicotinic acid is added when evaluating the fermentation of carbon compounds.

Differentiation of the genus *Zymobacter* from other genera

Table BXII.γ.104 indicates the salient features that differentiate *Zymobacter* from other phylogenetically related genera. Characteristics that distinguish *Zymobacter* from *Halomonas* and *Chromohalobacter* are ethanol and CO_2 production from glucose, growth in relationship to oxygen, halophilic property, and habitat.

TABLE BXII.γ.102. Specific growth rate of *Zymobacter palmae* T109[T] as affected by the initial concentration of glucose and maltose

	Specific growth rate μ (h^{-1}) at a sugar concentration of (%):							
Sugar	2.5	5	7.5	10	12.5	15	17.5	20
Glucose	0.47	0.43	0.38	0.26	0.19	0.08	0.07	0.05
Maltose	0.2	0.24	0.25	0.29	0.26	0.26	0.2	0.2

Phenotypically and ecologically, *Zymobacter* is similar to the ethanol-producing genera *Zymomonas* and *Saccharobacter*, both of which occur in sugar-containing niches, such as plant juices. The features that differentiate *Zymobacter* from these genera are highlighted in Table BXII.γ.105. *Zymobacter* is clearly differentiated from these two genera by flagellation, sugar fermentation, vitamin requirements for growth, osmotic tolerance, mol% G + C of DNA, and ubiquinone system.

Taxonomic Comments

Zymobacter belongs to the family *Halomonadaceae*. The 16S rRNA gene of *Zymobacter* palmae T109^T (accession number D14555) is

TABLE BXII.γ.103. Cellular fatty acids of *Zymobacter palmae*[a]

Fatty Acid	Range, %	Mean, %

[j]Strains T1093 (U78719), A-65 (X87220), and A-492 (X87222).

89.3–92.5% similar to that of *Halomonas* and 91.1% similar to that of *Chromohalobacter* (Dobson and Franzmann, 1996).

Zymobacter belongs to the family *Halomonadaceae*, which is in the class *Gammaproteobacteria*, and includes the marine genera *Halomonas* and *Chromohalobacter*. In contrast with these genera, *Zymobacter* is of terrestrial origin, is neither halophilic nor halotolerant, is facultatively anaerobic, and produces ethanol and CO_2. The nucleic acid similarity among the 16S rRNAs of these genera is about 90%, and, like *Halomonas* and *Chromohalobacter*, *Zymobacter* demonstrates the 15 signature sequences necessary to place it in the family *Halomonadaceae* (Dobson and Franzmann, 1996) (Table BXII.γ.106). *Zymobacter* (type strain of *Zymobacter palmae*) differs from *Chromohalobacter* and *Halomonas* at 16S rRNA positions 1424, 1439, 1462, and 1464 (*E. coli* numbering system), at which *Halomonas* has the sequences described as characteristic of its genera (Dobson and Franzmann, 1996) (Table BXII.γ.106). The 16S rRNA similarity of *Zymobacter* to another marine genus, *Oceanospirillum*, is 88.7–89.7%—similar to that between *Zymobacter* and *Halomonas* and *Chromohalobacter*. However, *Oceanospirillum* is phylogenetically distinct; it lacks the signature sequences of the *Halomonadaceae* (Dobson and Franzmann, 1996). Chemotaxonomically, the *Halomonadaceae* share the ubiquinone-9 respiratory system, whereas *Oceanospirillum* uses ubiquinone-8 (Sakane and Yokota, 1994). Because the genus *Zymobacter* and the species *Zymobacter palmae* were established in light of the taxonomic features of four strains isolated from a limited source (palm sap from the southern region of Japan), a precise circumscription of the attributes of this genus and species requires the isolation of strains from more varied sources.

The phenotypic features of *Zymobacter* are similar to those of the genera *Zymomonas* and *Saccharobacter*. All of these organisms are Gram negative, facultatively anaerobic, inhabit plant juice and the like, and produce ethanol and CO_2 from carbohydrates. Phylogenetically, *Zymobacter* is distinct from *Zymomonas*, which be-

The family *Pseudomonadaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Pseudomonas* (type genus), *Azomonas*, *Azotobacter*, *Cellvibrio*, *Mesophilobacter*, *Rhizobacter*, and *Rugamonas*. *Serpens* is also included.

Aerobic chemoorganotrophs with respiratory metabolism. Most are motile by means of flagella. *Azomonas* and *Azotobacter* fix nitrogen; *Azotobacter* forms cysts.

Type genus: **Pseudomonas** Migula 1894, 237[AL] (Nom. Cons., Opin. 5 of the Jud. Comm. 1952, 121.)

Genus I. **Pseudomonas** *Migula 1894, 237[AL] (Nom. Cons., Opin. 5 of the Jud. Comm. 1952, 121)**

Norberto J. Palleroni

Pseu.do' mo.nas or Pseu.do.mo' nas. Gr. adj. *pseudes* false; Gr. n. *monas* a unit, monad; M.L. fem. n. *Pseudomonas* false monad.

Straight or slightly curved rods but not helical, 0.5–1.0 × 1.5–5.0 μm. **Most of the species do not accumulate granules of polyhydroxybutyrate**, but accumulation of polyhydroxyalkanoates of monomer lengths higher than C_4 may occur when growing on alkanes or gluconate. Do not produce prosthecae and are not surrounded by sheaths. No resting stages are known. Gram negative. **Motile by one or several polar flagella**; rarely nonmotile. In some species lateral flagella of short wavelength may also be formed. **Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor; in some cases nitrate can be used as an alternate electron acceptor**, allowing growth to occur anaerobically. **Xanthomonadins are not produced.** Most, if not all, species fail to grow under acid conditions (pH 4.5 or lower). Most species do not require organic growth factors. Oxidase positive or negative. Catalase positive. Chemoorganotrophic. **Strains of the species include in their composition the hydroxylated fatty acids $C_{10:0\ 3OH}$ and $C_{12:0}$, and $C_{12:0\ 2OH}$, and ubiquinone Q-9.** Widely distributed in nature. Some species are pathogenic for humans, animals, or plants.

**Editorial Note:* The literature search for the chapter on *Pseudomonas* was completed in January, 2000. During the course of unavoidable publication delays, a number of new species were described or reclassified after the chapter was completed. It was not possible to include these species in the text of to include their characteristics in the comparative tables. The reader is encouraged to consult the studies listed in the Further Reading section and the *International Journal of Systematic and Evolutionary Microbiology* (2000–2003).

Pseu.do.mon.a.da′ ce.ae. M.L. fem. n. *Pseudomonas* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Pseudomonadaceae* the *Pseudomonas* family.

The family *Pseudomonadaceae* was circumscribed for this volume on the basis of phylogenetic analysis of 16S rRNA sequences; the family contains the genera *Pseudomonas* (type genus), *Azomonas*, *Azotobacter*, *Cellvibrio*, *Mesophilobacter*, *Rhizobacter*, and *Rugamonas*. *Serpens* is also included.

Aerobic chemoorganotrophs with respiratory metabolism. Most are motile by means of flagella. *Azomonas* and *Azotobacter* fix nitrogen; *Azotobacter* forms cysts.

Type genus: **Pseudomonas** Migula 1894, 237[AL] (Nom. Cons., Opin. 5 of the Jud. Comm. 1952, 121.)

Genus I. **Pseudomonas** *Migula 1894, 237[AL] (Nom. Cons., Opin. 5 of the Jud. Comm. 1952, 121)**

NORBERTO J. PALLERONI

Pseu.do′ mo.nas or Pseu.do.mo′ nas. Gr. adj. *pseudes* false; Gr. n. *monas* a unit, monad; M.L. fem. n. *Pseudomonas* false monad.

Straight or slightly curved rods but not helical, 0.5–1.0 × 1.5–5.0 µm. **Most of the species do not accumulate granules of polyhydroxybutyrate**, but accumulation of polyhydroxyalkanoates of monomer lengths higher than C_4 may occur when growing on alkanes or gluconate. Do not produce prosthecae and are not surrounded by sheaths. No resting stages are known. Gram negative. **Motile by one or several polar flagella**; rarely nonmotile. In some species lateral flagella of short wavelength may also be formed. **Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor; in some cases nitrate can be used as an alternate electron acceptor**, allowing growth to occur anaerobically. **Xanthomonadins are not produced.** Most, if not all, species fail to grow under acid conditions (pH 4.5 or lower). Most species do not require organic growth factors. Oxidase positive or negative. Catalase positive. Chemoorganotrophic. **Strains of the species include in their composition the hydroxylated fatty acids $C_{10:0\ 3OH}$ and $C_{12:0}$, and $C_{12:0\ 2OH}$, and ubiquinone Q-9.** Widely distributed in nature. Some species are pathogenic for humans, animals, or plants.

**Editorial Note:* The literature search for the chapter on *Pseudomonas* was completed in January, 2000. During the course of unavoidable publication delays, a number of new species were described or reclassified after the chapter was completed. It was not possible to include these species in the text of to include their characteristics in the comparative tables. The reader is encouraged to consult the studies listed in the Further Reading section and the *International Journal of Systematic and Evolutionary Microbiology* (2000–2003).

Note: The above-mentioned characteristics do not allow an absolute differentiation of this genus from other genera of aerobic pseudomonads[1] belonging to other ribosomal RNA groups. The following approaches add considerable solidity to the decision to assign newly isolated strains to *Pseudomonas*. One is the determination of sequence similarity in ribosomal RNA, which can be demonstrated either by hybridization techniques or, more practically, by nucleotide sequence determination. The second is determination of the fatty acid and ubiquinone composition. These two approaches will be discussed in separate sections of this chapter.

The mol% G + C of the DNA is: 58–69.

Type species: **Pseudomonas aeruginosa** (Schroeter 1872) Migula 1900, 884 (*Bacterium aeruginosum* Schroeter 1872, 126.)

Further descriptive information

General Comments The following sections provide further descriptive information on the properties of species assigned to the genus *Pseudomonas*, beyond the basic characteristics that have been highlighted in the above genus definition. Unfortunately, the comments that follow refer to only a few species, and the available information for these species is uneven. Thus, a literature survey shows that most references on *P. aeruginosa* are focused on its medical importance as an opportunistic pathogen; *P. putida* references are concentrated on its remarkable biochemical versatility; and those on *P. fluorescens* also highlight biochemical properties, some of which are directed to understanding its role in the promotion of plant growth. *P. stutzeri* and *P. mendocina* have attracted attention as denitrifiers, and, in recent years, an infamous side of their reputation is their potential activities as opportunistic pathogens.

Many of the species listed at the end of this chapter or in the tables are little known beyond the details published in the original species descriptions. In addition to these unavoidable limitations, the details that are given for the better known species of the genus represent, by necessity, a radical simplification of the mass of information found in the literature since the date of publication of the first volume of the *Manual* (Palleroni, 1984).

Cell morphology and fine structure The cells of *Pseudomonas* strains occasionally differ substantially in size and shape from the general definition. For instance, the original description of *"P. ovalis"* (now considered to be a synonym of *P. putida*) highlighted the oval shape of the cells, while the cells of other *P. putida* strains and of some plant pathogenic fluorescent species may far exceed the 5 μm indicated in the definition.

A morphological character that was used to differentiate members of the genus *Pseudomonas* from other aerobic pseudomonads was the inability of the former to accumulate endocellular granules of poly-β-hydroxybutyrate (PHB) when growing in media of low nitrogen content on various carbon sources. More recently, the fluorescent members of *Pseudomonas* were found to be able to accumulate polyhydroxyalkanoates (PHAs) composed of monomers of medium chain lengths (C_6 to C_{12}) when grown on carbon sources such as gluconate, alkanes, and alkenes (Huisman et al., 1989; Anderson and Dawes, 1990; Steinbüchel and Valentin, 1995). Further comments on this subject may be found in the section Procedures for Testing Special Characters, below.

Thin sections of cells of *Pseudomonas* show cell walls and membranes characteristic of Gram-negative bacteria. In freeze-etched preparations of *P. aeruginosa* cells, as many as nine layers can be defined, accounting for all the electron-dense and electron-transparent layers that can be observed in thin sections (Lickfield et al., 1972; Gilleland et al., 1973). Gilleland and collaborators have shown that the outer membrane of the cell wall could be split down the middle when the cells were freeze-etched in the presence of a cryoprotective agent (Gilleland et al., 1973), thus confirming an earlier interpretation of similar experiments. The outer layer thus separated from the outer membrane had in its inner face numerous spherical units, which are made up of protein and in some cases were aggregated in the shape of small rods. *P. aeruginosa* is extremely sensitive to the action of EDTA, which provokes cell lysis. The spherical elements were removed by EDTA treatment but could be restored by addition of magnesium ions, which also restored cell stability.

Flagella and pili (fimbriae) Typically, *Pseudomonas* cells have polar flagella. The flagellar insertion in some instances is not exactly polar but subpolar, and occasionally it may be difficult to differentiate the latter from the so-called degenerately peritrichous type observed in members of other genera. In addition to the polar flagella, lateral flagella of short wavelength may be produced by strains of some species (*P. stutzeri*, *P. mendocina*) and are shed much more easily than the polar flagella. Growth on solid media favors the formation of lateral flagella, which suggests that they may be involved in swarming of the population on solid surfaces (Shinoda and Okamoto, 1977).

The number of flagella has taxonomic importance. Based on the work performed at the University of California in Berkeley, the number of flagella (usually expressed as "one" or "more than one") was highly characteristic for all the strains of a species that have been examined. To get good results, it is advisable to follow well-controlled growth conditions and to express the results on a statistical basis, as indicated by Lautrop and Jessen (1964). Some practical recommendations and basic details of the technique described by these authors will be summarized in the section Procedures for Testing Special Characters. Unfortunately, they have not been followed in the description of most species. In Jessen's classical study of *P. aeruginosa*, 97% of the cells with stained flagella had only one flagellum, 3% two flagella at one pole, and only three cells (about 0.05% of the collection) had three flagella. According to the definition proposed by Lautrop and Jessen (1964), the group can be characterized as polar monotrichous. Only one strain deviated from the limit defined for monotrichous strains in having two flagella on 15% of the flagellated cells, instead of the accepted maximum of 10%.

The amino acid sequence of the flagella of a given species is not always homogeneous. An analysis of the virulence-associated locus *fliC* of *P. aeruginosa* revealed two types of flagellin genes, one variable and the other conserved. Differences in the flagellar sequences amount to about 35%, but the two proteins fold into similar structures during polymerization (Spangenberg et al., 1996). In two strains of *P. putida*, flagellins of apparent molecular masses of 81 kDa and 50 kDa, respectively, were identified. Within the chromosomal fragment encoding the large component, two genes homologous to two flagellin genes of *Salmonella typhimurium* and one gene homologous to a *P. aeruginosa* flagellin gene were identified. The deduced molecular mass of the product of

1. The word "pseudomonad" will be used quite often in this chapter. Although it may be clear to many, the precise meaning is given in the paper "The aerobic pseudomonads: a taxonomic study" by Stanier et al. (1966). It comprises all the species assigned to the genus *Pseudomonas* as classically defined. Ever since this publication, a fairly accurate definition has also been included in the editions of Webster Collegiate Dictionary.

the first flagellin gene was 68 kDa instead of 81 kDa, suggesting posttranslational modification. Both the N- and C-terminal sequences are conservative, while the middle section is variable (Winstanley et al., 1994). PCR amplification of flagellar genes of *P. aeruginosa* gave products that were analyzed for restriction fragment length polymorphism, and 13 groups could be defined, suggesting that this approach may provide a useful genetic marker for the study of genetic variation among closely related species (Winstanley et al., 1996).

Fimbriae (pili) of polar insertion have been reported for *P. aeruginosa* and *P. alcaligenes* in the early studies of Fuerst and Hayward (1969). No fimbriae have been observed in the strains of *P. fluorescens*, *P. chlororaphis*, and *P. putida* that have been examined.

The *P. aeruginosa* pili are about 6 nm wide, thinner than those of enteric bacteria. They act as receptors for various phages and are retractile (Bradley, 1972a, b), but not all the pili of this species have the property of withdrawing into the cell (Bradley, 1974). Fig. BXII.γ.121 shows the polar fimbriae of *P. aeruginosa*, whose genetic determinants are mobilized by the FP plasmids (Bradley, 1980b

P. aeruginosa produces type-4 pili, which are found in a number of pathogenic bacteria and are involved in cell adhesion to epithelial cells (Woods et al., 1980; Doig et al., 1988). The adhesive region is located at the tip of the pilus, but this mode of attachment is not universal among fimbriae of different species (Smyth et al., 1996). In the C-terminal region of pilin there is a disulfide loop of 12–17 amino acids, and even though pili of different prototypes have little sequence similarity, the loops in all cases are structurally similar. However, the loops do not seem to be essential in maintaining the functionality of the binding domain. In addition to the fimbriae, exoenzyme S and flagella are additional adhesins of importance in the attachment process (Hahn, 1997).

Type-4 pili not only determine attachment to epithelial cells, but also cause a form of surface translocation called twitching motility (Henrichsen, 1975; Bradley, 1980a). Adhesion of *P. aeruginosa* cells to mucin is pilus-independent. A gene *fliO* complemented mutations in motility and adhesion to mucin (Simpson et al., 1995). A gene homologous to the *fliF* gene of other species has been identified in *P. aeruginosa*. It is involved in both motility and adhesion to mucin. Further characterization of the markers involved showed that the basal body structures of flagella also are important for adhesion (Arora et al., 1996).

Pilus formation is genetically very complex and depends on the expression of more than 30 genes distributed in at least six regions of the *P. aeruginosa* chromosome (Mattick et al., 1996; Tan et al., 1996; Watson et al., 1996a). The locations of a number of the pili genes have now been determined. Some of the genes encode proteins highly homologous to factors involved in protein secretion (Alm and Mattick, 1995, 1997; Alm et al., 1996b; Hahn, 1997). At least four different mechanisms are known to participate in the assembly of fimbriae from subunits (Vu-Thien et al., 1996

Some years ago, it was found that the amino terminal sequence of *P. aeruginosa* pili had marked similarity with that of *Neisseria meningitidis* and *Moraxella nonliquefaciens* (Buchanan and Pearce, 1979). One of the gene clusters encodes proteins strikingly similar to chemotaxis components of enteric bacteria and the gliding *Myxococcus xanthus*. In *M. xanthus*, type-4 pili have a role in what has been called "social motility" (Darzins, 1994; Darzins and Russell, 1997; Wu et al., 1997b). Work done with polyclonal antibodies raised against pilins expressed by *P. aeruginosa*, *Moraxella bovis*, *Neisseria gonorrhoeae*, *Dichelobacter nodosus*, and *Vibrio cholerae* showed that these polypeptides have conserved antigenic and, in most instances, immunogenic determinants, which are located in the highly similar amino-terminal domains (Patel et al., 1991).

AlgR is considered to be a regulator of alginate production in *P. aeruginosa*; in addition, it is required for twitching motility. Adjacent to the *algR* gene, a sensor gene (*fimS*) has been identified, and AlgR and FimS appear to represent another example of the two-component signal transduction systems that have been identified in bacteria. AlgU, an alternate sigma factor, also affects both alginate production and twitching motility, indicating that type-4 fimbriae and alginate, two important virulence determinants, are closely related (Whitchurch et al., 1996).

A gene region identified in nonfimbriated, phage-resistant transposon mutants of *P. syringae* pathovar *phaseolicola* (in this treatment described as a pathovar of *P. savastanoi*) has a high degree of similarity with a *P. aeruginosa* region required for pilus type-4 production (Alm and Mattick, 1995). Pili mutants that have lost the twitching motility characteristic of type-4 fimbriae, could be complemented in *trans* by homologous or heterologous subunits from the same strains (PAO or PAK) and from strains of other species such as *Dichelobacter nodosus* (Watson et al., 1996b).

Composition of cell envelope The cytoplasmic membrane separates the bacterial cytoplasm from other components of the cell envelopes, and its efficiency as a barrier is related to the lipid bilayer composition, which may undergo relatively rapid changes to adjust its fluidity to changes in the composition of the medium and the physical conditions of the environment.

In contrast to the cytoplasmic membrane, the structure of the outer membrane is asymmetrical. It is composed of a special lipid (lipopolysaccharide, LPS) with hydrocarbon chains giving low fluidity to the inner region of the LPS. Toward the outside region, chains of carbohydrates give to the whole cells a specific antigenic identity. The outer membrane is quite effective as a barrier against passage of molecules such as the antibiotics, which may have a deleterious effect on the cells, but at the same it must be permeable to nutrients. This discrimination is effected by the presence of porins.

The outer membrane proteins of pseudomonads carry the designation Opr followed by a letter or a letter and number (Hancock and Carey, 1980). One monomeric *Pseudomonas* protein, OprF, is similar to OmpA of *E. coli*; it is highly antigenic and not specific toward the solutes that enter the cells (Nikaido, 1992). In *Pseudomonas*, porins are composed of monomeric proteins, and not trimeric proteins as in *E. coli*. The outer membrane of *P. fluorescens* can change its permeability in direct relationship with growth temperature, even though no difference in composition could be found to correlate with this transition. The effect was attributed to a change in the structure of the porins that affects their function, since a decrease in the growth temperature induced a reduction in the conductance in the major component, OprF, suggesting a structural change (De et al., 1997).

Protein fractions representing the OprF of two *P. fluorescens* strains were purified and characterized. A sequence similarity of 94% was found among OprFs of strains from origins as different as milk and soil (De et al., 1995). OprF of *P. aeruginosa* is a major outer membrane component, and as such it is potentially inter-

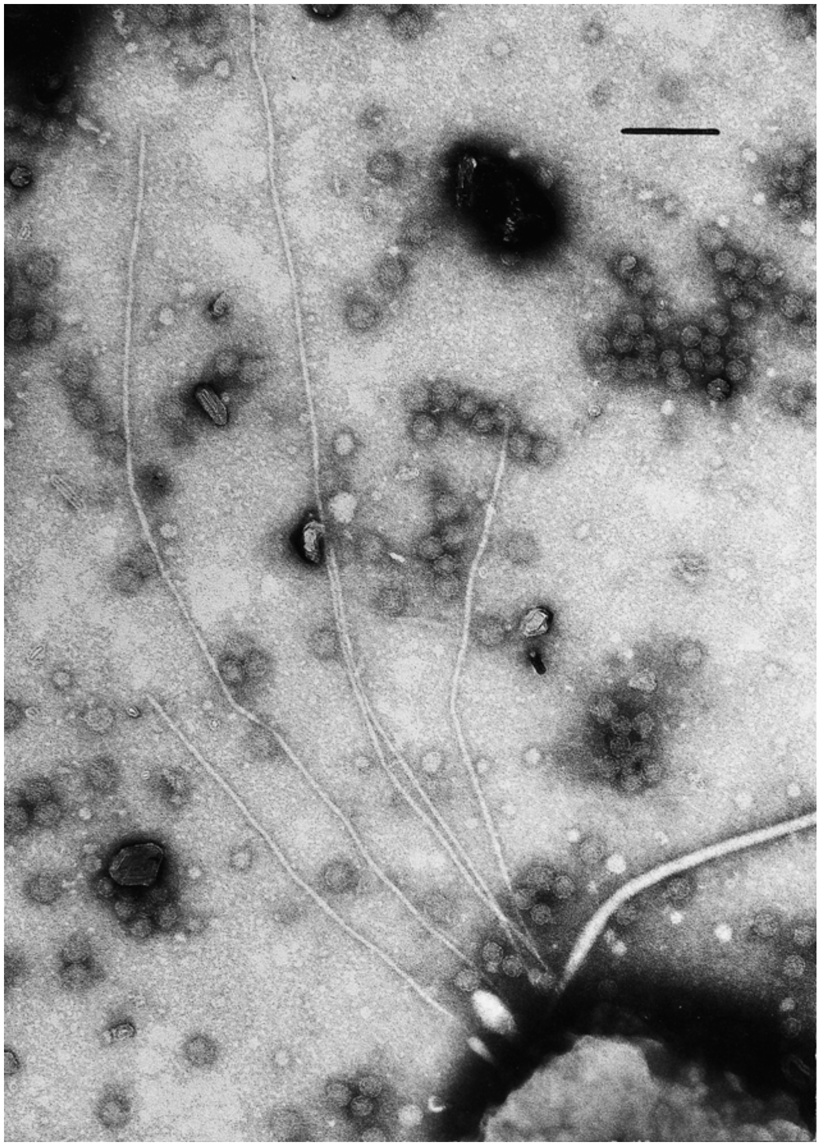

FIGURE BXII.γ.121. *Pseudomonas aeruginosa* strain PAC5 polar pili, which have been prevented from retracting by the adsorption of a pilus-specific bacteriophage; this can be seen scattered over the field. Bar = 0.1 μm. (Reproduced with permission from D.E. Bradley, Canadian Journal of Microbiology *26:*155–160, 1980, ©National Research Council of Canada.)

esting for the preparation of vaccines (Rawling et al., 1995). There are differences in the location of OprFs between the two species. Thus, while in *P. fluorescens* the protein is embedded in the outer membrane in such a way that it offers a surface-exposed region rich in proline, this region is absent in *P. aeruginosa* and in *P. syringae*. In addition, in *P. aeruginosa*, the entire protein is embedded, without an exposed region to the outside (De Mot et al., 1994).

An outer membrane protein of *P. fluorescens* that was inducible under conditions of phosphate limitation was purified and characterized (Leopold et al., 1997). It did not show similarity to any of the known outer membrane proteins. Its distribution among different strains of the species was uneven, i.e., it was not present in all strains, which simply may reflect the internal heterogeneity of *P. fluorescens*. A method of immunofluorescence microscopy involving cell permeability was developed to visualize the specific expression of the protein in cells exposed to limiting phosphate concentrations, in order to use the system to measure phosphate availability (Leopold et al., 1997). In *P. aeruginosa*, exposure to limiting phosphate provoked the expression of porin OprP. Only one of three lysine residues of this protein was required to form the specific phosphate binding site in OprP (Sukhan and Hancock, 1996).

Resistance to polymyxin B, gentamicin, and EDTA is associated with the outer membrane protein OprH in *P. aeruginosa*, which is expressed under magnesium-limiting conditions (Rehm and Hancock, 1996).

P. aeruginosa is able to simultaneously express two different LPS types, which migrate to different positions in electrophoresis and have been named bands A and B. The B band corresponds to the component that confers to the cell its O-antigen serological specificity and the A band to a common antigen. Two of the

eight genes that are part of the operon that controls band A biosynthesis and transport encode proteins that are highly similar to a number of proteins that are part of the ABC (acronym for "ATP-binding cassette") transport systems (Rocchetta and Lam, 1997). Of the two LPS O-polysaccharide species, one confers to the cells high hydrophobicity, and the other, hydrophilicity. The factors that provoke a change in the ratio between these two components affect both adhesion and survival (Makin and Beveridge, 1996).

Pigments and siderophores Early taxonomic treatments of the genus *Pseudomonas* included pigmentation as a generic character, but this is no longer valid. In fact, the colonies and other cell masses always display some colors due to normal cellular components, which, in some instances, become quite apparent. Thus, *P. stutzeri* is grouped with the nonpigmented species, even though the colonies of many strains become dark brown due to high concentration of cytochrome *c* in the cells.

In his comprehensive monograph on the taxonomy of *P. aeruginosa* and other fluorescent pseudomonads, Jessen (1965) listed six pigments produced by the type species: four phenazines (pyocyanin, pyorubin, chlororaphin, oxiphenazin), the *Pseudomonas* blue protein, and pyoverdine. Several phenazine pigments can be produced by a single strain (Chang and Blackwood, 1969). The best known and most characteristic of these pigments is the phenazine blue pigment pyocyanin, identified many years ago as the cause of the blue color of the pus of wounds infected with *P. aeruginosa*. Synthesis of pyocyanin by *P. aeruginosa* can be stimulated by growth in King A medium (King et al., 1954). It is inducible in a dose-dependent manner and its production is strongly enhanced by addition of L-*N*-(3-oxohexanoyl) homoserine lactone to the medium (Stead et al., 1996).

Phenazine pigments synthesized by other fluorescent pseudomonads are the green, almost insoluble, chlororaphin of *P. chlororaphis*, and the orange phenazine-monocarboxylic acid characteristic of *P. aureofaciens* (in the present treatment these taxa are considered to be subspecies of *P. chlororaphis*). The species *"P. lemonnieri"*, which was considered by Stanier et al. (1966) as a biovar of *P. fluorescens*, produces an intracellular blue pigment that has been chemically characterized (Starr et al., 1960, 1967). Some strains of *P. aeruginosa* are able to produce melanin pigments (Mann, 1969).

Other important pigments from the physiological and taxonomic standpoints are the pyoverdines. They are the typical yellow-green pigments of the so-called fluorescent pseudomonads. Jessen (1965) found that his collection of strains of *P. aeruginosa* contained 328 fluorescent strains producing pyocyanin, 18 fluorescent strains not producing pyocyanin, five nonfluorescent strains with pyocyanin, and three nonpigmented strains. Strains of this species lacking one or more of the characteristic pigments, however, could be identified based on other phenotypic properties, and, in general, pigmentation is a most striking but not always dependable characteristic for species identification. In any case, identification of fluorescent *Pseudomonas* species by examination of the fluorescence profiles of pigments diffusing into the medium has been proposed by Shelly et al. (1980).

Pyoverdines are also physiologically important because they function as efficient siderophores (Meyer and Abdallah, 1978; Meyer and Hornsperger, 1978). Their production is enhanced under conditions of iron-starvation. All pyoverdines share a quinoleinic chromophore, which is linked to peptides of different compositions and sizes. This may vary from 6–12 D- and L-amino acid residues. With minor exceptions, each fluorescent *Pseudomonas* type strain produces a pyoverdine with a specific amino acid composition (Budzikiewicz, 1993). However, within a single species there is a diversity of peptide structures.

The presence of D- and L-amino acid in pyoverdines as well as possible cyclic structures suggests a similarity the cyclic peptides of antibiotic properties produced by some Gram-positive bacteria and toxins synthesized by *Pseudomonas syringae* pathovars. These observations are indicative of a nonribosomal type of synthesis (Georges and Meyer, 1995; Merriman et al., 1995). In a search for components of such a system, high molecular weight cytoplasmic proteins have been identified. As expected, they are produced by cells of fluorescent pseudomonads in iron-deficient media, for which they have been named iron-repressed cytoplasmic proteins (IRCPs). They vary from M_r 180–600 kDa, and they give characteristic electrophoresis profiles for strains producing different pyoverdines. On the other hand, they are absent from mutants in pyoverdine synthesis and from cells of nonfluorescent pseudomonads (Georges and Meyer, 1995). As mentioned by Meyer et al. (1997), pyoverdines provide information of use in strain typing and epidemiological applications.

Using a system with a promotorless *lacZ* gene, 24 insertion mutants of *P. aeruginosa* unable to synthesize pyoverdine were isolated. All the mutations could be allocated within a 103-kb region ("pyoverdine region") at 47 min of the *P. aeruginosa* strain PAO genetic map, very near the catechol region (Tsuda et al., 1995). The genetic determinants of pyoverdine production occupy a region of at least 78 kb, but few genes have been characterized at present. *pvdE*, recently identified, codes for a protein that is a member of the ATP-binding cassette group of membrane transporters (McMorran et al., 1996). *pvdA* encodes an enzyme that catalyzes a key step in the synthesis. Three tightly iron-regulated regions are located in a fragment upstream of *pvdA*. Fur (ferric uptake repressor, a protein that controls expression of iron-repressible genes) indirectly controls *pvdA* transcription. When iron is not limiting, Fur blocks the *pvdA* promoter, thus inhibiting transcription of several pyoverdin genes (Leoni et al., 1996). Gene *pvdS* is also required for pyoverdine biosynthesis by *P. aeruginosa*. Under conditions of unlimited iron, Fur also acts here as a repressor, binding to the *pvdS* promoter and preventing expression (Cunliffe et al., 1995).

Because siderophores are iron-scavenging compounds, a large number of strains of *P. aeruginosa* have been analyzed by different methods for pyoverdine-mediated iron incorporation, and in all cases the collection could be subdivided into the same three groups, in spite of the inclusion of strains devoid of pyoverdine production in some of the groups (Meyer et al., 1997). The *P. aeruginosa* cells also are able to incorporate iron combined with siderophores of foreign origin. For instance, they can produce a receptor (PfeA) for the iron trapped by enterobactin, a siderophore synthesized by enteric bacteria. PfeA production depends on a regulator and a sensor, which are members of the family of two-component regulatory systems. The operon of regulator/sensor is probably regulated by iron, since the regulator gene in this system has a sequence similarity to the iron uptake regulator *fur*, the gene that codes for the above-mentioned Fur protein (Dean et al., 1996). Iron can be transported into *P. aeruginosa* not only by enterobactin but also by at least one of its breakdown products, 2,3-dihydroxybenzoyl-L-serine, in a process that is neither iron-repressible nor strongly energy-dependent (Spangenberg et al., 1995).

Attempts to complement a pyoverdine mutant from a *P. ae-*

ruginosa PAO cosmid bank resulted in the recovery of an apparent wild-type phenotype. Physical mapping indicated that the cloned fragment corresponded to a different region of the PAO chromosome and that the properties of the transconjugants were not the result of a true complementation. The yellow-green fluorescent compound was different in its properties from pyoverdine and it was named pseudoverdine. It lacks a peptide chain, but it resembles pyoverdine in its spectral properties (Stintzi et al., 1996).

Aside from pyoverdines, the fluorescent pseudomonads also produce other strain-specific, but chemically related, siderophores called pseudobactins. A method for isolation of pseudobactin from pseudomonads, and an assay for fluorescent siderophores based on reverse-phase HPLC, have been described (Nowak-Thompson and Gould, 1994). When grown in an iron-deficient medium, each of two strains of *P. putida* and *P. fluorescens* produced two different novel yellow-green fluorescent pseudobactins. All four compounds contained a dihydroxyquinoline-based chromophore. The receptor proteins of the two species are similar but not identical (Khalil-Rizvi et al., 1997). The composition of the corresponding peptides has been described, but the reason for the differences are not apparent, since the uptake system seems to consist of a single receptor in both organisms. Fragments of the peptide component of one pseudobactin have been synthesized. Antifungal peptides called pseudomycins have related structures, but the one mentioned here does not have activity against fungi (Koushik et al., 1997).

A *P. putida* strain WCS358 produces a fluorescent pseudobactin that has been described in detail (von der Hofstad et al., 1986). In spite of the results mentioned in the previous reference, the results here indicate that the ability of *P. putida* WCS358 to use different pseudobactins of various origins is related to the presence of multiple outer membrane receptor proteins (Koster et al., 1995).

In addition to the siderophores mentioned above, the fluorescent pseudomonads produce another one, pyochelin, which is not pigmented (that is, it does not have an absorption spectrum in the visible region), and appears to have low efficiency as an iron-scavenging compound (Liu and Shokrani, 1978). In the composition of pyochelin there is one molecule of salicylic acid (which is by itself a siderophore) condensed to two cysteinyl residues. In *P. aeruginosa*, the pathway of salicylate synthesis has been clarified: conversion of chorismate (which also acts as an intermediate of aromatic amino acid biosynthesis) to isochorismate, which is converted to salicylate plus pyruvate. These steps are catalyzed by two iron-repressible proteins, PchA and PchB (Serino et al., 1995).

The iron trapped by the siderophores is utilized by the producing organism presumably after reduction to ferrous ion, a step catalyzed by ferrisiderophore reductases. Ferripyoverdine reductase is ubiquitous among *Pseudomonas* species (Halle and Meyer, 1992), and since its activity is not under iron regulation, it is not part of the siderophore genetic system (J.-M. Meyer, personal communication).

There are earlier reports of other fluorescent compounds that have been isolated from fluorescent pseudomonads. These include four pteridine derivatives isolated from *"P. ovalis"* (presumably *P. putida*) (Suzuki and Goto, 1971); two fluorescent antibiotics isolated from *P. fluorescens*, which were named fluopsin C and fluopsin F (Shirahata et al., 1970); 6-hydroxymethylpteridine, an intermediate in folic acid synthesis (Viscontini and Frater-Schröder, 1968); and erithroneopterine of *P. putida* (Suzuki and Goto, 1972).

P. fragi, a nonpigmented member of the genus, does not produce siderophores in detectable amounts and it is very sensitive to iron-limiting conditions. Growth can be strongly stimulated by iron combined with siderophores of foreign origin. The siderophores include enterobactin, some pyoverdines, and siderophores of eucaryotic origin, such as transferrin, lactoferrin, and hemoglobin. Probably this property is related to the capacity of *P. fragi* to grow in milk, from which the first strain of this species was isolated many years ago (Gruber, 1905). Iron starvation in this species may induce the synthesis of the siderophore-mediated iron uptake system (Champomier-Vergès et al., 1996).

The following is a useful summary of siderophores produced by *Pseudomonas* species, kindly supplied by J.-M. Meyer from a manuscript submitted for publication. All strains of the fluorescent species *P. aeruginosa*, *P. fluorescens*, *P. chlororaphis*, and *P. putida* produce pyoverdines as main siderophores. Some strains also produce pyochelin and/or salicylic acid as secondary siderophores (Cox et al., 1981; Meyer et al., 1992; Visca et al., 1993). *P. stutzeri* ATCC 17588 produces desferrioxamines E and D2 (Meyer and Abdallah, 1980; Azelvandre, 1993); a different strain of *P. stutzeri* (RC7) gives a catechol-type siderophore (Chakraborty et al., 1990) and an unclassified *Pseudomonas* sp., aerobactin (Buyer et al., 1991). No siderophores have been detected in *P. stutzeri* YPL-1 (Lim et al., 1991), in *P. fragi* (Stintzi et al., 1996), and in *P. mendocina*. It is interesting to note here that the internal heterogeneity of the nonfluorescent species *P. stutzeri* is also reflected in the capacity for siderophore production.

P. alcaligenes, *P. mendocina*, and *P. flavescens* produce yellow to orange pigments that have not been chemically characterized. Strains of one of the biovars of *P. fluorescens*, which were originally assigned to the species *"P. lemonnieri"*, produce an intracellular insoluble pigment of structure related to that of indigoidine, the purple pigment of *"Pseudomonas indigofera"*. Both pigments are derivatives of 3,3′-bipyridyl (Kuhn et al., 1965). The pigment of *"P. lemonnieri"* has been reexamined, its chemical structure has been clarified, and it has received the name "lemonnierin" (Ferguson et al., 1980; Jain and Whalley, 1980). Pigments that are not soluble in water and remain associated with the cell mass are found in many former *Pseudomonas* species now classified in other genera.

Nutrition and growth conditions Strains of *Pseudomonas* species can grow in minimal, chemically defined media with ammonium ions or nitrate as nitrogen source and a single organic compound as the sole carbon and energy source. Some of the species previously assigned to *Pseudomonas* have true growth factor requirements, but none of the species belonging to the rRNA group I (Palleroni, 1984) has an absolute dependence on these nutritional supplements. In media of minimal composition, strains of phytopathogenic *P. syringae* grow very slowly in comparison with strains of the main saprophytic species, and that growth is enhanced by addition of small amounts of complex organic materials (yeast extract, peptones). However, in most cases no true dependence on organic growth factors can be demonstrated. Pantothenate is required by strains of *P. syringae* pathovar *avellanae*, now considered as an independent species, *P. avellanae* (Janse et al., 1996) (see List of Species). In addition, organic growth factors are required by some species of uncertain phylogenetic position (*P. iners*, *P. lanceolata*, *P. spinosa*) (see List of Species). Occasionally, attempts have been made to improve

the poor growth of phytopathogenic *Pseudomonas* in chemically defined media. In one such proposal, a defined medium for "*P. tomato*" (*P. syringae* pathovar *tomato*) includes L-asparagine, L-glutamine, or L-threonine as a nitrogen source, and D-galactose as carbon source. The organism grows in this medium as well as in complex media (Bashan et al., 1982).

From time to time the capacity for nitrogen fixation has been claimed for some species that later on proved to be unable to perform this function under strictly controlled conditions. In the first edition of this *Manual*, it was assumed that none of the *Pseudomonas* species could be considered legitimate nitrogen fixers; however, this ability is reported to occur in strains of the nonfluorescent species *P. stutzeri* (Krotzky and Werner, 1987; Puente and Bashan, 1994), which is also a vigorous denitrifier.

Requirement for sodium ions has been observed for *Pseudomonas elongata* which, according to Anzai et al. (2000) should be placed in the genus *Microbulbifer* following further taxonomic studies, and for *P. halophila* (described in the section Other Species). This requirement, which is one of the characteristics typical of so-called marine eucaryotes, has not been determined in the majority of *Pseudomonas* species.

P. aeruginosa can utilize one of many different sources of sulfur in the medium. The list includes inorganic and organic compounds, from which the aromatic sulfur compounds are excluded. If sulfur sources other than the preferred ones (sulfate, cysteine, or thiocyanate) are the only ones available, a set of 10 sulfate starvation induced (SSI) proteins are upregulated (Hummerjohann et al., 1998). One of these proteins is periplasmic and has high affinity for sulfate. Even though no similarity of the other nine SSI proteins to other proteins of known function has been detected, they also may represent scavenging elements for the S-sources preferred by the cells. Studies on the genetics of the starvation response have indicated the role of cysteine biosynthetic intermediates and the possibility that at least two independent co-repressors are operative in *P. aeruginosa* (Hummerjohann et al., 1998).

The ability to grow in very simple mineral media at the expense of many organic compounds has served as the basis for extensive nutritional characterization of a large number of strains, providing a mass of phenotypic data ideally suited for taxonomic studies by numerical methods. Aside from their taxonomic implications, nutritional investigations on the utilization of certain groups of compounds have served as the bases for many interesting studies on metabolic pathways, their regulatory mechanisms, and their phylogenetic significance.

The best growth temperature for growth of most strains is approximately 28°C. Some species grow at a substantial rate at 4°C and thus can be considered psychrotrophic. For others the maximum temperature is about 45°C, and therefore they are not true thermophiles. None of the members of the genus tolerates acidic conditions and growth is invariably negative at pH 4.5.

Metabolism and metabolic pathways The metabolism of *Pseudomonas* is typically respiratory with oxygen as the terminal electron acceptor, but some species also can use nitrate as an alternate electron acceptor and can carry out oxygen-repressible denitrification (dissimilatory reduction of nitrate to N_2O or N_2). In most cases, denitrification is the property of all members of a given species, and only a few strains may be unable to denitrify. Denitrification is not a species characteristic in *P. fluorescens*; only some biovars are able to denitrify (Stanier et al., 1966).

Some cytochromes are involved in denitrification through the participation of a special cytochrome oxidase that probably is a remnant of a very primitive mechanism dating from the pre-aerobic era of the planet (Yamanaka, 1964). An excellent review on the cellular and molecular aspects of denitrification has been published by Zumft (1997). *Pseudomonas* is rich in denitrifying species. The core structures of the denitrification apparatus in these and in denitrifiers belonging to other genera demand the participation of around 50 genes.

Assimilation of nitrate occurs through the reduction of nitrate to ammonia. Although there may be common intermediates in the assimilatory and dissimilatory routes of nitrate reduction (Hartingsveldt et al., 1971), the pathways are encoded by different sets of genes. Some mutations with pleiotrophic effects are due to alterations in a gene involved in molybdenum incorporation into the nitrate reductases (Sias et al., 1980). A comprehensive review on the diversity of enzymes involved in denitrification in the pseudomonads and the genetic organization is available (Zumft and Körner, 1997), as well as a description of the localization of the genes in the *P. aeruginosa* PAO map (Vollack et al., 1998). The genes for nitrate reduction (*nir*), nitric oxide reduction (*nor*), and nitrous oxide reduction (*nos*) have been located in a 30-kb gene cluster in the chromosome of *P. stutzeri* (Braun and Zumft, 1992), and a sequence analysis of a 9.72-kb internal segment that includes the genes is now available (Glockner and Zumft, 1996). Very useful accounts of the enzyme diversity and gene organization of the denitrification genes in denitrifying pseudomonads, as well as the regulatory elements of the denitrification system of *P. stutzeri*, have been published by Zumft and collaborators (Cuypers and Zumft, 1992; Zumft and Körner, 1997). As mentioned before, a review by Zumft (1997) includes much useful information on this subject.

The oxidative degradation of some substrates (particularly the aromatic compounds) or their intermediates by *Pseudomonas* occasionally involves the participation of oxygenases. Both mono- and dioxygenases coupled to a variety of electron donors are well represented in species of the genus. Oxygenases acting on aliphatic compounds such as alkanes may be part of complex systems, and this is also true for the oxidation of some compounds like camphor by *P. putida*, with steps involving oxygenases of considerable complexity that include the iron-sulfur protein putidaredoxin and cytochrome P-450_{CAM} (Gunsalus et al., 1971). Other systems include the iron protein rubredoxin (Lode and Coon, 1971) and cytochrome *o* (Peterson, 1970).

The classical reactions of the tricarboxylic acid cycle are found in all species of *Pseudomonas* that have been examined. A key reaction is the synthesis of citrate from oxaloacetate and acetyl-CoA, which is under a control system typical of absolute aerobic organisms (Weitzman and Jones, 1968). The control of peripheral catabolic enzymes (amidase, histidase, enzymes of aromatic compounds, and camphor metabolism) by intermediates of the tricarboxylic acid cycle are a manifestation of the central position that it occupies in metabolism. Those intermediates that are used for biosynthetic purposes can be replenished by carboxylation of pyruvate and by the action of the enzymes isocitrate lyase and malate synthase, which are part of the anaplerotic system known as the glyoxylate cycle (Kornberg and Madsen, 1958). A multienzyme complex of tricarboxylic acid cycle enzymes (fumarase, malate dehydrogenase, citrate synthase, aconitase, and isocitrate dehydrogenase) that catalyzes the reactions from fumarate to α-ketoglutarate has been identified in *P. aeruginosa* cells, from which it can be released by gentle osmotic lysis. The complex can be reconstituted from the individual enzymes provided that

one of the two citrate synthase isoenzymes is present (Mitchell, 1996).

A variety of macromolecules can be degraded by some strains by means of extracellular enzymes. Hydrolytic enzymes that have been studied in detail include the proteases of *P. aeruginosa* (Morihara, 1964; Morihara et al., 1965), which are important in infections caused by this organism. In addition to these early studies, others will be discussed in relation to pathogenesis to humans and animals.

One of the differences between *P. fluorescens* and *P. putida* is the ability of the former species to produce extracellular proteases, to which the property of gelatin liquefaction can be attributed. A metalloprotease of *P. fluorescens* that is inhibited by EDTA and has a trypsin-like activity has been found to be highly homologous to zinc metalloproteases of diverse origins (Kim et al., 1997a).

Carbohydrates The amylolytic activity of *P. stutzeri* is responsible for rapid starch hydrolysis, one of the characteristic phenotypic properties of the species. The enzymology of the exoamylase, which is responsible for the formation of maltotetraose as end product, has been examined at the molecular level, and the enzyme has been cloned (Morishita et al., 1997). Phytopathogenic pseudomonads have been found to hydrolyze pectin (Hildebrand, 1971; Ohuchi and Tominaga, 1973, 1975; Wilkie et al., 1973), xylan (Maino et al., 1974), and glycosides (Hayward, 1977).

Common monosaccharides (glucose, fructose, galactose, L-arabinose) are used by strains of most species of the genus, but growth of some of the species (*P. stutzeri*, *P. mendocina*, *P. syringae*) may be slow. Most hexoses are degraded by the Entner-Doudoroff pathway, which was discovered in studies on *P. saccharophila* (Entner and Doudoroff, 1952).

The fluorescent pseudomonads have multiple peripheral pathways for glucose oxidation that converge for the synthesis of 6-phosphogluconate, which is further degraded by the Entner-Doudoroff pathway (Eisenberg et al., 1974). Of these routes, one involves direct oxidation of the sugar (oxidative pathway), and either gluconate or 2-ketogluconate can serve as a precursor of 6-phosphogluconate. However, in *P. putida*, 6-phosphogluconate is synthesized preferentially from 2-ketogluconate (Vicente and Cánovas, 1973). Induction of the oxidative pathway in *P. aeruginosa* can only occur in the presence of oxygen. Under denitrifying conditions, only the so-called phosphorylative pathway (starting with the phosphorylation of glucose) is operative in this organism (Hunt and Phibbs, 1981).

A rather peculiar situation is represented by the oxidative degradation of glucose by *P. putida*, which has been shown to oxidize the sugar with a dehydrogenase peripherally located in the cells. This results in gluconate accumulation in the surrounding medium, from which it is taken back into the cells after induction of a specific energy-dependent transport system. The properties of this system are different from a second one specific for glucose uptake by the same cells (Schleissner et al., 1997).

The metabolism of fructose by several species of fluorescent and nonfluorescent pseudomonads occurs by means of a phosphoenol-pyruvate (PEP) phosphotransferase system. The product is fructose-1-phosphate, which may be further phosphorylated and cleaved by an aldolase. An isomerization of free mannose to fructose can be demonstrated in cell-free extracts of strains of many species (Alicia Palleroni and N.J. Palleroni, unpublished), although the significance of this conversion is obscure at present.

An excellent review on alternative pathways of carbohydrate metabolism by pseudomonads is available (Lessie and Phibbs, 1984).

Polyhydroxyalkanoates At the time the main body of *Pseudomonas* taxonomy was being developed, the general ideas on reserve materials of the species of rRNA group I were vague. As mentioned before, although other groups of aerobic pseudomonads accumulate PHB in granules easily observable under phase microscopy, particularly when grown in media of low nitrogen and high carbon content, with few exceptions the species of rRNA similarity group I (Palleroni, 1984) now classified in the genus *Pseudomonas* did not seem to have the same capacity, and it was even assumed that the reserve material might be dispensable proteins, because of production of ammonia during respirometric studies on the endogenous metabolism of cells. Later it was discovered that the fluorescent pseudomonads (typical representative species of the genus *Pseudomonas*) were able to accumulate PHAs of medium chain length (C_6 to C_{12}) (de Smet et al., 1983; Lageveen et al., 1988). The studies confirmed the inability of these organisms to accumulate PHB, and this inability remains a reliable negative characteristic for differentiation from most other aerobic pseudomonads (Anderson and Dawes, 1990). It has been suggested that the ability to accumulate the medium chain length PHAs, which is not dependent on the presence of a plasmid, may be in itself of taxonomic value (Huisman et al., 1989). Additional comments on this subject will be found in the section Differentiation of the Genus *Pseudomonas* from Other Genera.

Hydrolysis of PHAs for the utilization of these carbon reserve materials can be catalyzed by extracellular depolymerases, of which one, produced by a strain of *P. fluorescens*, has been purified and characterized (Schirmer et al., 1993). The depolymerases are considered to belong to the family of serine hydrolases (Schirmer and Jendrossek, 1994; Schirmer et al., 1995). All lipases and an esterase of *P. fluorescens* had hydrolytic action on triolein, but this property was absent from the PHA depolymerases tested, although these enzymes have the lipase consensus sequence in their structure. The finding confirms the differences in function between lipases and PHA depolymerases (Jaeger et al., 1995).

Biotechnological applications of some pseudomonad lipases have been reported (Tan et al., 1996).

Polyalcohols Genes involved in the conversion of 2,3-butylene glycol to central metabolites by *P. putida* have been characterized, and there is a high similarity between the genes that encode 2,3-butylene glycol dehydrogenase and those that encode alcohol dehydrogenases (Huang et al., 1994). Degradation of polyethylene glycol has been demonstrated with *P. stutzeri* (Obradors and Aguilar, 1991). The mannitol dehydrogenase of strains of *P. fluorescens* has a broad specificity, since it is also capable of oxidation of other polyalcohols such as sorbitol and arabitol (Brunker et al., 1997).

Acetamide and biochemical evolution Acetamide is used for growth by several species of aerobic pseudomonads, among them *P. aeruginosa* (Stanier et al., 1966). It is hydrolyzed with liberation of ammonia, which is used then as a nitrogen source, but the enzyme can also catalyze acyl transfer reactions. Amides hydrolyzed by the wild-type enzyme include propionamide, acetamide, formamide, and butyramide, in order of decreasing rates of hydrolysis. Among the amides there are excellent inducers (lactam-

ide) as well as anti-inducers (butyramide). Clarke and collaborators found this system to be admirably suited for studies of experimental evolution, during which it became possible to evolve amidases with altered substrate specificities, and the work of this group, performed during many years, stands out as a beautiful example of experimentation on evolution achieved in the laboratory (Brown et al., 1969; Betz and Clarke, 1972; Brown and Clarke, 1972; Betz et al., 1974). Among the many papers that followed these, a general article by Clarke and Drew (1988) gives a good account of the experimental evolution of the system.

The genetic organization and complete sequence of the amidase operon is now known (Drew and Wilson, 1992), as well as details of its transcription antitermination regulation (Wilson et al., 1996).

Aromatic compounds For obvious reasons, as in the preceding sections, the short review that follows has been restricted to very few of the many valuable reports available in a well-populated literature on the degradation of aromatic compounds and some derivatives.

Members of the genus *Pseudomonas* are notorious for their capacity of aerobic degradation of a number of hydrocarbons, aromatic compounds, and their derivatives, of which there are natural compounds and final products or intermediates from industrial activities. A considerable number of these compounds are toxic and are found widely dispersed as environmental contaminants. Many of them can be used for growth by *Pseudomonas* species. Compounds as diverse as benzoate, *p*-hydroxybenzoate, mandelate, tryptophan, phthalate, salicylate, polycyclic compounds, and many derivatives may be metabolized by strains of the group following pathways that converge to a common intermediate, β-ketoadipate. This intermediate is formed soon after the last aromatic intermediate is cleaved by a 1,2-dioxygenase, in a type of ring cleavage frequently referred to as an *ortho* cleavage. The attack of the aromatic rings and the mode of cleavage are properties of taxonomic importance that have been of help in the circumscription of the rRNA similarity group I, which comprises the *Pseudomonas* species. In recent times, much information has been added to our basic knowledge of this pathway, but few details will be mentioned here. A transporter and chemoreceptor protein from *P. putida* that is part of the β-ketoadipate regulon, PcaK, was localized in the membrane when it was expressed in *E. coli*, adding to our understanding of active transport in aromatic compound metabolism (Nichols and Harwood, 1997).

The *ortho* ring cleavage, however, is not the only type of ring opening that can be catalyzed by these organisms, and the conditions adopted for the experimental protocols should be precisely stated. Thus, in the *P. putida* type strain, cleavage of the diphenolic intermediate catechol can be caused by either a 1,2-dioxygenase or a 2,3-dioxygenase (which causes a *meta* cleavage) depending on whether the substrate on which the cells had grown was benzoate or phenol, respectively (Feist and Hegeman, 1969). Often the genes encoding for *meta*-cleavage systems are located in plasmids (Austen and Dunn, 1980), as in the case of the well-known plasmid TOL, but this is not always so. Hewetson and collaborators have presented evidence of an *ortho* pathway for *p*-cresol degradation catalyzed by enzymes encoded by plasmid genes (Hewetson et al., 1978). The *ortho*-enzymes (1,2-dioxygenases, also known as pyrocatechases) in different *P. putida* strains have all a common ancestry (Nakai et al., 1995).

The pathways of aromatic compounds degradation are still being extensively analyzed. Regulatory mechanisms, genetic organization of the genes involved, immunological properties of the enzymes, and molecular studies as the bases for strain improvement in possible bioremediation applications are all subjects of great basic and practical importance. Detailed reports on the molecular aspects of the analysis of aromatic hydrocarbon degradation have been published (Zylstra and Gibson, 1991; Zylstra, 1994). Figs. BXII.γ.122 and BXII.γ.123 have been taken from one of these sources (Zylstra and Gibson, 1991). Fig. BXII.γ.122 is a graphical representation of the main differences among aerobic pseudomonads in the initial steps of pathways of toluene degradation, and illustrates differences among some members of rRNA groups I and II (represented by *Burkholderia cepacia* and *Ralstonia pickettii*). The ring fissions of the dihydroxy intermediates (catechol, protocatechuic acid, and 3-methyl-catechol) occur in different ways. For organisms carrying the TOL plasmid (A) and *P. putida* F1 (E), the cleavage of the catechols results from the action of a 2,3-dioxygenase (*meta* cleavage), while cleavage of the protocatechuate by *P. mendocina* is of the *ortho* type (1,2-dioxygenase). Further details of the initial steps of toluene degradation by *P. putida* F1 are shown in Fig. BXII.γ.123.

Tolerance to toluene can develop in cells that normally are killed by contact with solvents. A *P. putida* strain able to grow in the presence of high concentrations of aromatic hydrocarbons was isolated from enrichments. The tolerance was inducible in this strain. Electron micrographs showed that the cells had a periplasmic space wider than that in the nontolerant cells and

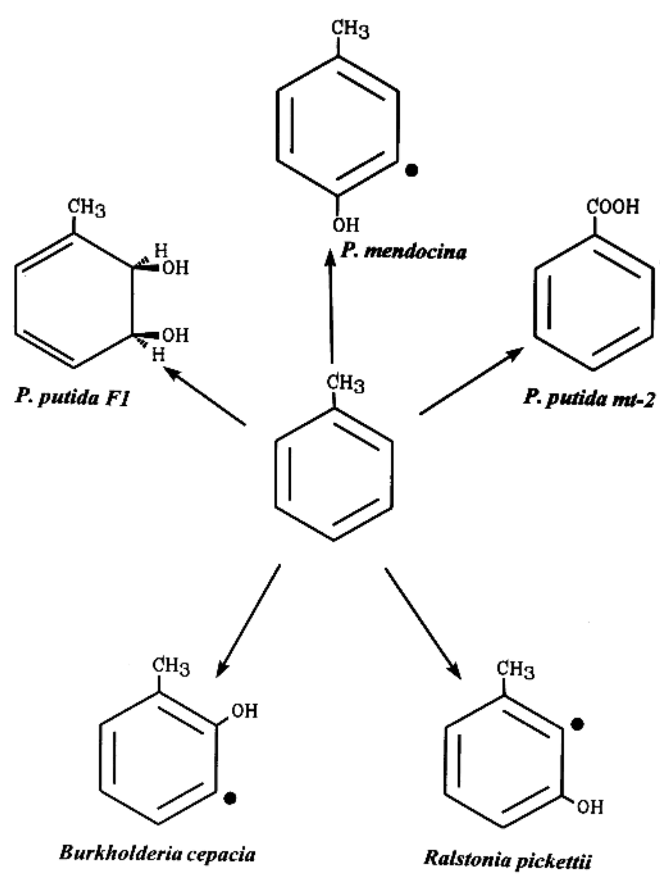

FIGURE BXII.γ.122. Pathways for the degradation of toluene by aerobic pseudomonads. The black dot indicates the position of the subsequent hydroxylation that precedes ring cleavage. For more details, see text and also Zylstra and Gibson (1991).

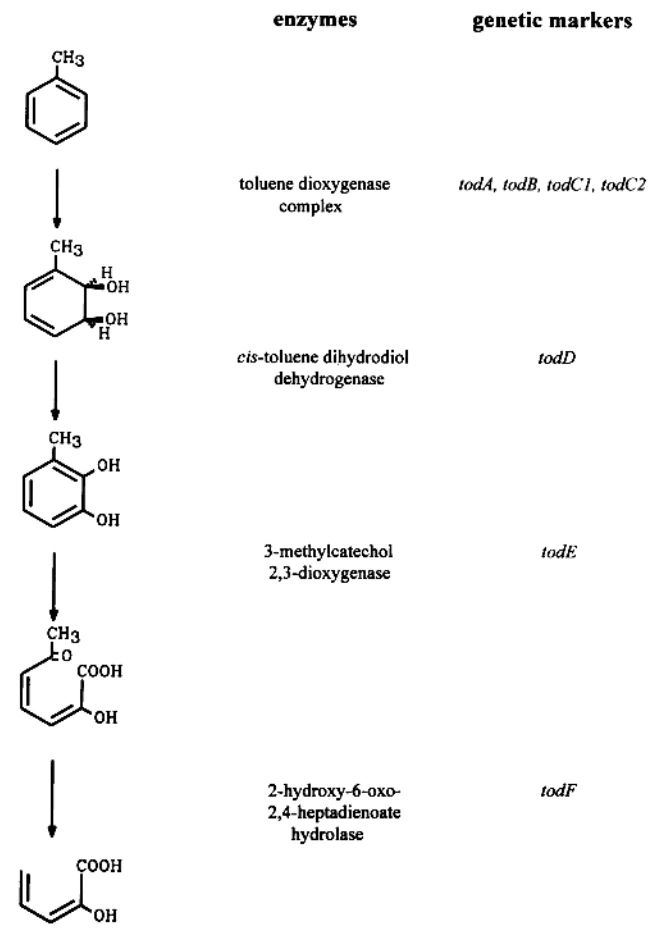

FIGURE BXII.γ.123. Initial steps in the pathway for the aerobic degradation of toluene by *Pseudomonas putida* strain F1. More details are found in Zylstra and Gibson (1991).

that the outer membrane integrity was preserved. Tolerance was also acquired to *m*- and *p*-xylene, and the strain gained the capacity of using these two compounds after receiving the plasmid TOL (Ramos et al., 1995). An energy-dependent efflux system may be part of the tolerance of this species to toluene (Isken and De Bont, 1996).

In a personal communication, J.A.M. de Bont has summarized as follows some of the mechanisms of tolerance to solvents: modification of the composition of the head groups of phospholipids (Ramos et al., 1997), of outer membrane proteins (Li et al., 1995; Ramos et al., 1997), of LPS (Pinkart et al., 1996), changes in the rate of turnover of membrane components (Pinkart and White, 1997), and most importantly, alterations in the composition of the fatty acids of phospholipids (Heipieper et al., 1994). This last is a very straightforward response, mostly due to the action of a *cis-trans* isomerase in *P. putida*. This enzyme has been cloned and expressed in *E. coli* (Holtwick et al., 1997). The isomerization is quite fast and does not demand an energy input. The presence of solvents triggers this activity, but other stress factors (heavy metals, high temperatures, low pH, and water stress due to salt) can act as inducers (Heipieper et al., 1996).

As expected, plasmid TOL, which was discovered in a strain now classified as *P. putida*, has continued receiving much attention. There are interesting relationships between the pathways encoded by TOL genes and those chromosomally located in the host. Thus, when growing on unlimited amounts of toluene, a *P. putida* carrying TOL lost the capacity of using xylenes and toluates, but could grow on toluene by using initially the enzymes of the TOL upper pathway and the chromosomal system for benzoate metabolism (Brinkmann et al., 1994). Catabolite repression by succinate and glucose on the TOL enzymes has been examined (Duetz et al., 1994; Holtel et al., 1994).

The catabolism of toluene and *o*-xylene in *P. stutzeri* has been analyzed by gene cloning (Baggi et al., 1987; Bertoni et al., 1996).

In studies on the degradation of polycyclic aromatic hydrocarbons (PAHs), a mixed natural population in which *P. aeruginosa* and *P. putida* were represented was more efficient in the degradation of the poorly soluble components of the mixture than any of the pure cultures isolated from the population. The latter in turn were more active on the more water-soluble compounds (among them acenaphthene, fluorene, phenanthrene, and fluoranthene) (Trzesicka-Mlynarz and Ward, 1995).

Naphthalene degradation by *P. stutzeri* has been found to be catalyzed by enzymes encoded by highly homologous sets of catabolic genes, although the hosts had been allocated to four different genomovars (Rosselló-Mora et al., 1994c).

Many reports in the literature refer to the degradation by *Pseudomonas* species of a number of derivatives of simple aromatic compounds including *p*-cymene (Eaton, 1996, 1997), nitrophenols (Rani and Lalithakumari, 1994; Meulenberg et al., 1996; Michan et al., 1997), and styrene (O' Connor et al., 1995; Marconi et al., 1996; Beltrametti et al., 1997).

Due to their widespread use in a number of applications based on highly desirable physical and chemical characteristics, the halogenated derivatives of hydrocarbons and aromatic compounds occupy an outstanding position in the studies on environmental microbiology. Many of the multitude of halogenated compounds are toxic and, due to their remarkable stability, they tend to persist in the environment, where they are slowly degraded by a number of organisms, under both aerobic and anaerobic conditions. In the aerobic degradation of these recalcitrant compounds, the pseudomonads are among the most active organisms, and some of them also are involved in the anaerobic degradation when nitrate is present as an alternate electron acceptor. The biodegradation of many halogenated organic compounds has been adequately summarized in reviews (Häggblom, 1992; Fetzner and Lingens, 1994).

In view of the fact that anaerobic bacteria are more active in the initial degradation of haloaromatics that are reductively dehalogenated, attempts have been made to combine this property with the ability of aerobic bacteria for active degradation of the aromatic ring. A proper combination of genes in a *P. putida* strain resulted in the metabolism of polyhalogenated compounds by sequential reductive and oxidative reactions (Wackett et al., 1994).

In *P. putida* chloroaromatic and methylaromatic compounds are degraded via *meta*-cleavage pathways. The chlorocatechol produced in the first case usually inactivates the 2,3-dioxygenase, but one strain was developed with a resistant dioxygenase and had the ability to degrade both toluene and chlorobenzene via the *meta*-cleavage route (Mars et al., 1997).

Phenol, monochlorophenols, monochlorobenzoate, dichlorophenols, 2,3,5-trichlorophenol, and several alkylbenzenes, were oxidized by a strain of *P. putida* by means of an inducible toluene dioxygenase. A study of this property revealed not only the remarkable versatility of the species, but also the influence

of other factors (e.g., growth rate) on the competence of the cells for use as bioremediation agents (Heald and Jenkins, 1996).

The degradative enzymes that convert these unusual compounds to intermediates of the central metabolism in distantly related hosts frequently show a high level of similarity. A rather extreme case is illustrated by a comparative study of the deduced amino acid sequences of components of the polychlorinated biphenyl degradation systems of the Gram-positive *Rhodococcus globerulus* and of Gram-negative bacteria, which showed a high similarity between the toluene dioxygenase of *P. putida* and the biphenyl dioxygenase of the Gram-positive organism, suggesting a possible transfer of genes crossing the Gram-positive/Gram-negative barrier (Asturias et al., 1995). This is certainly a reminder of the danger of drawing phylogenetic conclusions based on similarities found in metabolic systems involved in the degradation of these unusual organic substrates.

Amino acid catabolism One aspect that has attracted the attention of biochemists and bacteriologists for many years is the utilization of arginine by the pseudomonads. Among the degradative pathways, the arginine deiminase ("dihydrolase") system has been used by taxonomists since the early 1960s for differentiation of species. The reactions catalyzed by the system are the conversion of arginine to citrulline, and of citrulline to ornithine, with liberation of ammonia (Slade et al., 1954). Motility of the cells can be activated by air or arginine (Sherris et al., 1957). In the latter case the required energy is provided by the ATP formed in the citrulline to ornithine step. This system is constitutively produced by fluorescent pseudomonads but it is inhibited under aerobic conditions.

A rise of pH in the medium with arginine, because of ammonia liberation, indicates the presence of the dihydrolase system, and this is the basis of one of the determinative methods (Thornley, 1960). This method is still widely used because it is simpler (although less reliable) than methods based on arginine disappearance. Presence of arginine deiminase is not diagnostic for species of the genus *Pseudomonas* (for instance, *P. stutzeri* is negative, while species now assigned to other genera of aerobic pseudomonads are positive).

Several other pathways of arginine degradation have been described for species of *Pseudomonas*. They are characterized by the following key reactions: arginine oxidase in *P. putida* and arginine decarboxylase in fluorescent *Pseudomonas* species (Stalon and Mercenier, 1984), arginine dehydrogenase in *P. aeruginosa* (Jann et al., 1988), and arginine succinyl transferase in fluorescent *Pseudomonas* species and in *P. mendocina* (Vander Wauven and Stalon, 1985; Stalon et al., 1987). The arginine decarboxylase/agmatine deiminase pathway appears to be characteristic of *Pseudomonas*, and it is the source of polyamines (Stalon and Mercenier, 1984). A brief discussion on the importance of these compounds as taxonomic tools will be given below, in the section on taxonomic considerations.

Pseudomonas species use only one of the various agmatine catabolic pathways, in which there is participation of an inducible agmatine deiminase system. Evidence for the presence of arginase (which converts arginine to ornithine and urea) has not been found in any *Pseudomonas* species. Further studies on arginine metabolism by organisms of this genus have included a number of ureido and guanido compounds, with findings that suggest that the corresponding screening may be of taxonomic value (Tricot et al., 1990).

A study of the distribution and induction of guanidinoacetate amidinohydrolase (GAH), guanidinopropionate amidinohydrolase (GPH), and guanidinobutyrate amidinohydrolase (GBH) among some fluorescent species of *Pseudomonas* has shown the presence of GBH in most strains, with arginine as an inducer (Yorifuji et al., 1983). GPH was detected in *P. aeruginosa* only, and the results further indicate that this species lacks the *P. putida* enzyme(s) required for degradation of L-arginine to 4-guanidinobutyrate.

The information collected on the metabolism of arginine and related compounds suggests an interesting phylogenetic scenario. The arginine deiminase pathway may be a primitive remnant from the time when anaerobic conditions prevailed on our planet, and amino acids may have provided both building blocks and energy (Prieto et al., 1992). If so, the appearance of arginine oxidase may have occurred in more recent times.

In summary, in spite of the variety of arginine catabolic pathways among the aerobic pseudomonads, members of the genus *Pseudomonas* are characterized by the presence of the arginine decarboxylase/agmatine deiminase system. The finding of arginine dehydrogenase in *P. aeruginosa* (Jann et al., 1988) would require a survey of other species not yet tested in order to assess its phylogenetic significance.

Lysine catabolism can occur in *Pseudomonas* by at least three different pathways eventually converging to glutarate, which generates acetyl-CoA. For short, these pathways may be called the "oxygenase", the "pipecolate", and the "cadaverine" routes (Chang and Adams, 1971; Miller and Rodwell, 1971; Fothergill and Guest, 1977), and their distribution in species of *Pseudomonas* is indicated in Table BXII.γ.108.

Amino acid biosynthesis Catabolic pathways offer a larger variety of metabolic routes than the biosynthetic ones. A good example is the diversity of arginine degradative pathways discussed above. In contrast, similar anabolic routes can be used by widely different organisms. Biosynthetic pathways also are interconnected with other pathways and regulatory systems, and consequently there is a selective pressure favoring their conservation, thus preventing perturbations in pathways belonging to the same network. However, taken in combination with its regulatory mechanisms, a given biosynthetic pathway often can be used as a tool for the exploration of distant relationships among organisms.

The regulatory mechanisms of biosynthetic pathways of some aliphatic amino acids in the pseudomonads have interesting phylogenetic implications. The regulation of activity of aspartokinase and homoserine dehydrogenase is clearly different in organisms of the fluorescent group and species now assigned to other genera. Long ago it was found that *P. stutzeri* and *Burkholderia cepacia* (formerly *Pseudomonas cepacia*) resembled the fluorescent species (Cohen et al., 1969). In fact, this was one of the first findings suggesting a phylogenetic relationship between *P. stutzeri* and other species of *Pseudomonas*. However, *B. cepacia* also showed similarities with the fluorescent pseudomonads, in spite of its phylogenetic position in a different branch of *Proteobacteria*.

The multibranched pathway of biosynthesis of aromatic amino acids has offered not only more variations in biochemical details, but also a richer source of regulatory information. These are the reasons for which Jensen and his collaborators chose the interconnected pathways as a model for the study of phylogenetic relationships among the aerobic pseudomonads. The results of this work, which has direct taxonomic implications (Byng et al.,

TABLE BXII.γ.108. Distribution of lysine catabolic pathways in some fluorescent *Pseudomonas* species and *Burkholderia cepacia*[a]

Lysing catabolic pathways	*P. aeruginosa*	*P. fluorescens*	*P. putida* biovar A	*P. putida* biovar B	*Burkholderia cepacia*
Oxygenase	−	+	+	+	−
Pipecolate	+	+	+	−	+
Cadaverine	+	+	−	−	−

[a]For symbols see standard definitions. Taken from Palleroni (1984); data from Miller and Rodwell (1971), Chang and Adams (1971), and Fothergill and Guest (1977).

1980, 1983; Whitaker et al., 1981b) were in agreement with the subdivision of the pseudomonads into five so-called rRNA homology groups (Palleroni et al., 1973). In fact, the enzymatic assays are simpler than the hybridization methods of ribosomal similarity studies, which makes the former good determinative tools indeed.

Glutamine synthetase, an important enzyme involved in nitrogen metabolism, has been subjected to immunological comparative studies that were expressed in combination with the results of nucleic acid hybridization experiments (Baumann and Baumann, 1978). These studies, aside from representing further confirmation of the internal subdivision of the pseudomonads, have useful determinative applications.

Genetics Some of the *Pseudomonas* species have attracted a great deal of attention from bacterial geneticists because of their widespread occurrence, their biological and medical importance, their nutritional and biochemical versatility, and the simplicity of conditions required for their cultivation in the laboratory.

Of them, *P. aeruginosa* is by far the best known from the genetic point of view. Strain PAO ("*Pseudomonas aeruginosa* One") is the one that has been most extensively studied. A detailed genomic map including more than 360 genes is now available (Holloway et al., 1994). This map represents the last of a number of reports from the Department of Genetics of Monash University, Clayton, Australia (see below), in combination with work performed elsewhere on the construction of physical maps. Recent additions to the genomic map available for strain PAO include the physical mapping of 32 genes by application of modern molecular techniques. The approach used will increase the number of genes included in databases, where now nearly 40% of the genes of the species are represented (Liao et al., 1996).

A second strain of *P. aeruginosa*, PAT ("*Pseudomonas aeruginosa* Two"), is also familiar to geneticists, and its map closely resembles that of PAO. The strains have different geographical origin, and their similarity is a confirmation of the homogeneity of the species already noticed by many taxonomists.

The three best-known systems of genetic exchange, namely, conjugation, transduction, and transformation, have been observed in strains of *P. aeruginosa*. Conjugation and transduction have been most important in genetic studies of this species. In contrast, transformation occurs in *P. stutzeri*, *P. mendocina*, and other nonfluorescent members of the genus under natural conditions. Conjugation, which results in transfer of substantial chromosomal segments, has been the most effective source of information for mapping purposes in *P. aeruginosa* genetic studies. The transfer depends on the chromosomal mobilizing ability (cma) of some plasmids, of which FP2 has been used extensively, and to a lesser extent, FP5, FP39, and FP110. Each of these fertility plasmids has one predominant attachment site, and this was the main reason that delayed the demonstration of circularity of the map. This was finally achieved based on 2- and 3-factor crosses with cma plasmids FP2, FP5, FP110, and R68.45 (Royle et al., 1981).

An approach recently introduced in the study of bacterial genomes combines the action of endonucleases that infrequently cut the chromosome, with pulsed-field agarose gel electrophoresis (PFGE), which makes possible the resolution of large DNA fragments. A limited number of cuts per genome is desirable for genomic restriction mapping (McClelland et al., 1987), with clear advantages over frequently cutting endonucleases for the production of fingerprints characteristic of different taxa (Mielenz et al., 1979; Dobritsa, 1985; Sorensen et al., 1985). Application of this principle has resulted in a practical method for constructing and analyzing macrorestriction patterns of 234 strains of different species of aerobic pseudomonads (Grothues and Tümmler, 1991). The restriction nucleases *AsnI*, *DraI*, *SpeI*, *XbaI*, and *PacI* are among the most appropriate by being specific for AT-rich regions (which are less common than GC pairs in *Pseudomonas*), or for sites including the extremely uncommon tetranucleotide CTAG (McClelland et al., 1987).

The macrorestriction patterns are compared for the number and position of the bands, and use of appropriate equations often indicates a correlation between the estimated similarities of fingerprints and conventional taxonomic groupings. The results obtained by Grothues and Tümmler (1991) in general confirm the classification of pseudomonads based on extensive numbers of phenotypic properties and nucleic acid hybridization studies.

Comparisons involving mol% G + C content of the chromosome, codon usage, and genome size can be used for the calculation of similarity coefficients useful for determinative purposes. The genome restriction patterns also have the practical advantage of helping in epidemiological studies. Differences in these parameters were found between strains susceptible or resistant to multiple antibiotics (Yamashita et al., 1997).

Differences in restriction fragment size distribution may result from various chromosomal rearrangements and/or mutations at the restriction sites, which suggests that the methodology based on restriction fingerprints should be supplemented with other approaches to determine the degree of similarity of the fragments. Large genomic rearrangements have been observed in *P. aeruginosa* strains isolated from clinical samples or from the environment (Schmidt et al., 1996c). The former came mostly from cystic fibrosis cases. A 95-kb plasmid was detected in environmental strains, and it was integrated in the chromosome in cystic fibrosis strains. Exchange of DNA blocks and large DNA inversions led to divergence of clones in this species. The presence of inversions only in cystic fibrosis strains suggests that this niche causes or tolerates substantial changes in the genome (Römling et al., 1997).

A study on pathovars of fluorescent plant pathogenic pseudomonads (Grothues and Rudolph, 1991) indicated that two strains belonging to the same pathovar, but of different origins, can give almost identical restriction fingerprints. However, this is not always the case. Pathogens of wide host range give more diverse restriction patterns than those of restricted host range. The methodology was also used for the examination of repre-

sentative strains of *P. stutzeri*, a species notorious for its heterogeneity (Stanier et al., 1966; Palleroni et al., 1970). The results show a marked correlation of genome structure with fatty acid composition, and with data of nucleic acid hybridization experiments (Rainey et al., 1994b). A high degree of heterogeneity in macrorestriction patterns was also observed by another group of workers, which did not correlate with the subdivision of the species in genomovars. The marked heterogeneity of this species is attributed, at least in part, to large chromosomal rearrangements (Ginard et al., 1997). The results of these two groups also indicate that the genome size of *P. stutzeri* ranges from 3.4–4.64 Mba for the strains subjected to their studies.

Pseudomonas species other than *P. aeruginosa* have been less rewarding subjects for chromosomal mapping. This is unfortunate in the case of a species like *P. putida*, which has been extensively investigated from the biochemical viewpoint. This species has presented serious problems for the development of a satisfactory chromosome transfer system, and, consequently, a less detailed chromosome map is available (Mylroie et al., 1977; Strom and Morgan, 1990). Circularity of the *P. putida* map strain PPN (related to strain ATCC 12633, which was the subject of many metabolic studies for many years) has been demonstrated (Dean and Morgan, 1983). A genetic map of *P. syringae* pathovar *syringae* is also available (Nordeen and Holloway, 1990). The situation is even more regrettable in the case of the very complex species *P. fluorescens*, with many strains extensively known for their phenotypic properties. A good starting point now is the report on a complete physical map of a strain of the species with a genome of 6.63 Mbp. A total of 139 restriction sites and 31 genes have been located in the map (Rainey and Bailey, 1996). Similarly, an efficient mutagenic procedure using electroporation for *P. fluorescens* and a transposon delivery vector has been described (Artiguenave et al., 1997). A *recA* mutant has been obtained, and sequence studies have shown that the chromosomal organization was very similar to that of *P. aeruginosa* and *Azotobacter vinelandii*. The regulatory region and the structural gene differed from those of *Burkholderia cepacia*. By insertion of a kanamycin cassette in the *recA* gene, the mutant obtained had an increased UV sensitivity and was much impaired in its recombinatorial activity (De Mot et al., 1993).

A *recA* mutant strain of *P. stutzeri* is also available (Vosman and Hellingwerf, 1991). It is completely deficient in natural transformation with chromosomal DNA and it is sensitive to UV and methyl-methane sulfonate. The wild-type gene complements an *E. coli recA* mutant (Bennasar et al., 1996).

Plasmids, phages, bacteriocins Plasmids are important components of the genetic makeup of *Pseudomonas*. Some of them act as fertility factors, some (R plasmids) may impart resistance to various agents, and others confer the capacity of degradation of unusual carbon sources, thus contributing to the nutritional versatility that is a striking feature of many members of the genus. A large number of *Pseudomonas* plasmids have been described in the past decades, and it is impossible to cover all references here. Some of the plasmids are mentioned in other sections of this chapter. Examples of the properties of *Pseudomonas* encoded by plasmid genes are:

1. Resistance characters to antibiotics and other antibacterial compounds, such as carbenicillin, chloramphenicol, gentamicin, kanamycin, streptomycin, tetracycline, tobramycin, sulfonamides;
2. Resistance to chemical and physical agents (borate, chromate, various metal ions, organomercurials, tellurite, ultraviolet radiation);
3. Resistance to bacteriophage propagation; interference with lysogenization by some temperate phages; DNA restriction and modification;
4. Resistance to bacteriocins.

Various other characteristics due to plasmid genetic determinants are the chromosome donor ability, donor-specific phage susceptibility, inhibition of bacteriocin production, fertility inhibition, incompatibility with other plasmids, and, most important for some species, utilization of various organic compounds not normally used for growth by species other than the aerobic pseudomonads. Occasionally plasmids are found that confer on the cells the capacity to use simple organic compounds. Thus, for instance, a *P. fluorescens* plasmid that carries genes of resistance to ampicillin, kanamycin, and streptomycin also allows the host to grow on malonate because of a plasmid gene encoding malonate decarboxylase. The plasmid (pPSF1) can be transferred to *E. coli*, where the ability to grow on malonate can also be expressed (Kim and Kim, 1994).

Plasmids can be classified most effectively by incompatibility, that is, by the incapacity of a given plasmid to coexist in the same cell with other plasmids of the same group. In *Pseudomonas*, at least 10 incompatibility groups have been defined (Jacoby, 1977; Korfhagen et al., 1978). Useful information on *P. aeruginosa* plasmids may be found in a chapter by Jacoby (Jacoby, 1979). In general it can be stated that most of the research with *Pseudomonas* plasmids has been focused on the fluorescent species, and the information on other species is fragmentary.

Plasmids of the various incompatibility groups have different host ranges. The widest range is that of the IncP-1 plasmids, while those of groups 2 and 5–9 are more specific. IncP-2 plasmids include R factors and plasmids carrying genes for the degradation of unusual carbon compounds. Some of them are among the largest of *Pseudomonas* plasmids, exceeding 300 MDa, while the majority range from 10–60 MDa. Outside of the IncP-2, degradative plasmids are also found in the P-9 group.

Degradative plasmids named CAM, OCT, SAL, NAH, TOL, and XYL are involved in the degradation of camphor, *n*-octanol, salicylate, naphthalene, toluates, and xylene, respectively, and have received much attention because they confer to the cells the capacity to degrade environmental pollutants. The naphthalene degradative enzymes of plasmids identified in *P. fluorescens* are also involved in the degradation of high molecular weight polyaromatic hydrocarbons other than naphthalene (Menn et al., 1993).

Of the above-mentioned plasmids, TOL, which was originally isolated from a strain now classified as *P. putida*, is the best known and it still receives a great deal of attention by bacteriologists. An excellent review of the properties of TOL and naturally occurring variants is available (Assinder and Williams, 1990). The upper and lower operons of this plasmid seem to have different origins. In support of this hypothesis, it has been found that their respective codon usages are different, but they are the same for the genes within each operon (Harayama, 1994). TOL can be transferred from cell to cell by conjugation, which occurs at a sufficiently high rate to maintain the plasmid in a dense microbial community without the help of selective pressures (Smets et al., 1993).

Comai and Kosuge (1980) have presented evidence for plas-

mid involvement in the oxidative degradation of tryptophan to the plant hormone indoleacetic acid (IAA) by *P. savastanoi*. Concentrations of IAA higher than those normally found in plant tissues result in gall formation (Gardan et al., 1992

The range of antibiotic resistance determined by plasmids and the mechanisms by which the resistance is manifested are similar to those found in *E. coli*. Some plasmids are transferred from cell to cell by conjugation; others lack this capacity, but some of them can be mobilized by other conjugative plasmids.

Many different lytic and temperate bacteriophages have been identified in *Pseudomonas*, particularly in *P. aeruginosa*. Their morphological diversity is at least as great as for phages of other bacterial genera. Lysogeny is a very common phenomenon in *P. aeruginosa*, and transducing phages have been very useful in linkage studies. Most *Pseudomonas* phages contain double-stranded DNA, but some are RNA phages, including one with double-stranded RNA (Semancik et al., 1973; Vidaver et al., 1973). The sequence of *P. aeruginosa* single-stranded RNA phage PP7 has been determined and the results suggest that the phage is related to coliphages but branched off before the coliphages diverged into separate groups (Olsthoorn et al., 1995).

An example of a rather unusual application of a *P. stutzeri* bacteriophage has been its use for the selection of denitrification-negative mutants. The procedure takes advantage of the fact that the phage (phi PS5) adsorbs to the outer membrane protein NosA. Mutants defective in NosA production do not grow with N_2O and are resistant to the phage (Clark et al., 1989).

Even though host specificity is the rule, some bacteriophages attack different but related species, with interesting taxonomic implications (M.P. Starr, personal communication). This approach to bacterial classification was attempted many years ago by Billing, in an effort to improve the methodology for the differentiation of phytopathogenic pseudomonads (Billing, 1963, 1970a). The sensitivity tests were not very useful in themselves, but they were valuable as a complement of the biochemical tests of identification. Pathovars of *P. syringae* isolated from pear could be distinguished by phage sensitivity but not by serological tests from the strains isolated from cherry. On the other hand, pathogenic and saprophytic pseudomonads could not be distinguished by their lysotypes (phage types or phagovars) (Crosse and Garrett, 1963).

Phage sensitivity can also be used successfully as a method of typing *P. aeruginosa* strains, but the procedure is not considered sufficiently reliable to be used by itself as an epidemiological tool without comparison to other typing procedures (Brokopp and Farmer, 1979).

Some factors required for phage nucleic acid replication appear to have been conserved through evolution in some groups of Gram-negative bacteria. One of the elements required for *in vitro* replication of sex-specific single-stranded RNA coliphage Qβ is the so-called host factor (HF). This is a heat-resistant RNA-binding protein of molecular weight 12,000, usually present in *E. coli* as an hexamer (Franze de Fernández et al., 1972). In *P. putida*, a polypeptide of molecular weight 11,000 gives an immunological cross-reaction with HF and allows Qβ replication *in vitro* (DuBow and Blumenthal, 1975). Material cross-reacting with *E. coli* HF antiserum was found in extracts of *P. aeruginosa*, *P. fluorescens*, *P. putida*, and in other species of different rRNA similarity groups (Palleroni, 1984)), but the material was heat stable only when it came from organisms of RNA similarity groups I and V (*Pseudomonas*, *Xanthomonas*, and *Stenotrophomonas*), which are located in neighbor branches in the *Gammaproteobacteria* (DuBow and Ryan, 1977).

Bacteriocins are proteins produced by some bacterial strains, which have a lethal action on other strains of the same species. They have been frequently detected in *Pseudomonas*, and in *P. aeruginosa* they have been named pyocins (from the old name *P. pyocyanea*) and aeruginosins, although both names are improper. Pyocin can be mistaken for pyocyanin, the blue diffusible pigment characteristic of the species, and aeruginosin has been used for two red pigments produced by some strains of *P. aeruginosa* (aeruginosins A and B) (Holliman, 1957; Herbert and Holliman, 1964).

Different types of *P. aeruginosa* bacteriocins have been described. One resembles bacteriophage contractile tails, a second one has the appearance of slender, flexuous rods, and a third (S type) is amorphous and is sensitive to proteolytic attack (Govan, 1974a, b). A novel S-type pyocin has been characterized by molecular techniques (Duport et al., 1995).

Bacteriocin typing can be performed in two ways, which are based on production of these elements, or on sensitivity to them, respectively. The first approach is more commonly used, and it requires a collection of sensitive strains (Govan, 1978; Brokopp and Farmer, 1979). Bacteriocin production by species other than *P. aeruginosa* has been reported in a few instances (Vidaver et al., 1972; Smirnov et al., 1984). In a study on bacteriocin typing of unknown *P. syringae* strains, the specificity was uneven, and the highest level was shown for the case of the phaseolicins of *P. syringae* pathovar *phaseolicola* (in this treatment described as a pathovar of *P. savastanoi*) (Vidaver et al., 1972). In an extension of these studies, the correlation found between bacteriocin type and host plant of origin of phytotoxin production was rather poor (Vidaver and Buckner, 1978). The approach is probably susceptible to further refinements, since 86% of the strains examined were able to produce bacteriocins.

Antigenic structure Again here, the literature is dominated by the number of papers dedicated to *P. aeruginosa*, reflecting in this case, as in others, the medical importance of this species.

Agglutination of intact *P. aeruginosa* cells can be caused by specific antibodies elicited in animals by specific components that are similar to the O-antigens of other Gram-negative bacteria. The heat-stable O-antigen, considered the most stable marker for *P. aeruginosa*, is represented by one of the components of the lipopolysaccharide (LPS). The specificity is related to the composition of the polysaccharide chains (the O antigens themselves) projecting to the outside of the cells. The LPS of *P. aeruginosa* has O-specific polysaccharide chains with unbranched oligosaccharides including amino sugars that are not acetylated (Wilkinson, 1983).

P. aeruginosa shows a marked serological diversity. The LPS composition determines at least 17 heat-stable O antigens, and antisera are adequate for serotype identification, in spite of variations in titer and specificity. In experiments using a panel of 48 monoclonal antibodies against eight of the serotypes, various degrees of activity were shown by some of the antibodies, one of which bound to all serotype strains and also to strains of *P. fluorescens* and *P. putida* (Gaston et al., 1986). A further refinement of this approach showed that the antigenic specificity of various parts of the LPS molecule could be clearly demonstrated by preparing monoclonal antibodies recognizing the inner core, outer core, and lipid A regions of LPS. Antibodies to the complex (lipid A + core + one repeat of the O-specific polysaccharide chain)

reacted with a lower number of serotypes than the antibodies recognizing the outer core without the oligosaccharide. The specificity was even lower for the antibodies that recognized the inner core, since they reacted not only with the largest number of serotypes tested, but with all the other Gram-negative species included in the experiment (de Kievit and Lam, 1994).

Mild heating of a cell suspension reduces the agglutinability by specific antisera, but the property can be fully recovered by a more intense treatment (100–120°C for 2–2.5 h). The alginate of mucous strains that can be selected under appropriate conditions (Govan and Fyfe, 1978) or isolated from cystic fibrosis cases (Doggett, 1969) does not interfere with the O-antigenicity.

In addition to the immune response against *P. aeruginosa* LPS, which in its early manifestation consists of IgM antibodies (Høiby, 1979), there is a humoral response to cross-reactive antigens that are present in other, mostly Gram-negative, bacteria (Høiby, 1975). A heat labile antigen common to a wide range of bacteria has been isolated from *P. aeruginosa* and shown to be an acidic protein composed of subunits of molecular weight 62,000, present in the cytoplasmic fraction of the cells (Sompolinsky et al., 1980a, b).

Various other antigens have been identified in *P. aeruginosa*. Heat-labile surface antigens are represented by flagella and fimbriae (Bradley and Pitt, 1975; Pitt and Bradley, 1975). An extracellular slime can elicit the production of an agglutinin, and exoenzymes such as phosphatases, proteases, and phospholipases can also act as antigens. The outer membrane protein OprF was subjected to epitope mapping, and, as mentioned before, the fact that it is a major component suggests that it may be a good candidate for use as a vaccine and as a target for monoclonal antibodies for immunotherapeutic applications and for diagnosis (Rawling et al., 1995).

Isolation and characterization of monoclonal antibodies for outer membrane antigens have been described (Hancock et al., 1982). As a practical identification tool for the identification of glucose oxidizing *Pseudomonas* species, Mutharia and Hancock (1985) have proposed the use of a monoclonal antibody (MA1-6), specific for a single antigenic epitope on the outer membrane lipoprotein H2 of *P. aeruginosa*. The epitope was detected in all 17 serotype strains of *P. aeruginosa*, in numerous clinical isolates of the same species, and in other *Pseudomonas* species but not in species of other rRNA similarity groups (Palleroni, 1984). Two strains of *P. aeruginosa* (out of a total of 52) failed to give the reaction. In a *P. aeruginosa* collection that included 30 environmental isolates, no major differences in outer membrane proteins (other than quantitative variations in lipoprotein H2 content) or lipopolysaccharide patterns were observed when compared with those of previously studied clinical isolates (Hancock and Chan, 1988).

Similar conclusions on the advantages of using monoclonal antibodies against outer membrane proteins, in addition to other tools useful for determinative purposes, have been reached from experiments on the detection of the lipoprotein I gene in species of *Pseudomonas* (De Vos et al., 1993), as an extension of the original observations by Saint-Onge et al. (1992).

Many schemes of serotyping have been proposed, but the system of Habs (1957) has gained wide acceptance and, with some modifications, is in general use. Habs defined 12 somatic groups that could be identified by agglutination tests. Different additional proposals and modifications include the addition of 5 O-groups. Standard strains and typing sera are commercially available.

In the opinion of Brokopp and Farmer (1979), serological typing of *P. aeruginosa* based on the O-antigens produces more reliable evidence for relatedness than can be obtained by other, less specific typing methods. Thermolabile surface antigens can also be used for serotyping, and various methods based on flagellar (H) antigens have been proposed (Verder and Evans, 1961; Lányi, 1970). These approaches have not been widely accepted, the main reason being the difficulties encountered in the preparation of specific flagellar antisera (Brokopp and Farmer, 1979).

For epidemiological purposes, serotyping is the most important typing method and, as usually practiced, consists of the reaction of a cell suspension toward a standard set of antibody preparations. Serotyping can be supplemented by other typing methods, such as production and sensitivity to bacteriocins and lytic phages, biotyping (or characterization of strains by their biochemical and physiological properties) and antibiograms, and sensitivity to antibiotics.

To these procedures we now have to add modern techniques based on molecular concepts. One of them is the arbitrary PCR fingerprinting of strains, which provides a simple and practical typing approach considered to be more discriminatory than the traditional serotyping scheme, although the maximum discriminatory power is achieved by a combination of both methodologies (Hernández et al., 1997). Comparative typing of *P. aeruginosa* also has been carried out by random amplification of polymorphic DNA or pulsed-field gel electrophoresis of DNA macrorestriction fragments (Renders et al., 1996), to which we can add the fingerprinting of whole cell proteins (Khan et al., 1996), and studies on comparative ribotyping and genome fingerprinting (Bennekov et al., 1996).

In the field of fluorescent plant pathogenic pseudomonads, the serological approach has had variable success, and has not helped substantially in the circumscription of nomenspecies. The lack of a solid taxonomic frame of reference has often made it very difficult to interpret the resolving power of the serological techniques. Otta and English (1971) were unable to define a precise serological differentiation of virulent strains from nonvirulent ones. On the other hand, species-specific antigens could be identified in *P. syringae* pathovar *phaseolicola* (described here as a pathovar of *P. savastanoi*) (Guthrie, 1968) and in *P. syringae* pathovar *lachrymans* (Lucas and Grogan, 1969a, b). *P. syringae* strains isolated from different groups of host plants could be distinguished immunologically (Otta, 1977). In general, however, the reproducibility of serological data by different authors using different strains of the same nomenspecies appears to be rather poor.

Susceptibility to antibiotics Many aerobic pseudomonads are resistant to a number of antibacterial agents. This subject is of particular medical importance because members of this group are serious opportunistic human pathogens and are often isolated from patients and clinical materials. The capacity to resist antibiotics is included in some of the descriptions of new taxa.

As expected, most of the available information on *Pseudomonas* refers to *P. aeruginosa* because of its importance as a serious opportunistic human pathogen. The antibiotics that are most effective in the treatment of *P. aeruginosa* infections include some β-lactams, such as carbenicillin and ticarcillin, third-generation cephalosporins (cefsulodin, cephoperazone, ceftazidime), the synthetic monocyclic β-lactam aztreonam, carbapenems (among them the extremely broad-spectrum semisynthetic imipenem), the aminoglycosides (gentamicin, tobramycin), and the quino-

lones (ciprofloxacin). In practice, *P. aeruginosa* infections are treated with a mixture of tobramycin and some β-lactams active against *Pseudomonas*, such as piperacillin or azlocillin. Various quinolones are in use for the treatment of chronic or mild corneal or urinary infections.

P. aeruginosa and other fluorescent *Pseudomonas* species are in general resistant to β-lactams other than those indicated above. Carbenicillin is moderately effective and was extensively used in therapeutic applications either by itself or in mixtures with aminoglycosides. Carbenicillin produces cell enlargement and filament formation, but the sensitivity of the cells is not very high, and years ago the emergence of resistant *P. aeruginosa* mutants was reported (Lowbury et al., 1969; Gaman et al., 1976). The mucoid strains that are frequently found in infections in cystic fibrosis patients are somewhat more resistant to the antibiotic.

Resistance to carbenicillin may be due to β-lactamases coded for by genes carried by plasmids of the incompatibility group 1 (IncP-1) that can be transferred to *E. coli* (Lowbury et al., 1969), but similar genes may be found in host restricted IncP-2 plasmids (Bryan, 1979). Seven different kinds of β-lactamases have been identified in 24 *Pseudomonas* plasmids belonging to at least eight of the incompatibility groups (Jacoby and Matthew, 1979). β-lactamase genes are not invariably carried by plasmids and, in fact, there is in *P. aeruginosa* a constitutive penicillinase (Furth, 1975) and an inducible cephalosporinase (Sabath et al., 1965; Sykes and Matthew, 1976) whose genetic determinants are chromosomal.

Even though the third-generation cephalosporin ceftazidime is considered to be highly effective against many *P. putida* strains (Yang et al., 1996b), a metallo-β-lactamase gene *blaIMP* was detected by PCR in a number of Gram-negative organisms, among them resistant strains of *P. fluorescens* and *P. putida* (Senda et al., 1996). It is also interesting that the response to β-lactam antibiotics in *Pseudomonas* can result in their utilization as substrates for growth. A soil strain of *P. fluorescens* was able to grow at the expense of benzylpenicillin as carbon, nitrogen, and energy source (Johnsen, 1977). This property also is present in pseudomonads now assigned to different genera (for instance, *Burkholderia cepacia*) (Beckman and Lessie, 1979).

Aside from the production of enzymes such as the β-lactamases, the pseudomonads are able to resist many antibiotics by mechanisms such as a low cell wall permeability, the production of modifying enzymes, and efflux systems. The most abundant porin in the outer membrane, OprF, is probably very important in reducing the permeability to antibiotics, although other porins may be involved.

Enzymes capable of modification of aminoglycosides as a resistance mechanism have been described, and they correspond to the types already known for the enteric bacteria. These enzymes catalyze phosphorylation, adenylation, or acetylation of the antibiotics, although the resistance of *P. aeruginosa* to the aminoglycosides may be largely nonenzymatic.

A useful and comprehensive review on multidrug efflux systems present in both eucaryotes and bacteria has been published by Paulsen et al. (1996). Drug accumulation and efflux system studies suggest that *P. aeruginosa* has at least two different proton motive force-dependent efflux systems (Li et al., 1994, 1995). A chromosomal operon was discovered that confers multidrug resistance to this organism, with three genes, *mexA*, *mexB*, and *oprM*, encoding for components of a transport system originally shown to be able to correct a defect in iron metabolism (Poole et al., 1993a, b; Ryley et al., 1995). Prior to this work, it was known that OprM was involved in conferring resistance to multiple drugs, and it was later confirmed as a component of the efflux system. The operon *mexAB/oprM* is inducible under iron-limiting conditions, and is co-regulated with components of the pyoverdin-mediated iron transport. Mutants lacking *mexA* or *mexB* are unable to grow under conditions of iron limitation in the medium. All *P. aeruginosa* strains that have been examined have the operon, although its components seem to operate with unequal efficiencies according to the strain.

Mutations in the operon result in intracellular accumulation of chloramphenicol, tetracycline, norfloxacin, benzylpenicillin, carbenicillin, and quinolones. A second efflux system was later identified (*mexC-mexD-oprJ*) encoding proteins that prevent the cytoplasmic accumulation of quinolones, tetracycline, chloramphenicol, and the cephems (Li et al., 1994, 1995; Liu et al., 1995b; Poole et al., 1996).

The most common mechanisms of gentamicin resistance in *P. aeruginosa* are enzymatic modifications of the antibiotic consisting of *N*-acetylation, O-adenylation, and, to a much lesser extent, phosphorylation. These properties are controlled by plasmid genes, mainly IncP-2 plasmids (Bryan et al., 1972, 1973, 1974; Jacoby, 1974a, b). Permeability factors may also be involved in the case of gentamicin and other aminoglycosides (Mathias et al., 1976; Bryan, 1979).

Polymyxins are very active against *P. aeruginosa* and other pseudomonads when tested *in vitro*, but their efficacy *in vivo* is limited. Resistance is unstable, and this condition seems to correlate with an increase in EDTA tolerance. Gilleland and Murray (1976) noted in these variant strains the disappearance of the particles characteristic of the concave cell wall layer separated by freeze-etching (see above in the section on fine structure), but the particles reappeared by growth in the absence of polymyxin, and acquisition of temporary resistance is accompanied by a decrease in the phosphorus content of the outer membrane.

Sensitivity to metals and metalloids Copper compounds are extensively used in agriculture, and since only minute amounts are needed for nutrition, the excess can affect higher organisms as well as procaryotes, among which the plant pathogens are of particular interest. In *P. syringae* strains that carry the operon *cop*, copper is excluded by combination with components of the periplasm and in outer membrane. A two-component sensory transduction mechanism similar to equivalent systems in other organisms operates in the regulation of expression of copper resistance, and it has strong similarity with a gene that seems to regulate the uptake or efflux of copper in *"Streptomyces lividans"* (Mills et al., 1993).

Inducible copper resistance in *P. aeruginosa* is encoded by chromosomal genes, although the strains that were examined had plasmids (Vargas et al., 1995b).

In *P. fluorescens* isolated from copper-contaminated soil, a chromosomal locus with determinants for copper resistance and competitive fitness was cloned, and genes responsible for conferring copper resistance and production of cytochrome *c* were identified (Yang et al., 1993a, 1996a). A *P. putida* strain isolated from electroplating effluent could accumulate cupric ions in a concentration as high as 6.5% of its dry weight. The capacity was highest when the culture was previously grown under sulfate-limiting conditions (Wong and So, 1993).

Acid-labile sulfide levels were found to be generally higher in silver-resistant *P. stutzeri* strains than in sensitive ones. The resis-

tance to the metal may be due to formation of silver sulfide complexes, since no complex formation with polyphosphate or metal-binding proteins has been found to be the cause (Slawson et al., 1992).

Three plasmids were found in a silver-resistant strain isolated from a silver mine. The largest plasmid (MW 49.4 $\times 10^6$), which specifies silver resistance, is nonconjugative, but it could be transferred to *P. putida* by mobilization with plasmid R68.45 (Haefeli et al., 1984).

P. fluorescens detoxifies aluminum by elaboration of a soluble, aluminum-complexing metabolite. When iron was present in the medium, the two trivalent metals were immobilized in a lipid-rich complex containing Al, Fe, and P, after an early stage in which aluminum was found to be associated with phosphatidylethanolamine (Appanna et al., 1995; Appanna and Hamel, 1996). Workers from the same group examined the adaptation of *P. fluorescens* to stress caused by excess of cesium (Appanna et al., 1996), and were also involved in determining the basis for resistance of the species to various metals (aluminum, iron, zinc, calcium, and gallium). These metals were supplied as complexes with citrate, which was completely oxidized. As in the case of the resistance to aluminum mentioned above, the metals appeared associated to phosphatidylethanolamine, which later was found in the lipid-rich complex where the metals were located (Appanna and St. Pierre, 1996). In a study on the mechanism of metal-citrate complexes by *P. fluorescens*, the biodegradation depended on the nature of the complex. Thus, the bidentate ferric, nickel, and zinc citrate complexes were readily degraded, while the tridentate cadmium and copper citrates were not. The latter, similarly to uranium citrate, were neither transported inside the cells nor metabolized by cell-free extracts (Joshi-Tope and Francis, 1995).

About one-half of the *P. aeruginosa* known plasmids confer resistance to mercuric ions (Jacoby and Shapiro, 1977). A plasmid (pPB) was found to confer mercury and organomercurial resistance to a *P. stutzeri* strain. The plasmid had two regions of functional and independently regulated *mer* genes, probably transcribed from different promoters (Reniero et al., 1995). Resistance to chromium, boron, and tellurium was also determined by some *Pseudomonas* plasmids (Summers et al., 1978). After growth in the presence of increasing concentrations of tellurite, strains of *P. aeruginosa* and *P. putida* harboring certain plasmids that determine tellurite resistance accumulated crystalline structures containing tellurium in their periplasmic space. From there, these materials were released into the medium in vesicles that are pinched off the outer membrane (Suzina et al., 1995).

Operons of genes coding for arsenic resistance are usually carried in plasmids. Arsenate is reduced to arsenite, which is eliminated by an export system. A chromosomal operon was identified and cloned in *E. coli* and was able to hybridize with chromosomal of other enteric bacteria and *P. aeruginosa*. This chromosomal operon may be the evolutionary precursor of the plasmid operons, with the advantage of a multicopy system as a means of natural amplification (Diorio et al., 1995).

Antibiotic production Plant root colonization by certain strains of the species *P. fluorescens* and *P. putida* may result in an enhancement of plant growth, an effect that is accompanied by a selective inhibition of other bacterial species and fungi. In part this action is due to the production of siderophores, which remove iron required by organisms that lack systems for utilization of the ferric siderophores. An example is pseudobactin 358 (produced by *P. putida* WBS358) whose structure, resembling that of other siderophores, has been elucidated (Van der Hofstad et al., 1986). The molecular aspects of iron assimilation by the pseudobactin-producing organisms have been analyzed (Leong et al., 1992).

Fragments of the peptide component of pseudobactin do not have fungicidal activity, although they resemble the antifungal compounds pseudomycins (Okonya et al., 1995). However, the fluorescent organisms do produce antifungal antibiotics. Thus, a strain of *P. fluorescens* produces the antibiotics pyrrolnitrin, pyoluteorin, and 2,4-diacetylphloroglucinol, which are able to suppress root diseases due to fungal pathogens. Of the three compounds, the latter represents an important factor in the control of plant diseases. A 6.5-kb chromosomal fragment has been isolated that contains the genes that encode the biosynthetic enzymes (Bangera and Thomashow, 1996). An examination of this and other molecular aspects has led to identifying a sigma factor encoded by gene *rpoS* that has an influence on the production of the antibiotics, on the biological control activity, and on the survival capacity of the strain on plant surfaces (Fedi et al., 1996). Pyrrolnitrin requires the participation of four genes, the only determinants that appear to be absolutely necessary for the complete biosynthesis (Hammer et al., 1997).

In a *P. fluorescens* strain, the production of the above antifungal compounds and of an extracellular protease can be abolished by mutations of an antibiotic production gene (*apdA*). Interestingly, the sequence of this gene is strikingly similar to that of genes that encode sensor kinases required for the pathogenicity of *P. syringae* pathovar *syringae* and *P. viridiflava*, suggesting that *apdA* encodes a putative sensor kinase component of a classical two-component regulatory system that, in this case, is required for the synthesis of a secondary metabolite (Corbell and Loper, 1995).

A different strain of *P. fluorescens* was able to produce three antibiotics: 2,4-diacetyl-phloroglucinol, pyoluterin, and +(S)-dihydroaeruginoic acid. This last compound (detected for the first time in the reported investigations) inhibits phytopathogenic fungi—among them, *Septoria tritici* (Carmi et al., 1994). Antifungal compounds produced by *P. fluorescens* include chitinase, cyanide, and pyrrolnitrin, all of which have a protective action on a variety of seedlings against damping-off caused by *Rhizoctonia solani* (Gaffney et al., 1994). Brominated derivatives of pyrrolnitrin were synthesized by a strain of *P. aureofaciens* (in this treatment considered to be a subspecies of *P. chlororaphis*) (Van Pée et al., 1983). The characteristics of fluorescent species of the genus *Pseudomonas* that participate in the inhibition of plant root pathogens have been analyzed in a useful review (O'Sullivan and O'Gara, 1992).

Miscellaneous antibiotics produced by fluorescent pseudomonads include (1) karalicin, an antibiotic isolated from a strain in the *P. putida*/*P. fluorescens* cluster, with some inhibitory action on yeasts, and a weak antiviral activity against herpes simplex viruses (Lampis et al., 1996a, b); (2) fluviols, a group of antibiotics with antitumor activity that were isolated from *P. fluorescens* and described (Smirnov et al., 1997); (3) 2-alkyl-quinolones, which inhibit growth of *Helicobacter pylori*, were produced by *P. aeruginosa* strains (Lacey et al., 1995); (4) fluopsins C and F (Shirahata et al., 1970); and (5) obafluorin, a β-lactone produced by *P. fluorescens*, with activity against *Bacillus* species. In spite of its β-lactone structure, this compound is hydrolyzed by β-lactamases (Wells et al., 1984); fosfomycin (phosphonomycin), is produced by a strain of *P. syringae* (Shoji et al., 1986).

An interesting practical application has been found for alginate, which is notorious for causing complications in cystic fibrosis cases. The polysaccharide has been found to be a convenient carrier for seed inoculation with genetically modified *P. fluorescens* strains producing antifungal antibiotics (Russo et al., 1996).

Pathogenicity for plants and mushrooms Phytopathogenic pseudomonads are allocated to three of the five rRNA similarity groups (Palleroni, 1984). Only the ones in rRNA group I, the present genus *Pseudomonas*, will be discussed here. Various symptoms produced in plants by these organisms such as tumorous outgrowth, rot, blight or chlorosis, and necrosis are the consequence of alterations of the normal metabolism of plant cells by substances excreted by the pathogens. Among these excretions there are toxins, plant hormones, and enzymes capable of attacking various components of plant tissues.

Bibliographic sources of the original papers describing various hydrolytic enzymes produced by phytopathogens can be found in the first edition of the *Manual* (Palleroni, 1984). Various nomenspecies of plant-pathogenic bacteria described in this treatment as pathovars of *P. syringae* have been found to produce phytotoxins capable of producing disease symptoms in susceptible plants. Table BXII.γ.109, taken from published information (Durbin, 1992), presents a summary of well-known examples of toxins as well as their respective targets of mode of action. Several phytotoxins have an amino acid of peptide nature (Leisinger and Margraff, 1979), and one of them, tabtoxin, has a β-lactam structure, a rare example among secondary metabolites of *Pseudomonas* (Stewart, 1971; Durbin et al., 1978).

Toxins do not necessarily parallel the host specificity of the respective phytopathogen (Patil, 1974). Their importance as taxonomic tools is very limited but their practical significance is considerable. In certain instances their production correlates with the presence of plasmids, and this has provoked renewed interest in them (Leisinger and Margraff, 1979). Loss of a plasmid by treatment with acridine orange resulted in loss of syringomycin production (González and Vidaver, 1979), but no correlation was observed between phaseolotoxin production and the presence of plasmids in *P. syringae* pathovar *phaseolicola* (described in this treatment as a pathovar of *P. savastanoi*) (Jamieson et al., 1981).

High concentrations of the plant hormone indole-3-acetic acid produced by *P. savastanoi* are thought to be the cause of tumors in plants of the family Oleaceae (Wilson and Magie, 1964).

The interpretations given to data on host–parasite interactions in plant pathology have been deeply influenced by experiments making use of the genetic variability of the host species and of the pathogenic organisms. The main ideas developed during the first three-quarters of the 20th century, and the consequent conceptual changes in the interpretation of the host-pathogen interactions have been reviewed (Ellingboe, 1981).

In recent times, work performed by H.H. Flor with a fungal pathogen of flax gave origin to the gene-for-gene hypothesis. According to this hypothesis, the development of disease or the production of a well-circumscribed hypersensitive reaction in plant tissues depends on matching genes of resistance in the host plants with avirulence genes in the pathogens. In genetic experiments, host resistance was found to be dominant over susceptibility, and the pathogen avirulence dominant over virulence. Matching host resistance with avirulence in the pathogen results in "incompatibility", manifested in a hypersensitive reaction in the host tissues. In the other three combinations (resistant host/virulent pathogen, susceptible host/avirulent pathogen, and susceptible host/virulent pathogen), a "compatible" association is established, which results in disease. These concepts are being subjected to scrutiny in the genetic study of a number of pathovars of the fluorescent species *P. syringae* (Vivian, 1992), which has opened new horizons in attempting to understand the role played by the avirulence genes in the gene-for-gene hypothesis.

Pathogenicity for humans and animals Some references on this subject have been cited on sections of this chapter dealing with outer membrane composition, genetics, pili, and flagella.

As stated by Mekalanos (1992) in an excellent review on environmental signals that control virulence in bacteria, an expanded view of virulence comprises not only the properties directly linked to the pathogenic ability of microorganisms (adherence to host tissues, production of toxins, invasion mechanisms, host defenses) but also other factors involved in "house-

TABLE BXII.γ.109. Some toxins produced by phytopathogenic *Pseudomonas* species and pathovars[a]

Species	Toxins	Target or mechanism
P. syringae		
P. syringae pathovar *atropurpurea*	Coronatine	
P. syringae pathovar *coronafaciens*	Tabtoxinine-β-lactam	Glutamine synthetase
P. syringae pathovar *garcae*	Tabtoxinine-β-lactam	Glutamine synthetase
P. syringae pathovar *glycinea*	Coronatine, polysaccharide	
P. syringae pathovar *lachrymans*	Polysaccharides	
P. syringae pathovar *maculicola*	Coronatine	
P. syringae pathovar *morsprunorum*	Coronatine	
P. syringae pathovar *phaseolicola*[b]	Phaseolotoxin	Ornithine transcarbamylase
P. syringae pathovar *savastanoi*[b]	Indole acetate, cytokinins	
P. syringae pathovar *syringae*	Syringomycins	Plasma membrane
	Syringopeptins	
	Syringotoxins	Plasma membrane
P. syringae pathovar *tabaci*	Tabtoxinine-β-lactam	Glutamine synthetase
P. syringae pathovar *tagetis*	Tagetitoxin	Chloroplastic RNA polymerase
P. syringae pathovar *tomato*	Coronatine	
P. tolaasii	Tolaasin	Plasma membrane

[a]For symbols see standard definitions. Modified from Durbin (1992). The nomenclature used is the one preceding the proposal by Gardan et al. (1992).

[b] *P. syringae* pathovar *savastanoi* is described in this treatment as an independent species, *P. savastanoi*, and pathovar *phaseolicola* is considered as a pathovar of *P. savastanoi*; see description of this species in the list of species).

keeping" functions. In regard to opportunistic pathogens such as the fluorescent pseudomonads and, in particular, *P. aeruginosa*, the functions in this "gray area" can lead to different interpretations. Thus, competition of *P. aeruginosa* for iron in the host tissues by production of a strong chelator such as pyochelin is on the whole comparable to the reaction of this organism in an iron-deficient artificial medium. However, the fact that pyoverdine, the main iron-scavenging compound produced by *P. aeruginosa*, allows normal growth of pyoverdine-negative mutants in a medium containing human iron-transferrin complex justifies considering pyoverdine production as a component of *P. aeruginosa* virulence complex (Meyer et al., 1996). In addition, iron-bound pyochelin acts as an efficient catalyst for hydroxyl radical (HO·) formation, and it contributes to endothelial cell damage from exposure to the superoxide radical (O_2^-) and H_2O_2 (Britigan et al., 1997).

P. aeruginosa seldom infects healthy individuals outside the hospital environment, and the condition of the host is essential in determining the clinical relevance of this opportunistic pathogen. Strains of *P. aeruginosa* can be isolated from a bewildering variety of sources, since perhaps it is one of the most, if not the most, common species in nature. Numbers are very low in human feces, which may be due to competition with other species, since the numbers increase significantly because of antibiotic treatments (Levison, 1977).

In chronically debilitated and immunocompromised patients, *P. aeruginosa* is capable of causing serious and even fatal infections. Individuals with extensive burns, or those who have been subjected to surgical procedures, catheterization, and treatment with broad-spectrum antibiotics, are particularly vulnerable targets. Factors involved in the transmission of *P. aeruginosa* in hospitals have been reviewed and analyzed, and preventive measures are being recommended (Doring et al., 1996).

Iron and osmolarity are mentioned by Mekalanos as environmental signals inducing in *P. aeruginosa* the expression of dissimilar virulence determinants. Control of these and other factors provoked by environmental signals usually act at the transcription level (Mekalanos, 1992). *P. aeruginosa* controls the expression of multiple genes coding for virulence factors by means of LasR, a transcriptional activator, a key component that acts in a cell-density manner ("quorum sensing"), with participation of a *Pseudomonas* autoinducer and an *N*-acylhomoserine lactone. Production of virulence factors (exotoxin A, elastase, alkaline protease, alginate, phospholipases, and rhamnolipids acting as extracellular surfactants) can be stimulated in mutants by gene transfer, or by addition of the synthetic *N*-acylhomoserine lactones (Ochsner and Reiser, 1995). Characteristically, quorum sensing becomes maximal at the time the culture is entering the stationary phase of growth (Rust et al., 1996; Albus et al., 1997).

A global activator, GacA, is responsible for the production of exoenzymes and secondary metabolites in *P. aeruginosa*. Its inactivation resulted in reduced formation of the cell density signal and of LasR. Amplification of the *gacA* gene carried on a multicopy plasmid causes early and enhanced production of LasR and of the lactone. GacA is important in the regulation of the synthesis of virulence factors (Reimmann et al., 1997).

P. aeruginosa exotoxin A is a virulence factor resembling diphtheria toxin in its mode of action. It is able to transfer an ADP-ribosyl group to elongation factor 2, causing translation termination, inhibition of protein synthesis, and cell death (Vasil et al., 1977). The toxin is a protein of 613 amino acid residues, of which residues 60–120 are of importance for excretion and contain information for interaction with eucaryotic cells (Lu and Lory, 1996). The toxin is excreted when the cells grow under iron-limiting conditions, and its production is repressed when iron is not limiting, which suggests that the ferric uptake regulator Fur is involved, as in pyoverdine synthesis. However, the situation is more complicated, and accessory iron regulatory systems may be involved (Barton et al., 1996; Ochsner et al., 1996). The genetic picture is quite complicated. A regulatory gene (*ptxR*) is involved, and when introduced in a multicopy plasmid, it increases toxin production four- to fivefold, while other virulence factors remain unchanged.

P. aeruginosa is able to produce several proteases. In fact, the organism can cause serious corneal infections and conditions that complicate diseases of the respiratory tract and burn cases, and in all these instances proteases are responsible for the tissues alterations. The most notorious of the proteases as a virulence factor is elastase, with activity on elastin, which lines the blood vessels. The protease is produced in the cell as a precursor of 54 kDa, but it is excreted as a smaller molecule (39.5 kDa) (Morihara and Homma, 1985). Various other proteases produced by the same organism are the cause of lesions in different human and animal tissues. Their importance in pathogenesis is not easy to determine, but mutants defective in protease formation are known to be less virulent.

Alginate is an exopolysaccharide produced by several species of *Pseudomonas*. Various aspects of this extracellular product already have been mentioned, one of which refers to the relationship to fimbriae, which, like alginate, are involved in adherence to tissues (Baker, 1990). A recent review covers important aspects of alginate biosynthesis by bacteria (Gacesa, 1998). The effect that environmental sensory signals have on alginate production as a virulence factor has been examined by DeVault et al. (1989). Specific factors that have been examined include osmolarity, which affects alginate formation by various fluorescent pseudomonads (Singh et al., 1992), and metals (Kidambi et al., 1995).

The *P. aeruginosa* alginate has been the one most thoroughly studied, but production of the polysaccharide also has been detected and characterized in *P. mendocina* (Govan et al., 1981; Hacking et al., 1983; Anderson et al., 1987; Sengha et al., 1989), *P. putida* (Govan et al., 1981), *P. fluorescens* (Govan et al., 1981; Conti et al., 1994; Smit et al., 1996), and even *P. syringae* (Kidambi et al., 1995). Sequences of alginate genes have been detected in other alginate producers and nonproducers belonging to rRNA similarity group I and in species of other rRNA similarity groups (Palleroni, 1984; Fialho et al., 1990; Fett et al., 1992). Similarity of the genetic determinants of alginate in *P. aeruginosa* and *Azotobacter vinelandii* (Ertesvag et al., 1995; Rehm et al., 1996) suggests either a transfer of these determinants among related members of *Proteobacteria*, or else a relic of common ancestry.

Interest in the *P. aeruginosa* alginate, which was first identified in *Pseudomonas* more than three decades ago (Linker and Jones, 1966), derives mostly from its importance as a virulence factor causing respiratory tract infections that aggravate the condition of many cystic fibrosis patients.

Alginate is composed of alternating units of mannuronic and L-guluronic acids joined by a β (1,4) linkage, where part of the carboxyl groups of mannuronic acid are acetylated. The polymer does not show the repetition of a certain type of unit, but instead there are regions where one or the other uronic acid predominates.

The steps of alginate biosynthesis are formulated starting with fructose-6-phosphate, going through mannose-6-phosphate,

mannose-1-phosphate, GDP-mannose, and GDP-mannuronic acid (steps catalyzed by enzymes encoded by the genes *algA*, *C*, *A*, and *D*, respectively), followed by polymerization, acetylation, epimerization, and final export of the alginate polymer (Chakrabarty, 1998). The genetic aspect of the process is quite complicated because it includes participation of many biosynthetic and regulatory proteins encoded by many more genes than the ones above indicated. The genes have been mapped in three regions of the *P. aeruginosa* chromosome (Goldberg, 1992).

The polymer is not used as a reserve material, and its synthesis demands energy that is not recovered by the cells. It is hard to think of a role other than protection of the pathogen against the host defenses. Secretion of alginate represents a detoxification mechanism to protect the bacterial cells against accumulation of toxic energy-rich nucleoside triphosphates under conditions that prevent active multiplication (Chakrabarty, 1998).

P. stutzeri is frequently isolated from clinical materials but rarely causes disease. In the few cases in which it was the cause of infections, the patients often had another serious underlying disease, and they responded to antibiotics (aminoglycosides, some of the β-lactams, or cephalosporins) (Noble and Overman, 1994).

Ecology Numerous natural materials are good sources for the isolation of strains of *Pseudomonas*, as well as of strains of species of other rRNA groups now assigned to different genera. It is unfortunate that few procedures can be recommended for the selective isolation of *Pseudomonas* species with exclusion of these other organisms. In some of the habitats, strains of *Pseudomonas* species may represent a minority of the microbial flora; however, certain conditions—a pH close to neutrality, organic matter in solution, a temperature in the mesophilic range, a good supply of dissolved oxygen—together with a capacity for rapid growth in the absence of complex organic factors can favor their predominance. Even in media of extremely low nutrient content, pseudomonads occasionally multiply to a considerable extent. Thus, *P. aeruginosa* has been found capable of growth at the expense of minor impurities present in hospital distilled water (Favero et al., 1971).

Strains of many species are ubiquitous, and isolation data often throw little light on their ecology. When dealing with organisms of such versatility, ecological conclusions are particularly difficult to draw. Of the 57 strains of fluorescent *Pseudomonas* species isolated by den Dooren de Jong, 23 had their origin in soil, and with one exception all were classified as *P. putida*, while all other strains were gelatin-liquefiers isolated from water, and were assigned to *P. fluorescens* (den Dooren de Jong, 1926). However, the conclusion that *P. putida* is a soil organism whereas *P. fluorescens* predominates in water could not be supported by an analysis of isolation data of many other strains from the collections of the Department of Bacteriology at Berkeley, California, and of the Seruminstitut in Copenhagen (unpublished observations). Obviously, a decision on this point is not easy in view of the possibility of cross-contamination of materials from the two habitats.

In recent years, more precise data regarding habitats have become available. An early observation suggests that the predominant fluorescent pseudomonads in wheat rhizosphere comprise one of the biotypes of *P. fluorescens* (Sands and Rovira, 1971). Many other reports have confirmed the fact that these organisms proliferate in general in plant rhizospheres, where they seem to have a stimulating effect on plant growth. In part, this may be due to inhibition of plant pathogenic organisms by iron starvation (Kloepper et al., 1980; Sarniguet et al., 1995) and to the utilization of the iron-siderophore complex by the plants (Powell et al., 1980). An additional beneficial effect is suggested by studies on the rhizosphere of plants growing in the Canadian Arctic, in which *P. putida* can grow and stimulate root elongation of plants during spring and winter at 5°C, as shown by using a strain that can survive exposure to −20°C to −50°C. Following growth at 5°C, the strain secreted a protein with antifreeze activity (Sun et al., 1995). A numerical taxonomic analysis of strains of fluorescent pseudomonads associated with the roots of tomato plants has been published (Stenström et al., 1990).

A recent survey indicates that of the species of bacteria isolated from the rhizosphere of wheat, 40% stimulated plant growth, 40% were inhibitory, and 20% had no effect (Lugtenberg and De Weger, 1992). The properties of fluorescent *Pseudomonas* species that are involved in the suppression of pathogenic species in the root system of plants have been reviewed (O' Sullivan and O' Gara, 1992).

A gnotobiotic system for the study of colonization of plant rhizospheres by *Pseudomonas*, based on seed inoculation and subsequent estimation of different parameters, has shown that many strains were outcompeted by a chosen *P. fluorescens* strain. Slow-growing and autoxotrophic mutants of this strain were at a disadvantage, indicating that growth rate and the capacity for multiplication in the absence of exogenous growth factors were important for the persistence of a strain in the rhizosphere community (Simons et al., 1996).

Many species of *Pseudomonas* have been isolated from *Lolium* leaves (Stout, 1960). *P. fluorescens* has been found frequently, and *Burkholderia cepacia* and *Stenotrophomonas maltophilia* less so (Austin et al., 1978). In their review of the literature, these authors mention isolation of *P. fluorescens* from leaves of *Phaseolus vulgaris*, *Fagus*, and *Pinus* by various workers, and consider that this species is indigenous to leaf surfaces. Whether the strains can become opportunistic plant pathogens is an open question, but some of the epiphytic pseudomonads have definite pathogenic potentialities, as was suggested by Billing (1970b) for *P. viridiflava*.

Plant pathogenic pseudomonads are normally isolated from lesions in plant hosts, which are natural enrichment cultures. Because of their ecological niches, these bacteria may offer some of the most interesting materials for the study of bacterial speciation (Palleroni and Doudoroff, 1972). In general, animals are not as good sources of *Pseudomonas* species, unless these are involved in infections as opportunistic pathogens.

In different areas, speciation of plant pathogens may proceed at different rates according to the selective forces imposed by various environmental factors. Some pathovars of pathogenic species may develop as distinctive ecotypes according the selective pressures predominating in a given area (Garrett et al., 1966).

Continued association with living hosts is important to the survival of members of the *P. syringae* group (Schroth et al., 1981). The association does not necessarily have to involve lesions, since the pathogen may be able to survive as an epiphyte on hosts as well as on nonhosts (Ercolani et al., 1974). Survival of the *P. syringae* pathovars in soil may not be long, in contrast with other fluorescent species (Schroth et al., 1981).

A brief discussion of a few points related to modern biotechnological applications of *Pseudomonas* strains may be pertinent to the present discussion. It has been reassuring to observe that the introduction of a plant growth-promoting strain of *P. fluorescens* and a genetically modified derivative did not appreciably disturb

the indigenous microflora when introduced to the soil (Mahaffee and Kloepper, 1997), and that carbon-starved *P. fluorescens* had a good survival capacity and resistance to stress in this environment (Van Overbeek et al., 1995).

The attractive possibility of using genetic means to improve the metabolic versatility of *Pseudomonas* species for the degradation of environmental pollutants has raised questions about the convenience of keeping the lateral spread of genes in the environment under control. These questions have stimulated the development of ingenious methodologies to quantify the degree of horizontal transfer of genes (Jaenecke et al., 1996), to prevent such transfer (Diaz et al., 1994), and to contain the spread of inoculated strains (Jensen et al., 1993b). Modern biotechnological developments also have resulted in improvements for observation of cells in natural environments. These improvements include the combined use of an appropriate probe and scanning confocal laser microscopy (Moller et al., 1996b), as well as in the construction of a biosensor for monitoring metabolic activities *in situ* with a bioluminescent reporter *P. fluorescens* strain (Heitzer et al., 1994).

Pseudomonas species are important members of natural microbial communities. The capacity of these organisms to react to environmental changes is in part related to their capacity to exchange genetic material. An evaluation of this process may be attempted using a strategy that tries to avoid selecting for the characters acquired by the recipients during exchange. The core of the procedure is the use in donor cells of an engineered *lazZ* reporter gene whose expression is shut down by chromosomal repressors at the levels of transcription and translation. The gene will be freely expressed when it can escape repression in the new host, which, consequently, can be identified (Jaenecke et al., 1996).

The consequences of the high surface/volume ratio in procaryotes are manifested, among other things, in concentrating on their surface components of the liquid medium. Fine-grained minerals precipitate around the cell clusters as consequence of their activities when the cells are either freely suspended ("planktonic"), or attached to surfaces with formation of a biofilm. LPS is important in the attachment, which results in a biofilm. Membrane vesicles containing degradative enzymes may bleb off the cell surface and have a predatory action against cells of surrounding populations, with liberation of nutrients that help the growth of the biofilm, as suggested by results obtained with a *P. aeruginosa* model system (Beveridge et al., 1997).

Enrichment and Isolation Procedures

Direct isolation of *Pseudomonas* species often can be achieved from many natural materials, especially soil and water. From these materials, direct isolation in solid complex or minimal media is feasible. When heavy contamination with fungi is expected, these media can be supplemented with antifungal compounds such as cycloheximide (Actidione), which is added to the medium after autoclaving (final concentration, 20–50 μg/ml), from a concentrated solution that does not need to be sterilized.

A medium that is frequently used for direct isolation especially by plant pathologists is medium B[2] of King et al. (1954), which enhances pyoverdin production by fluorescent organisms but is also satisfactory for nonpigmented strains as a general purpose medium. Some selective solid media have been developed based on medium B. An example is a medium that contains penicillin G, novobiocin, and cycloheximide (Sands and Rovira, 1970). These compounds do not inhibit the fluorescent pseudomonads, and their colonies can be identified on the plates by the characteristic diffusible, fluorescent pigment. A modification of this medium later was published for the isolation of *Pseudomonas* species with pectolytic properties (Sands et al., 1972). The medium contains sodium polypectate, and the pectolytic activity is detected by flooding the plates after growth with a solution of hexadecyltrimethylammonium bromide, which precipitates intact pectin. Once identified, the colonies are isolated as soon as possible since the compound is toxic to the cells.

Two selective media containing the detergent lauroyl sarcosine and the antibiotic trimethoprim, and differing in having either Casamino acids (medium S1) or L-asparagine (medium S2), gave good selectivity and detection of fluorescence on initial plating. Of the two media, S1 gave the highest recovery, although S2 was more selective (Gould et al., 1985).

Selective media for the oxidase-negative fluorescent phytopathogens have been described (Sands et al., 1980).

Some methods for the isolation of certain species may go through an initial enrichment step. The lesions produced by plant pathogenic pseudomonads on various plant organs represent a natural enrichment, from which direct isolation can be attempted. The lesions selected should not be too old, when other organisms may have gained access to the diseased tissues. Isolation of denitrifying pseudomonads (*P. aeruginosa*, *P. stutzeri*, *P. mendocina*, some biovars of *P. fluorescens*, etc.) after enrichment is often successful. The denitrification experiment can be performed using particular carbon sources as electron donors, and the incubation can be done at a temperature that favors multiplication of the desired organism. However, due to our ignorance of the proper conditions, or unpredicted transformations by other organisms in the microflora, these experiments may fail to give the expected results.

It is convenient to keep in mind that that species of aerobic pseudomonads other than the ones mentioned above may predominate in the enrichment cultures. In the chapter on *Burkholderia* in this *Manual*, a table has been included that summarizes the properties of *Pseudomonas* species that are able to denitrify, together with selected species of denitrifiers of other rRNA groups.

Methods of enrichment and isolation are dispersed in a number of publications, and some of them are very specific for species originally assigned to *Pseudomonas* but now allocated to newly created genera and phylogenetically belonging to other rRNA groups (Palleroni, 1984) than group I. Additional details may be found in the second edition of the treatise *The Prokaryotes* (Palleroni, 1992a), and in the first edition of this *Manual* (Palleroni, 1984).

Maintenance Procedures

Most *Pseudomonas* strains can be maintained on slants of common bacteriological media (nutrient agar or other standard complex media, or various chemically defined media with the addition of 0.5% yeast extract and 0.1% lactate or glycerol), with transfers every 1–2 months. Slants can be stored at 4–8°C. The collection examined by Stanier et al. (1966) included a number of strains of fluorescent and nonfluorescent *Pseudomonas* species that had been kept on slants of ordinary media with periodic transfers since the 1920s, and their phenotypic properties appeared to have remained essentially unchanged. In contrast, some strains

2. Medium B (g/l): protease-peptone (Difco), 20.0; Bacto-agar (Difco), 15.0; glycerol, 10.0; K_2PO_4, 1.5; and $MgSO_4 \cdot 7H_2O$, 1.5. The pH is adjusted to 7.2.

of *Pseudomonas* species as well as members of other rRNA groups (Palleroni, 1984) are not so easy to maintain for long periods in slants in the refrigerator.

Lyophilization is generally reliable for long-term preservation, particularly when proteinaceous material (e.g., skim milk) is used as an ingredient of the suspending fluid. There are many variations of lyophilization procedures traditionally followed by various laboratories, with good results. A substantial proportion of the cell mass of cultures of *Pseudomonas* species does not survive even the most careful lyophilization procedure, and lyophilization has been replaced in many laboratories by freezing cultures at a temperature of −20°C or lower (usually from about −70° to −80°C in mechanical freezers or at lower temperatures in liquid nitrogen) after addition of a cryoprotective agent to the liquid before freezing (for instance, 5–10% glycerol, final concentration).

Procedures for Testing Special Characters

Flagellar number and insertion The observation of these characteristics is best done on smears prepared by the method described by Jessen (1965), combined with results expressed on a statistical basis, as mentioned earlier (Lautrop and Jessen, 1964). On clean microscope slides, thin smears are prepared from dilute suspensions in distilled water of bacteria that have grown in broth agar cultures at 23°C or 30°C for about 18 h. Best results are obtained using freshly poured solid media whose surface has been dried in an incubator for no more than 1 h. The number of cells with flagella in the smears often varies with the degree of dryness of the agar medium in which the strains have been growing. The smears are stained for flagella by the method of Leifson (1960)[3]. Only slides with well-dispersed cells and well stained for flagella should be used. The number of flagella on each of the first 50–100 flagellated cells is noted. Cells with flagella at both ends are disregarded, since they probably represent cells in an early stage of their division. Some results of this technique have been mentioned in the early section on flagella and pili (fimbriae).

Screening of nutritional and other physiological properties The medium described by Stanier et al. (1966) has been used extensively for nutritional screenings and for testing various physiological properties of cultures of pseudomonads. One disadvantage of this medium is that not all cultures tolerate well the heavily chelated composition of the medium. More satisfactory results are obtained with a formulation that is both simpler and safer, such as the medium recommended by Palleroni and Doudoroff (1972)[4], which is most satisfactory for autotrophic and heterotrophic enrichments and as a general medium for cultivation and short-term preservation. Minimal media of similar composition have been described (Schlegel and Lafferty, 1971; Zavarzin and Nozhevnikova, 1977). These last authors recommend supplementation of the medium with minor elements for best results with fastidious organisms, but such additions are unnecessary when dealing with *Pseudomonas* strains.

Good heterotrophic growth in all these minimal media can be obtained by addition of a single organic compound as a carbon and energy source (usually 0.1%, final concentration). Experimental details of the nutritional analysis have been extensively discussed elsewhere (Stanier et al., 1966; Palleroni and Doudoroff, 1972). Ideally, the analysis should be performed under conditions that prevent cross-feeding or competition among the various strains when the medium is solidified with agar and several strains are patched on a single plate. Organic impurities in the agar may also be a serious problem. For critical tests, liquid media may be preferable, although the amount of work involved and the facilities required may be considerably greater. Carbon compounds that are to be tested in different concentrations or that require special treatments for their use in nutritional screenings have been discussed by Palleroni and Doudoroff (1972). Description of many species of aerobic pseudomonads performed at Berkeley included nutritional studies using many organic compounds as substrates. The studies were extended to the plant pathogenic pseudomonads in two laboratories (Misaghi and Grogan, 1969; Sands et al., 1970).

At present, the studies on nutritional properties of various prokaryotic groups are more often performed using commercial kits designed to reduce the labor involved in traditional procedures. Some of them (API, Biotype-100 strips, Biolog GN Microplate System, Hayward, CA) have been used in studies on *Pseudomonas*, and the results will be briefly discussed below in the section on taxonomic comments.

Biosynthesis of medium-chain-length polyhydroxyalkanoic acids (mcl-PHAs) The following observations on the biosynthesis and detection of mcl-PHAs have been provided by Birgit Kessler, a member of B. Witholt's group at the Swiss Federal Institute of Technology in Zürich.

1. As with poly-β-hydroxybutyrate (PHB), accumulation of mcl-PHAs can be elicited in a medium of high C/N ratio, and the polymer can be detected after staining with Sudan Black or by direct observation under phase contrast microscopy. However, granules of the two polymers cannot be differentiated by either procedure, and the identification procedure may involve either gas chromatographic analysis (Timm and Steinbüchel, 1990) or a solubility test. The mcl-PHAs are soluble in acetone, while PHB is not.
2. Assimilation of medium- and long-chain-length fatty acids (saturated, unsaturated, or certain branched and substituted acids) enables the cells to accumulate mcl-PHAs. Some *Pseudomonas* strains (*P. aeruginosa* PAO and *P. putida* KT2442) accumulate mcl-PHAs when grown on carbohydrates. In contrast, *P. oleovorans* lacks this capacity, but it accumulates mcl-PHAs when grown on alkanes. Growth on butyrate and β-hydroxybutyrate induces production of small amounts of PHAs, and the granules can be seen under phase contrast directly or after staining with Sudan Black.
3. Several species of aerobic pseudomonads have been tested for their capacity of PHB and/or PHA accumulation (Timm and Steinbüchel, 1990). Production of both types of polymers by a single strain did not receive special attention, but recently a strain of an unidentified *Pseudomonas* sp. was found

---

3. Leifson's reagent for flagella staining (Leifson, 1960): 1.2% solution of basic fuchsin in 96% ethanol, 3% solution of tannic acid in water, and 1.5% solution of NaCl in water. Equal parts of the three reagents are mixed before use. The mixture can be left overnight in a refrigerator, where a precipitate may form. The clear stain is applied over the smear, and after about 2–3 min a fine precipitate will form. At this point, the staining is interrupted by washing the slides with water at room temperature. The final point may have to be ascertained by trial and error before optimal conditions are defined. Absolute cleanliness of the slides is essential for good results.

4. Medium of Palleroni and Doudoroff (1972) (g/l of 0.33 M Na-K phosphate buffer, pH 6.8): NH_4Cl, 1.0; $MgSO_4 \cdot 7H_2O$, 0.5; ferric ammonium citrate, 0.05; and $CaCl_2$, 0.005. The first two ingredients are added to the buffer and sterilized by autoclaving. The ferric ammonium citrate and calcium chloride are added aseptically from a single stock solution that has been sterilized by filtration.

with such capacity when grown on fatty acids or carbohydrates.

Pigment production Perhaps the most widely used medium for pyoverdine production is the medium B of King et al. (1954). Paton (1959) has described a medium whose preparation involves extensive treatment of the solution and the agar with iron-chelating agents, but the removal of iron is so complete that it often results in inhibition of bacterial growth (Garibaldi, 1967). Garibaldi recommends instead a medium that is based on the well-known iron-chelating capacity of conalbumin, a component of egg-white.[5] Luisetti and collaborators (1972) recommend a medium[6] for the enhancement of fluorescent pigment production by plant pathogenic and other pseudomonads that fail to fluoresce in the medium B of King and collaborators.

A point frequently incorrectly stated or disregarded altogether in descriptions of procedures for the detection of pyoverdins by fluorescent pseudomonads is the type of ultraviolet lamp to be used for observing fluorescence. Only the "true" fluorescent pigment will fluoresce under a source of short wavelength ultraviolet light (around 254 nm). Some species belonging to rRNA group II (Palleroni, 1984) (*Burkholderia cepacia*, *B. gladioli*, *B. caryophylli*) produce diffusible yellow-green pigments that are sometimes mistaken for the fluorescent siderophores.

Medium A of King et al. (1954) is generally recommended for the production of phenazine pigments to which pyocyanin belongs. In our experience, this medium is not always very effective, but unfortunately no alternative can be recommended. Phenazine pigment production, therefore, appears erratic, particularly with cultures that have been kept for a long time under ordinary laboratory conditions.

The blue pigment of *P. fluorescens* biovar IV (*"P. lemonnieri"*) can be produced abundantly by fresh cultures in the potato medium[7] familiar to mycologists. As mentioned earlier, the pigment is related to indigo iodine (Starr et al., 1967). Interestingly, this same medium induces the production of indigo iodine by an unrelated organism, *Corynebacterium insidiosum* (Starr, 1958).

Ring fission mechanisms The *ortho* or *meta* cleavage of two central intermediates in the metabolism of aromatic compounds (catechol and protocatechuate) can be tested by the method originally suggested by K. Hosokawa (Stanier et al., 1966). After growth in a chemically defined medium with an aromatic substrate, the cells are suspended in 0.02 M Tris buffer (pH 8). To each 2-ml portion of suspension are added a drop of toluene and 0.2 ml of either 0.1 M catechol or 0.1 M protocatechuate. A bright yellow color appearing in a short time (usually within a few seconds) indicates a *meta* cleavage. The tubes are shaken for 1 h at 30°C, and then tested for the appearance of β-ketoadipate (indicative of an *ortho* cleavage) by the Rothera reaction, as follows. Solid ammonium sulfate is added to saturation and the pH is brought up to about 10 by the addition of two drops of 5 N ammonium hydroxide. One drop of freshly prepared 25% sodium nitroprusside in water is added. A deep purple color indicates a positive reaction.

Arginine dihydrolase reaction The method giving the most unequivocal results is the direct one, based on an estimation of arginine disappearance under anaerobic conditions. A bacterial suspension (200 Klett units, as measured with green filter 54) is incubated for 2 h at 30°C in the presence of arginine (2.5×10^{-4} M) under anaerobic conditions. The tubes are immersed in a boiling water bath for 15 min and arginine is estimated by the method of Rosenberg in a sample of the supernatant after removing the cells. A control, without addition of arginine, is included in the experiment (Rosenberg et al., 1956).

The Rosenberg procedure is cumbersome and time-consuming, and other methods appear to be much simpler and sufficiently reliable. Among them, the method of Thornley (1960) is perhaps the most convenient. As recommended by Lelliott et al. (1966), Thornley's medium[8] can be conveniently dispensed in 3-ml portions into 5-ml screw cap vials. After autoclaving, the vials are inoculated by stabbing and sealed with melted paraffin. Anaerobic formation of ammonia from arginine can be detected by a change of color of the indicator within 3 d.

Acid production from carbohydrates As pointed out by Palleroni and Doudoroff (1972), the reaction of acid production from carbohydrates is not necessarily correlated with nutritional data, since the acid produced by oxidation of a sugar may not always be a suitable carbon source for growth. However, this should not diminish the taxonomic value of the test. More serious, though, is the objection of redundancy, in that a single enzyme may affect the oxidation of several different sugars (Weimberg, 1962).

Acid production from carbohydrates has been used very extensively for descriptive purposes since the last century, and it is still being used in various laboratories. It is described here among the recommended procedures, provided that the results are interpreted with proper reservations. The method of choice is that described by Hugh and Leifson (1953), which gives clear and reproducible results. The main advantage of this method is the use of a medium containing a low concentration of peptone[9]. If the concentration is high, the deamination can neutralize a positive acid reaction from the sugar.

Hydrolysis of Tween 80 This reaction is indicative of lipolytic activity, and is carried out in the medium of Sierra (1957)[10]. The medium is usually dispensed in Petri dishes and is spot-inoculated with the cultures. During the incubation, the plates are observed daily for opacity around the patches, due to formation of insoluble calcium soaps (Sierra, 1957). It the reaction has been negative for 10 d, the bacterial mass may be scraped off to observe

5. Garibaldi's medium: sterile egg white is drawn aseptically from eggs that have been sterilized externally by immersion in 70% ethanol for 5 min, drained and flamed to remove the residual alcohol. The egg white is warmed to 45°C and added aseptically to give a final concentration of 10% (v/v) to any commercial complex solid medium that has been autoclaved and cooled to 45°C. After mixing, the medium is dispensed into Petri dishes. A solution of the protein conalbumin (available commercially) that has been sterilized by filtration can be used instead of egg white at a final concentration of 1.7 mg/ml of medium.

6. Medium of Luisetti et al. (1972) (g/l): vitamin-free Casamino acids, 10.0; K_2HPO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 1.0; sucrose, 10.0; gelatin, 30.0; and agar, 20.0; pH 7.0.

7. A formula recommended by D.C. Hildebrand (personal communication), who has isolated a number of strains of these organisms, is as follows. Sliced potatoes (250 g) are steeped in 1 liter of water at 65°C for 1 h. The preparation is filtered through three layers of cheesecloth, and 2.0 g of glucose and 20.0 g of agar are added to the solution. The medium is sterilized at 20 psi for 30 min.

8. Thornley's medium (g/l): peptone, 1.0; NaCl, 5.0; K_2HPO_4, 0.3; agar, 3.0; phenol red, 0.01; and L-arginine-HCl, 10.0; pH 7.2.

9. Hugh-Leifson medium (g/l): peptone, 2.0; NaCl, 5.0; K_2HPO_4, 0.3; agar, 3.0; bromothymol blue, 0.03; and carbohydrate, 10.0; pH 7.1.

10. Sierra's medium (g/l): Bacto-peptone (Difco), 10.0; NaCl, 5.0; $CaCl_2 \cdot H_2O$, 0.1; and agar, 17.0. Tween 80 is sterilized separately and added to the medium after autoclaving to give a final concentration of 10.0 g/l.

the medium under the patch. The presence of a precipitate, however, may be due to release of endocellular lipases by lysis of part of the population, and therefore, for practical purposes, the reaction is considered negative.

Nitrate reduction and denitrification Reduction of nitrate to nitrite can be tested according to Lelliott et al. (1966), and denitrification according to Stanier et al. (1966). Some of the problems encountered in the denitrification test have been discussed by Palleroni and Doudoroff (1972).

Miscellaneous tests Additional tests that are performed in the identification of *Pseudomonas* species include the following, with references to bibliographic sources for the methods: oxidase test (Kovács, 1956; Stanier et al., 1966); levan formation from sucrose (Lelliott et al., 1966; Stanier et al., 1966); gelatinase (Skerman, 1967); and the egg yolk reaction (Lelliott et al., 1966; Stanier et al., 1966). In testing for catalase, the usual procedure of placing a drop of hydrogen peroxide solution on top of a colony and observing the formation of bubbles is usually satisfactory, but occasionally the reaction may be so weak as to require observation under a dissection microscope, or sensitive detection methods involving the use of an oxygen electrode (Auling et al., 1978).

A number of additional techniques have been added as taxonomic tools to supplement the phenotypic analysis of the aerobic pseudomonads. The results of many of these methods will be summarized below under general taxonomic comments, and the papers cited are sources of information on the methodologies followed in each case. The methods described in these bibliographic references cover various aspects of nucleic and protein studies, the analysis of the fatty acid composition, as well as the description of numerical procedures for data processing.

Differentiation of the genus *Pseudomonas* from other genera

The first edition of the *Manual* included a discussion of the properties that distinguish the aerobic pseudomonads of the genus *Pseudomonas sensu lato* from other phenotypically similar Gram-negative, nonsporulating aerobic bacteria. The reader is referred to this source for comments on this subject in its broader sense (Palleroni, 1984).

Over a quarter of a century ago, strains of *Pseudomonas* species were subjected to experiments of ribosomal RNA–DNA hybridization. Based on the conservative nature of the ribosomal RNA cistrons that had been demonstrated in species of the genus *Bacillus* (Doi and Igarashi, 1965; Dubnau et al., 1965), these experiments attempted to disentangle the phylogenetic complexity that was suspected in the unrelated genus *Pseudomonas*. The results were indeed very striking. The rRNA–DNA hybridization experiments clearly suggested an internal subdivision of *Pseudomonas* into five rRNA groups that seemed "to be very distantly related to each other phylogenetically . . . [deserving] at least independent genus (and possibly family or order) assignment" (Palleroni et al., 1973). One of these groups, which included the type species, *P. aeruginosa* (rRNA group I), was to retain the genus name. It showed a closer relationship to *Xanthomonas* and to *E. coli* than to other groups of pseudomonads.

It was soon realized by other workers that extension of this approach to comparative studies of other bacterial taxa could yield results of use "as an index of general relatedness [to] provide a sound base on which to construct taxonomic or maybe identification schemes" (Johnson and Francis, 1975). This prophetic statement found ample corroboration in the years that followed.

Pseudomonas species were examined again at Gent (Belgium) on a much broader basis, but using essentially the same experimental approach, nucleic acid hybridization, and the results, published 10 years later (De Vos and De Ley, 1983), confirmed the conclusions of the original observations. In view of the phylogenetic diversity demonstrated in the genus *Pseudomonas* as classically defined, one of the striking consequences from the taxonomic point of view was that the set of basic properties that had been considered characteristic for this group of organisms—i.e., rod shaped, Gram negative, nonsporeforming, motile by means of polar flagella, and aerobic—was inadequate for practical diagnosis of the genus *Pseudomonas*. The circumscription of *Pseudomonas* is now restricted to the members of rRNA similarity group I of Palleroni et al. (1973), and it is unfortunate that the similarities to members of other groups (which, in the first place, was the basic reason for their original assignment to the genus *Pseudomonas*) make it difficult to define discrete sets of differential phenotypic characters.

The hybridization methods originally designed for the evaluation of rRNA similarities (Palleroni et al., 1973; De Vos and De Ley, 1983) were eventually replaced by other procedures (oligonucleotide cataloging, rDNA nucleotide sequences). Their use, as expected, confirmed the results of the earlier hybridization experiments. Sequencing the 16S rDNA gene after amplification by PCR is now universally used as the basis for assignment of new species to the genus *Pseudomonas*. As shall be mentioned below, fatty acid analysis can also be effective in differentiating *Pseudomonas* from the other similarity groups.

Pseudomonas sensu stricto (rRNA similarity group I) is still a group of considerable heterogeneity. Internal subgroups can be defined based on plant pathogenicity or pigment production. Among the pigments, the fluorescent siderophores are characteristic of the so-called fluorescent pseudomonads, and production of these compounds is sufficient *per se* to allocate a strain in the genus *Pseudomonas*.

However, the genus also includes nonfluorescent species. It is interesting to note that during the early phenotypic studies carried out at Berkeley, in spite of the differences in pigmentation, a phylogenetic relationship was suspected between some pigmented and nonpigmented species. Obviously, the extensive phenotypic study to which the strains had been subjected implied the expression of a considerable proportion of genes, and it was observed that "the nutritional spectrum of the [alcaligenes group, that is represented by strains that are the least nutritionally versatile of all aerobic pseudomonads] recall[ed] in many respects that of the fluorescent pseudomonads, but it [was] much narrower, notably in the areas of sugars and sugar-acids, and of aromatic compounds" (Stanier et al., 1966). In agreement with the above inference, the numerical taxonomic studies of Sneath et al. (1981), based on part of the published data from the Berkeley group, resulted in a three-dimensional graphical representation, where the so-called fluorescent complex is placed on the same side of the horizontal plane as the nonfluorescent species *P. stutzeri* and *P. alcaligenes*. Although discrete sets of phenotypic properties appear to be inadequate for an absolute differentiation of *Pseudomonas* from other genera of aerobic pseudomonads, the wealth of information contained in extensive nutritional screenings can provide, after appropriate processing, a generally satisfactory graphical representation of the relationships between *Pseudomonas* and other rRNA similarity groups (Sneath et al.,

1981). The position of nonfluorescent species is uncertain in graphical representations of values obtained using the Gower or the pattern coefficients, but association of *P. stutzeri* and *P. alcaligenes* is more distinct when using three-dimensional representation by principal coordinate analysis of Euclidean distances (Sneath et al., 1981). Moreover, the phylogenetic representation of Fig. BXII.γ.124 shows that the nonfluorescent species *P. alcaligenes* and *P. pseudoalcaligenes*, are placed in the neighborhood of the versatile fluorescent species *Pseudomonas aeruginosa*.

The original descriptions of the various phenotypic groups of *Pseudomonas* species included the inability of species of group I to accumulate PHB granules as carbon reserve material, with the exception of some *P. pseudoalcaligenes* strains that appeared to accumulate small amounts of the polymer. The diagnostic value of this negative characteristic appeared to be rather limited: on the one hand, the species of group V (*Xanthomonas* and *Stenotrophomonas*) are also negative, and on the other, the present treatment includes some species (*P. corrugata*, *P. amygdali*, *P. ficuserectae*) that have been reported in the literature to be able to accumulate PHB. However, *P. corrugata* and *P. ficuserectae* actually do not synthesize PHB but instead accumulate PHAs of different monomer composition than PHB, thus buttressing the taxonomic value of inability to accumulate PHB as a generic character (Kessler and Palleroni, 2000). The lack of ability to form PHB is shared by species of group V (*Xanthomonas* and *Stenotrophomonas*), which is interesting in view of the relatively close relationship of this group with group I (*Pseudomonas*). (See also the chapter on *Stenotrophomonas* in this *Manual*.)

The main body of the present treatment of the genus *Pseudomonas* comprises the species listed in group I of the first edition of the *Manual*. In addition, there are species that were not included in the early experiments, although they were mentioned as probable members of group I, and were later assigned to *Pseudomonas* mainly from additional screenings performed at the University of Gent, Belgium (De Vos and De Ley, 1983; De Vos et al., 1985, 1989). An excellent source of information on the genuine *Pseudomonas* species as well as the present position of many species assigned to *Pseudomonas* but now transferred to rRNA groups other than group I (Palleroni, 1984) is the review article by Kersters et al. (1996). The list of species below will refer with special detail to species whose assignment to *Pseudomonas* has been decided based on phylogenetic criteria.

Taxonomic Comments

The proposed division of the aerobic pseudomonads into five RNA similarity groups has received confirmation from numerous contributions by workers in many different laboratories. The investigations have followed various approaches, including investigations on metabolic pathways and their regulatory mechanisms, nucleic acid similarity studies, amino acid sequences of selected proteins, immunological studies, and cell wall composition. The results obtained by application of these approaches were extensively discussed in previous reviews (Palleroni, 1975, 1986, 1992a, b, 1993), and determinative keys have been proposed (Palleroni, 1977; Bergan, 1981; Stolp and Gadkari, 1981). The data add considerable precision to the circumscription of the genus *Pseudomonas*, and some of the methodologies can be of help for determinative purposes.

Interest in the taxonomic intricacies of this genus has not subsided, and of particular interest is a compilation of papers published by members of a consortium of European research groups in vol. 19, pp. 465–568 of *Systematic and Applied Microbiology*. These reports represent to a great extent further explorations into the formidable phenotypic and genomic diversity of the genus *Pseudomonas* as presently circumscribed using a number of experimental approaches.

In addition to the techniques for the determination of special properties already described, this section includes a discussion of other methods or variations of previous methodologies that have been particularly informative in taxonomic analysis of *Pseudomonas* species. Details of the experimental procedures may be found in the respective bibliographic sources.

Nutritional and metabolic studies Even though the formidable body of phenotypic information collected at Berkeley constituted a very appropriate subject for numerical taxonomic studies, this type of data treatment was reported only for a fraction of the available strains. A considerable amount of work was done in this area, but it remained unpublished, except for a few selected instances (Sands et al., 1970; Palleroni et al., 1972; Champion et al., 1980). Numerical treatment of phenotypic data also is available in original Ph.D. theses from the Department of Bacteriology (Ballard, 1970; Barrett Ralston, 1972).

A more extensive numerical analysis of published nutritional data of the Berkeley collection has given results in very good agreement with the proposed groupings, as indicated by Sneath et al. (1981). Their paper includes an illustrative three-dimensional representation using the system of principal coordinate analysis. A different system of data processing not requiring a complete matrix with all pairwise comparisons also results in useful three-dimensional representations, and it has been applied to published data of the pseudomonads (Hildebrand et al., 1984).

In addition to the extensive phenotypic studies performed at Berkeley on many strains of aerobic pseudomonads following conventional bacteriological techniques, in recent times additional observations have been performed using available commercial kits. Many strains of *Pseudomonas* species were subjected to nutritional studies using API Biotype-100 strips (BioMérieux, La Balme les Grotes, France) for carbon assimilation and the Biolog GN MicroPlate System (Biolog Inc.), which is based on substrate oxidation as detected by the change of color of an indicator (Grimont et al., 1996). Each of these systems included a list of nearly 100 organic compounds, the data obtained were analyzed by computerized systems, and the results were represented graphically in dendrogram form. *P. aeruginosa*, *P. tolaasii*, *P. mendocina*, *P. cichorii*, *P. viridiflava*, *P. fragi*, *P. stutzeri*, *P. agarici*, *P. alcaligenes*, and *P. pseudoalcaligenes* appeared as homogeneous phenons. In contrast, some of the fluorescent species (*P. putida*, *P. fluorescens*, *P. marginalis*) did not form discrete clusters but were found distributed in several phenons, confirming the heterogeneity previously reported elsewhere.

In general, according to Grimont et al. (1996), there was a remarkable correlation between the Biotype-100 data and the results obtained over 30 years ago using a more conventional methodology (Stanier et al., 1966; Ogawa et al., 1992). This is in agreement with the basic idea behind the two approaches, which rely on the utilization of substrates for growth. The work of Stanier et al. (1966) did not include testing for the production of acid from carbohydrates, a technique widely used at the time. As discussed elsewhere (Palleroni and Doudoroff, 1972) and in a previous section of this chapter, in spite of their reproducibility the results of the oxidation tests may be redundant; i.e., one enzyme may produce acid from more than one substrate. On

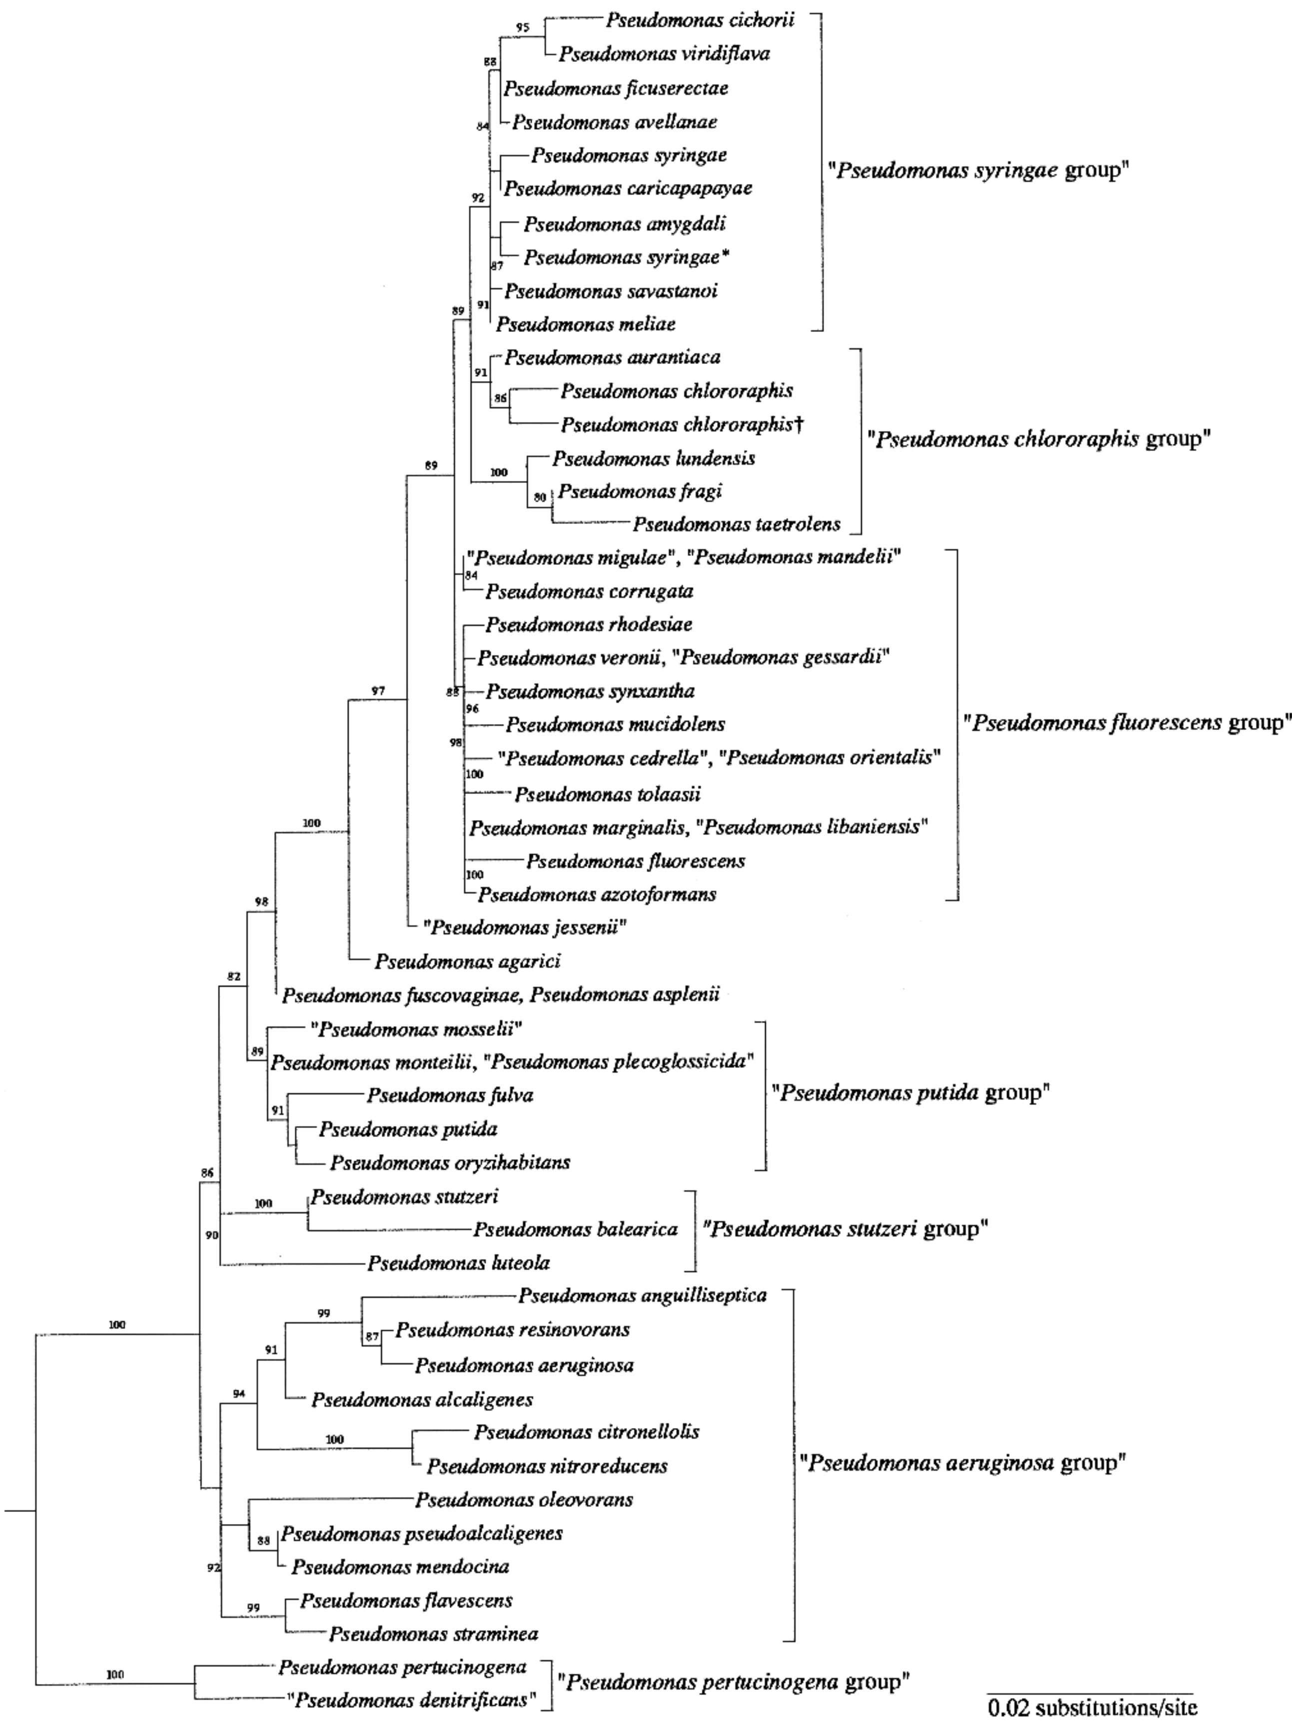

FIGURE BXII.γ.124. Phylogenetic tree of species of the genus *Pseudomonas* derived from the 16S rDNA sequences. Bootstrap values of 80% or higher are indicated at the branch points. *Escherichia coli* (V00348) was used as the root organism. (Reproduced with permission from Y. Anzai et al., International Journal of Systematic and Evolutionary Bacteriology *50:* 1563–1589, 2000, ©International Union of Microbiological Societies.)

the other hand, acid production does not necessarily correlate with utilization of a given substrate for growth. However, acid production from carbohydrates in some instances is useful and provides an additional metabolic test.

A study of strains of *P. putida* and other fluorescent pseudomonads was performed by a determination of the assimilation of carbon compounds of three chemical families (carbohydrates, acids, and amino acids); this was done using the API system (BioMérieux, La Balme les Grotes, France) and following a methodology described elsewhere for a numerical taxonomic study on nonfluorescent species of *Pseudomonas* (Gavini et al., 1989a). This determination was supplemented by an extensive enzymatic study using kits from the same manufacturer for testing 59 peptidase, 10 esterase, and 20 oxidase activities (Elomari et al., 1994). Five main phenotypic clusters were obtained by application of the unweighted pair group average linked method and the Dice similarity coefficient. Of these, one group (II) was identified as *P. putida* biotype A, and could be subdivided into four subclusters, IIa–IId. Strains of cluster II were characterized by ribotyping (see below) using the restriction enzyme *Pvu*II, and seven ribotype subclusters were obtained. Two phenotypic subclusters correlated completely with two ribotype clusters. Based on the results of these studies, the authors urged a revision of *P. putida* and its biovars (of which A represents the "genuine" *P. putida*). The studies indicated the convenience of creating a third biovar, in confirmation of a similar suggestion that emerged from the studies of Barrett et al. (1986), and they serve to illustrate once again the enormous complexity of the species of the fluorescent group. In future studies, the *P. putida* biovars may be circumscribed more precisely as different species (Elomari et al., 1994).

The phenetic taxonomy of a large number of fluorescent pseudomonads isolated from tomato roots was performed using Jaccard similarity coefficients (Stenström et al., 1990). The field strains belong to the *P. fluorescens/P. putida* complex, and a suggestion was made to convert the biovars of the first species to the rank of individual species. Once again, the *P. putida* strains included a group that differed from the two known biovars (Stenström et al., 1990).

The usefulness of 36 determinative tests was estimated for 32 pathovars of the phytopathogenic fluorescent species *P. syringae*. The results allowed differentiation of pathovars in some cases, but in others, no distinctive clusters could be detected (Young and Triggs, 1994).

A numerical taxonomic analysis of the nonfluorescent species of RNA similarity group I (*Pseudomonas*), including a large number of strains, suggested that there may be future subdivision in a larger number of species than those recognized at present (Gavini et al., 1989a). Since the analysis was restricted to phenotypic properties, further work using molecular approaches will be necessary to substantiate such suggestion. Other examples illustrate the power of the numerical analysis of extensive phenotypic data for defining clusters that, upon further analysis, may be segregated as biovars or even described as independent species within a population of related strains. One case in point is the circumscription of *P. lundensis*, which, as mentioned in the species description (see below in list of species), had been previously identified as a well-defined cluster within a collection of strains isolated from meat (Molin and Ternström, 1982, 1986). It was similarly defined independently by an analysis of a collection of fluorescent strains from the Berkeley collection (Barrett et al., 1986). The studies resulted in defining four clusters of strains, of which two were identified as *P. fragi*. The other two clusters, of fluorescent pseudomonads, could not be identified as any of the described biovars of *P. fluorescens* or *P. putida*. The authors emphasized the value of substrate utilization tests for elucidating the relationships among *Pseudomonas* strains (Shaw and Latty, 1982).

The numerical analysis of a collection of strains isolated from tomato pith necrosis demonstrated that the strains of *P. corrugata* constituted a single phenon. This study served as the basis for an emended description of this species (Sutra et al., 1997). Numerical taxonomic studies of strains isolated from natural mineral waters led to the discovery of the new species *P. rhodesiae* (Coroler et al., 1996) and *P. veronii* (Elomari et al., 1996).

Mol% G + C studies The original phenotypic studies by Stanier and collaborators in 1966 were supplemented with base composition determinations of the DNA of the strains (Mandel, 1966), which were later extended for inclusion in the description of new species under study in the same laboratory. In modern species descriptions, mol% G + C values of the DNAs are routinely included, although they are still missing for some of the species assigned to the genus.

DNA–DNA hybridization studies The phenotypic studies on the aerobic pseudomonads were followed by DNA–DNA hybridization studies, and, by virtue of the wide range of similarity values obtained, the results provided the first clues of the profound genomic differences among the species of this group of organisms. The results eventually suggested the need for similarity studies involving molecules of a more conservative nature. Within the genus *Pseudomonas*, the DNA–DNA hybridization studies included experiments with strains of the *P. stutzeri* group (Wendt-Potthoff et al., 1992), with fluorescent organisms (Palleroni et al., 1972), and with miscellaneous members of other groups. In all these experiments, the hybridizations were done by the competition technique of Johnson and Ordal (1968), but in later experiments the S1 nuclease procedure described by Johnson (1994a) was chosen.

The most important taxonomic application of DNA–DNA hybridization techniques involving the whole genome is in defining relationships at the species level. When applied to strains of aerobic pseudomonads, the hybridization experiments confirmed the relationships among species of the same phenotypic groups; at the same time, as mentioned above, the values were very low or negligible for species of different groups, even among strains of species that unequivocally could be assigned to the same genus. In spite of these observations, in some instances the results of DNA hybridization experiments occasionally have been used to attempt the precise circumscription of genera. One example was the proposal of two new generic names (*Chryseomonas* and *Flavimonas*) (Holmes et al., 1987) for two species previously assigned to the genus *Pseudomonas* (Kodama et al., 1985); the low DNA similarity values obtained in hybridization with DNA of *Pseudomonas* species were taken as the basis for such a proposal. Later studies suggested that the newly created generic names should in fact be considered as junior subjective synonyms of *Pseudomonas* (Anzai et al., 1997), and they are described as such in the present treatment.

Restriction analysis of the whole genome A useful approach adopted for the characterization of bacterial genomes combines the action of endonucleases that infrequently cut the chromosome with pulsed-field agarose gel electrophoresis for the separation of large DNA fragments. A limited number of cuts per

genome is desirable for genomic restriction mapping (McClelland et al., 1987), with clear advantages over frequently cutting endonucleases for the production of fingerprints characteristic of different taxa (Mielenz et al., 1979; Dobritsa, 1985; Sorensen et al., 1985). Application of this principle has resulted in a practical method for constructing and analyzing macrorestriction patterns of 234 strains of different species of aerobic pseudomonads (Grothues and Tümmler, 1991). The restriction nucleases *AsnI*, *DraI*, *SpeI*, *XbaI*, and *PacI* were found to be most appropriate by being specific for AT-rich regions, or for sites including the extremely uncommon tetranucleotide CTAG (McClelland et al., 1987).

The macrorestriction patterns are compared for the number and position of the bands, and use of appropriate equations often indicates a correlation between the estimated similarities of fingerprints and conventional taxonomic groupings. The results obtained by Grothues and Tümmler (1991) in general confirm the classification of pseudomonads based on extensive numbers of phenotypic properties and nucleic acid hybridization studies.

Strains sharing the same mol% G + C contents in the chromosomal DNA, the same codon usage, and similar genome size, give similarity coefficients useful for determinative purposes. The genome patterns also have the practical advantage of helping in epidemiological studies. Differences have been found between *Pseudomonas* strains that are susceptible or multiply resistant to antibiotics (Yamashita et al., 1997).

Differences in restriction fragment size distribution may result from various chromosomal rearrangements and/or mutations at the restriction sites, which suggests that the methodology based on restriction fingerprints should be supplemented with other approaches to determine the degree of homology of the fragments. Large genomic rearrangements have been observed in *P. aeruginosa* strains isolated from clinical samples or from the environment (Schmidt et al., 1996c). The former strains came mostly from cystic fibrosis cases. A 95-kb plasmid was detected in environmental strains and it integrated into the chromosome in cystic fibrosis strains. Exchange of DNA blocks and large DNA inversions led to divergence of clones in this species. The presence of inversions only in cystic fibrosis strains suggests that this niche causes or selects for substantial changes in the genome (Römling et al., 1997).

A study of pathovars of fluorescent plant pathogenic pseudomonads (Grothues and Rudolph, 1991) indicated that two strains belonging to the same pathovar, but of different origins, can give almost identical restriction fingerprints. However, this is not always the case. Pathogens of wide host range give more diverse restriction patterns than those of restricted host range. The methodology was also used for the examination of representative strains of *P. stutzeri*, a species notorious for its heterogeneity (Stanier et al., 1966; Palleroni et al., 1970). The results show a marked correlation of genome structure with fatty acid composition, and with data of nucleic acid hybridization experiments (Rainey et al., 1994b). A high degree of heterogeneity in macrorestriction patterns that did not correlate with the subdivision of the species in genomovars was also observed by another group of workers, and the marked heterogeneity of *P. stutzeri* was attributed, at least in part, to large chromosomal rearrangements (Ginard et al., 1997). The results obtained by these two groups of workers also indicate that the genome size of *P. stutzeri* ranges from 3.4–4.64 Mb for the strains subjected to their studies.

Rotating field electrophoresis was used to separate fragments of DNA of common and of genetically modified strains of *Pseudomonas* species after digestion with rare-cutting restriction endonucleases. The technique was adapted to the identification of *Pseudomonas* strains deliberately released in the environment. The fingerprints were different for strains of the same species, although they were identical for related strains, and the differences were not affected by the presence of natural or genetically modified plasmids (Claus et al., 1992).

Sequence determination of 16S/23S spacer regions A study of the genomic organization of the ribosomal RNA genes in the *P. aeruginosa* has been the basis for the hypothesis that this species carries at least four sets of genes, each containing the genes for 16S, 23S, and 5S (Hartmann et al., 1986). Much information is now available for the 16S rRNA genes, in contrast with the other components of the ribosomal RNA complex, and it has been suggested that the spacer regions between the respective genes may be interesting subjects for sequence studies applicable to identification and typing procedures. Working with *Pseudomonas* strains isolated from different types of soils, Gill et al. (1994) amplified the spacer regions by PCR and subjected them to sequencing studies. The results suggest a limited degree of variability among strains identified as *P. putida* and *P. fluorescens*. However, the data may be useful for the recognition of particular *Pseudomonas* environmental strains. A review with information on studies of the spacer regions in a number of bacterial species, including some aerobic pseudomonads, is now available (Gürtler and Stanisich, 1996).

Distribution of repetitive sequences in the genome These sequences have been taken as the basis for genomic studies based on amplification of the fragments separating the repeated sequences. Work on pseudomonads (Louws et al., 1994) is an extension of studies performed mostly on rhizobia and *Xanthomonas* (Judd et al., 1993), following an original report suggesting the use of the distribution of the repetitive sequences as a tool for the characterization of the genome (Versalovic et al., 1991).

Identification of special genetic markers Saint-Onge et al. (1992) succeeded in cloning and sequencing the lipoprotein I gene (*oprI*) of *P. aeruginosa* PAO. The sequence showed similarity to published sequences from other sources, and oligonucleotide primers were designed to amplify the gene by PCR. The amplified gene or the oligonucleotide primers are convenient identification tools in Southern blot analyses. DNA obtained from small amounts of material taken from colonies could be used for amplification, and when bands of the expected mobility were obtained, they could be further identified by the use of a probe prepared with the amplified gene from *P. aeruginosa*. The gene was identified in species of *Pseudomonas* (rRNA similarity group I) and in strains of the genera *Chryseomonas* and *Flavimonas*, whose genomic DNAs reacted with the probe in Southern blots. Saint-Onge and collaborators concluded that the *oprI* gene was found primarily in strains of group I, but they wisely added that it would be of interest to search for other indications leading to a reclassification of the organisms assigned to these newly created genera. Evidence supporting this prediction was eventually found, and, as mentioned above in the section on DNA–DNA hybridization, supported the conclusion that the genera *Chryseomonas* and *Flavimonas* should be considered as synonyms of *Pseudomonas* (Anzai et al., 1997). The main conclusions of the work of Anzai and collaborators are summarized graphically in Fig. BXII.γ.125. For the time being, the two genera *Chryseomonas* and *Flavimonas* should be considered as junior subjective synonyms of *Pseudomonas*.

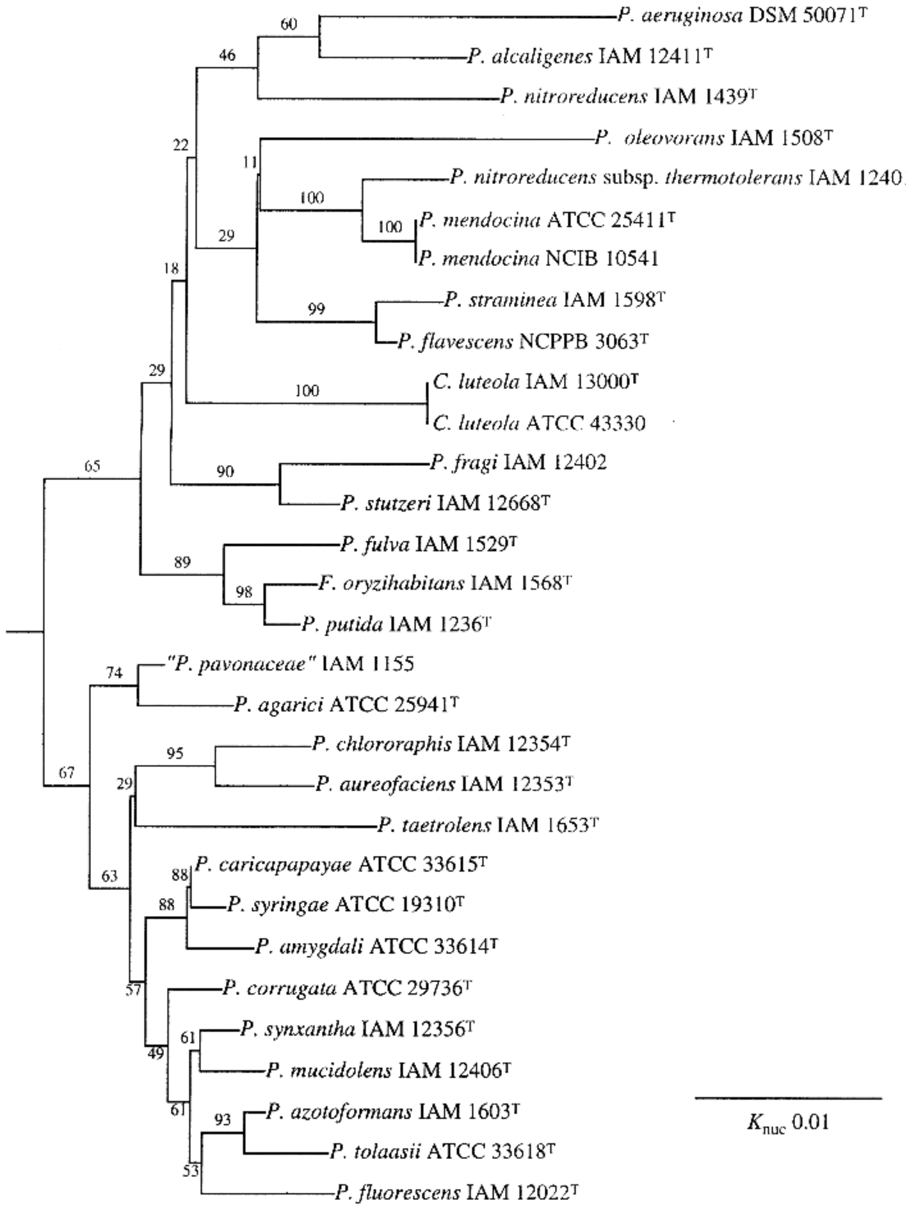

FIGURE BXII.γ.125. Phylogenetic tree for different species of the genus *Pseudomonas* derived from 16S rDNA sequence similarities to show the relative position of *Chryseomonas* and *Flavimonas*. Bootstrap values are indicated at the branch points. The confidence limits for the position of the branches has been estimated using the bootstrap analysis. *Escherichia coli* was chosen as root organism. (Reproduced with permission from Y. Anzai et al., International Journal of Systematic Bacteriology *47:* 249–251, 1997, ©International Union of Microbiological Societies.)

Additional confirmation of the relationship among species of *Pseudomonas* came from work demonstrating that four alginate production genes were conserved within the group (Fialho et al., 1990). Conservation also was observed in the *oprP* gene in various species of similarity group I (Siehnel et al., 1990).

rRNA–DNA hybridization This technique has had fundamental importance in *Pseudomonas* taxonomic and phylogenetic studies because its application resulted in the demonstration of the complexity of the aerobic pseudomonads as a bacterial group (Palleroni et al., 1973). Because of these studies, *Pseudomonas* is now restricted to one of five rRNA similarity groups. In these early studies, the competition technique was used (see Kilpper-Bälz, 1991, for a review of the methodology). Later, modifications of the hybridization technique were used by other workers, confirming and extending the original results (De Vos and De Ley, 1983; De Vos et al., 1985, 1989). Since the development of practical methods for sequencing the components of the rRNA operon, rRNA–DNA hybridization methods are seldom being used for taxonomic purposes.

rRNA gene sequencing Following the initial rRNA–DNA hybridization studies on the aerobic pseudomonads, oligonucleotide catalogs (Uchida et al., 1974) were used for phylogenetic characterization of bacterial species. Comparisons among catalogs were expressed numerically by means of association coefficients (S_{AB}), and the values could be represented graphically in dendrograms (Fox et al., 1977). Cataloging eventually gave way

to a more comprehensive approach directed to the determination of the total sequence of ribosomal RNA components. Initially this was achieved by the isolation of rRNA and DNA synthesis by transcriptase reaction, but the advent of the PCR technique has greatly simplified the experimental methodologies by avoiding RNA isolation, and it is widely used today. An article by Moore et al. (1996) specifically refers to determination and comparison of the 16S rRNA sequences of *Pseudomonas* species. A European compilation of pseudomonad sequences is available (van de Peer et al., 1996).

The results of the contribution by Moore et al. (1996) have been summarized in the creation of "lineages", which are grouped into two "clusters", the *P. aeruginosa* intrageneric cluster and the *P. fluorescens* intrageneric cluster. Within the first cluster there are four lineages: the *P. aeruginosa* lineage (*P. aeruginosa*, *P. citronellolis*, *P. alcaligenes*, *P. stutzeri*), the *P. resinovorans* lineage (*P. resinovorans*, *P. balearica*), the *P. mendocina* lineage (*P. mendocina*, *P. pseudoalcaligenes*, *P. oleovorans*), and the *P. flavescens* lineage (only *P. flavescens*). Within the *P. fluorescens* cluster there are located five lineages: the *P. fluorescens* lineage (*P. fluorescens*, *P. marginalis*, *P. tolaasii*, *P. chlororaphis*, *P. aureofaciens*, *P. viridiflava*), the *P. syringae* lineage (*P. syringae*, *P. amygdali*, *"P. coronafaciens"*, *P. ficuserectae*), the *P. cichorii* lineage (*P. cichorii*), the *P. putida* lineage (*P. putida*, *P. asplenii*), and the *P. agarici* lineage (*P. agarici*) (Moore et al., 1996). It is, however, hard to draw any solid conclusions on the proposed classification. In the first place, since only type strains have been included in the published sequences, it is impossible to know the intraspecific variations, and although several strains of some of the species have been included, the selection has not taken into account the degree of heterogeneity in both DNA similarities and in phenotypic features characteristic of some of these species. Thus, while *P. aeruginosa* and *P. mendocina* are notoriously homogeneous in their phenotypic and genotypic properties, they are represented by a total of 12 strains. On the other hand, a very heterogeneous species in both phenotypic features and in DNA similarity such as *P. stutzeri* is represented by only one strain. The authors did not find obvious correlations of their molecular data with the results of standard phenotypic criteria. This is actually information from papers published by other groups; data corresponding to the strains subjected to the 16S rRNA sequence analysis are not reported.

The above-mentioned study included a comparison of sequences of the 16S rRNA variable region (*E. coli* positions 453–479) for the various lineages and for the species within each lineage. With respect to this approach, it may be interesting to mention here the findings on the *P. putida* biovars reported by Yamamoto and Harayama (1998). In a study of fluorescent pseudomonads done on the basis of the sequences of 16S rRNA, gyrase B subunit (*gyrB*) and RNA polymerase σ70 factor (*rpoD*), they found that in *P. putida* B the pairwise distances estimated from the variable regions of the 16S rRNA gene correlated rather poorly with the synonymous distances estimated from the *gyrB* and *rpoD* genes. On the other hand, the correlation of the nonvariable regions of these genes was highly significant, and a recommendation is formulated that only the nonvariable regions should be used for phylogenetic analysis.

Ribotyping The methodology allows comparisons of restriction patterns of ribosomal RNA genes (Stull et al., 1988), and it became widely used for epidemiological purposes because of its capacity for detection of prokaryotic diversity at the infraspecific level. When applied to the aerobic pseudomonads (*Pseudomonas sensu lato*), using the restriction enzymes *Sma*I and *Hinc*II, followed by hybridization with 16 and 23S rRNA, the method was capable of resolving 169 and 159 unique ribotyping patterns, respectively (Brosch et al., 1996). Of the two enzymes, *Sma*I was the most discriminative, except for some of the species. An analysis of *P. putida* biovar A strains in combination with a phenotypic analysis supported earlier observations, and suggested that a revision of the taxonomic status and internal subdivision of this species might be in order (Elomari et al., 1994). These considerations are mentioned in some detail in the section on taxonomic comments for this species. The methodology has limitations from the phylogenetic point of view, particularly because of significant differences that may be created by single mutations. However, aside from being a useful typing tool (Grimont and Grimont, 1986), it also appears to have taxonomic implications, and some of the observations by Brosch and collaborators confirm the marked heterogeneity of some of the species, particularly *P. fluorescens*.

Nucleic acid probes Based on the capacity of nucleic acid hybridization for the elucidation of genomic relatedness among bacteria, the development of nucleic acid probes allows for high-resolution, rapid, automated identification of specific microorganisms when they are mixed with other members of natural communities. The preparation and use of probes have been described in detail (Stahl and Amann, 1991; Schleifer et al., 1993).

Schleifer et al. (1992) have described a very effective use of the nucleic acid probes for the specific identification of pseudomonads in the environment. More recently, Amann et al. (1996a) have described the application of such probes to the detection of certain *Pseudomonas* species and pseudomonad species now assigned to other genera. In this report, the main goal was to identify the target organisms as either "former" or "genuine" pseudomonads. Unfortunately, the title of the paper carries this distinction, which is most confusing, since all pseudomonads, no matter what genera they have been assigned to, are equally "genuine".

A simplified cell blot technique combined with the use of 16S rRNA-directed probes was used for the identification of environmental isolates. The sequence of a group probe identifying *P. aeruginosa*, *P. mendocina*, *P. fluorescens*, *Comamonas acidovorans*, and *"Flavobacterium lutescens"* is described (Braun-Howland et al., 1993).

Low molecular weight (LMW) RNA profiles As an important addition to phylogenetic methodologies, Höfle (1991) has proposed a "rapid genotypic approach that bridges the gap between the solid systematics of type strains and the everyday need for relating new isolates and old reference strains". His technique is based on the examination of profiles of low-molecular-weight (LMW) RNA components in *Pseudomonas* species using high-resolution gel electrophoresis (Höfle, 1988). The reference strains of this genus, according to the author, showed very specific band patterns with discriminative power at the genus and species level (Höfle, 1990).

Whole-cell protein fingerprinting Protein banding patterns obtained by polyacrylamide gel electrophoresis, particularly when performed under denaturing conditions, are highly characteristic at the strain level, and have been used for many years for the purpose of typing and classification. An interesting application is the verification of strain authenticity, a sensitive and rapid control method that bypasses lengthy and tedious proce-

dures for rechecking exchanged cultures (Kersters et al., 1994). At present, objective quantification of the band patterns, particularly when a substantial number of strains are analyzed, is being done by computer-assisted methods. Among the variants on the basic theme of protein separation in an electric field, electrophoresis in the presence of a denaturing agent such as sodium dodecyl ("lauryl") sulfate (SDS) (Laemmli, 1970) is the technique of choice. SDS polyacrylamide gel electrophoresis (SDS-PAGE) combines high resolution and good reproducibility, which from a practical point of view compensate for the fact that no specific identification of the bands is usually performed. A description of various methodologies and their evaluation has been conveniently summarized by Jackman (1985, 1987).

Of the various references available for descriptions of whole-cell protein fingerprinting methods, a recent publication of a one-dimensional electrophoretic analysis applied to *Pseudomonas* species is a convenient source of technical and bibliographic information (Vancanneyt et al., 1996a). Over 200 reference strains of various species were included. Aside from the few species for which only the type strain has been analyzed, uniform and distinct patterns were observed for many species of fluorescent and nonfluorescent organisms (*P. aeruginosa*, *P. agarici*, *P. alcaligenes*, *P. amygdali*, *P. caricapapayae*, *P. chlororaphis*, *P. chichorii*, *"P. coronafaciens"*, *P. corrugata*, *P. ficuserectae*, *P. fragi*, *P. mendocina*, *P. pertucinogena*, *P. tolaasii*, and *P. viridiflava*). In contrast, *P. fluorescens*, *P. marginalis*, *P. pseudoalcaligenes*, *P. putida*, *P. stanieri*, and *P. stutzeri* were found to be particularly heterogeneous, in confirmation with earlier data on their phenotypic characteristics.

Ribosomal proteins These proteins, similarly to the ribonucleic acids with which they are associated in the ribosome, are of a highly conservative nature. Obviously, this should be reflected in a comparison of their sequences. In fact, partial amino acid sequences of preparations of protein L30 from species of various ribosomal RNA similarity groups give clusters similar to those that had originally been defined in rRNA–DNA hybridization studies (Ochi, 1995). Despite different levels of conservatism, other ribosomal proteins (S20, S21, L27, L20, L31, L32, and L33 protein families) give comparable results.

Other membrane proteins The discussion on this point will be limited to the identification of lipoprotein I in species of *Pseudomonas*. Work performed on the specificity of the *P. aeruginosa* lipoprotein I gene used as a probe for rapid identification purposes was an extension of the experiments of Saint-Onge et al. (1992). The work included more strains of species of RNA group I (*Pseudomonas*), as well as the related *"Azotomonas"* and *Azomonas* species and other species of Gram-negative organisms. All of the species of *Pseudomonas* that were tested gave positive reactions of variable intensities in PCR and dot blot tests using monoclonal antibodies for the lipoprotein I, whereas species of other similarity groups and of other Gram-negative genera gave negative reactions. These data, still considered to be of a preliminary nature, suggest that *P. aeruginosa* can be differentiated from the other species of the same genus that have been tested, with the exception of *P. mendocina*, *P. pseudoalcaligenes*, and *P. oleovorans*, which have similar restriction patterns in their lipoprotein I gene (De Vos et al., 1993).

Fatty acid analysis Fatty acid composition and the quinone system have been used for groupings of *Pseudomonas* species (Ikemoto et al., 1978; Yamada et al., 1982; Oyaizu and Komagata, 1983). A study of the fatty acid composition of 50 strains of various *Pseudomonas* species revealed the presence of the straight-chain saturated acid of $C_{16:0}$ and straight-chain unsaturated acids $C_{16:1}$ and $C_{18:1}$ in all strains (Ikemoto et al., 1978). Distribution of hydroxy acids, cyclopropane acids, and branched-chain acids follows quite closely the accepted subdivision of the aerobic pseudomonads into RNA similarity groups. These cellular components are very useful for identification purposes.

The results of fatty acid and quinones analyses, performed on a collection of 75 strains that included phytopathogenic pseudomonads, have been reported (Oyaizu and Komagata, 1983). The survey gave a basis for the classification of the collection into groups with particular reference to the presence of 3-OH fatty acids, and some of the groups coincided with the RNA similarity groups already defined (Palleroni et al., 1973).

The analysis of a large number of fatty acid profiles obtained from a collection of 340 strains of pseudomonads that includes plant pathogenic species has been published (Stead, 1992). The results on the distribution of 2-OH and 3-OH fatty acids could serve as one of the bases for a subdivision of the collection into six groups warranting independent generic designations.

The above comments on fatty acid composition studies refer to *Pseudomonas sensu lato* and coincide in supporting the division of these organisms into the various genera that later were to be proposed in various communications from different laboratories. A summary of the results of the above sources is presented in Table BXII.γ.110.

In a more recent communication (Vancanneyt et al., 1996b) the fatty acid composition of whole-cell hydrolysates and phospholipid fractions are reported. The results confirm some of the conclusions of the above-cited references. In general, *Pseudomonas* species are characterized by the presence of $C_{10:0\ 3OH}$ and $C_{12:0\ 3OH}$ acids. When the fatty acid contents of phospholipids were taken into account, no clear separation could be found between *Pseudomonas* RNA group I organisms and RNA similarity groups II and III.

Polyamine composition Polyamine patterns appear to be good chemotaxonomic markers for the Gram-negative bacteria in the phylum *Proteobacteria*, allowing ready differentiation of some of the pseudomonad groups (Busse and Auling, 1988). In addition to quinone analysis, polyamines are useful for rapid

[a]Data taken from Oyaizu and Komagata (1983) and Stead (1992). Data in parentheses: not all strains of the group are positive.

identification at the genus level (Busse et al., 1989). This last contribution includes a discussion of various other approaches applicable to species and strain identification.

In an attempt to relieve the dearth of simple and reliable tests for the classification of newly isolated strains of the genus *Xanthomonas*, a determination of polyamine composition of strains of this genus and of phytopathogenic *Pseudomonas* species was introduced as a rapid chemotaxonomic identification tool (Auling et al., 1991). Spermidine was found to be the main polyamine of *Xanthomonas*, whereas strains of *Pseudomonas* RNA group I were characterized by the presence of putrescine. The polyamine pattern of *Azotobacter* and *Azomonas* was the same as that of the fluorescent pseudomonads, which are placed in the same branch of *Proteobacteria*. The results obtained by Auling et al. (1991) were confirmed in a more recent study by Goris et al. (1998). Aside from the presence of putrescine and spermidine mentioned above, the species of *Pseudomonas* could be divided into two sublineages, of which only one contained cadaverine. *P. aeruginosa* (as well as *Azotobacter vinelandii*) is in the sublineage that contains this polyamine.

List of species of the genus Pseudomonas

The following list includes those species whose assignment to the genus *Pseudomonas* has been definitely established. Part of the information for some of the species has been condensed in the form of tables representing updated versions of those of the first edition of this *Manual*.

The order is alphabetical, thus avoiding the problem of ordering the species on the basis of properties such as pathogenicity, pigmentation, or certain physiological peculiarities, which only seldom correlate with the order of groups based on 16S rRNA sequence similarities (Figs. BXII.γ.124 and BXII.γ.125). *Pseudomonas* can be subdivided into two big groups, the fluorescent and the nonfluorescent species and, with respect to plant pathogenicity, a subdivision of the genus into saprophytes and plant pathogenic species is possible. These subdivisions do not correlate with each other. Some correlations, however, are apparent. In Fig. BXII.γ.124 the plant pathogens congregate mostly in the so-called *P. syringae* group.

The members of some pairs of species (*P. migulae–P. mandelii*; *P. veronii–P. gessardii*; *P. cedrella–P. orientalis*; *P. marginalis–P. libanensis*; *P. fuscovaginae–P. asplenii*, and *P. monteilii–"P. ayucida"*) were found to have identical 16S rRNA sequences (see Fig. BXII.γ.124) (Anzai et al., 1997). It is to be hoped that the precise taxonomic allocation of these taxa may be further investigated. Some comments are included in the corresponding descriptions below.

A number of species assigned to *Pseudomonas* will not be treated here. As mentioned by Kersters et al. (1996), the phylogenetic position of the following species has not yet been determined. In the list that follows, references to the original descriptions are given in parentheses, and the number in italics refers to the page where the species is described in the first edition of this *Manual* (Palleroni, 1984): *P. antimicrobica* (Attafuah and Bradbury, 1989), *P. cissicola* (Goto and Makino, 1977), *P. flectens* (Johnson, 1956), *P. gelidicola* (Kadota, 1951), *P. halophila* (Fendrich, 1988), *P. indigofera* (Elazari-Volcani, 1939), *P. iners* (Iizuka and Komagata, 1964b), *P. lanceolata* (Leifson, 1962a), *P. mephitica* (Haynes and Burkholder, 1957), and *P. spinosa* (Leifson, 1962b). Since the descriptions of *P. antimicrobica*, *P. flectens*, and *P. halophila* are not given in the first edition of the *Manual*, they will be added at the end of the list of species, under the subtitle Other Species.

Table BXII.γ.111 lists a number of species previously assigned to *Pseudomonas sensu lato*, which have been transferred to various other genera or groups. The information has been taken mainly from Kersters et al. (1996), and also Behrendt et al. (1999) and Anzai et al. (1997). The paper by Kersters et al. (1996) includes a handy table with the current classification of the species that have been assigned to *Pseudomonas* prior to the subdivision of the genus into rRNA similarity groups, their present assignments, and references to the studies deciding phylogenetic allocations and/or revised taxonomic status for each species.

Recently, three new species have been added to the list of those requiring further confirmation—*Pseudomonas abietaniphila*, *P. multiresinivorans*, and *P. vancouverensis*, which are isolated from resin acids (Mohn et al., 1999a, b). Even though the reported catabolic activities of these organisms are unique, DNA–DNA hybridization data to confirm their genomic relationships vs. related organisms have not been reported. For this reason, the description of these species will be found at the end, in the section Other Species.

Finally, many new species of *Pseudomonas* have been described in the *International Journal of Systematic and Evolutionary Microbiology* since mid-2001, the cut-off point for inclusion of new genera and species in this edition of the *Manual*.

1. **Pseudomonas aeruginosa** (Schroeter 1872) Migula 1900, 884[AL] (*Bacterium aeruginosum* Schroeter 1872, 126.)
ae.ru.gi.no' sa. L. fem. adj. *aeruginosa* full of copper rust or verdigris, hence green.

Characteristics of the species are summarized in Tables BXII.γ.108, BXII.γ.112, BXII.γ.113, and BXII.γ.114. Rods, motile by means of a single polar flagellum. Two main colony types can be observed on common solid media. One is large, smooth, with flat edges and elevated center ("fried egg" appearance), and the other is small, rough, convex. On the large colonies, silver-gray metallic shining patches may be observed, and pitting is fairly common. Clinical materials are, in general, good sources of the large colony type, whereas the small type is commonly obtained from

[a]For symbols see standard definitions. Data from Bennasar et al. (1996) and Stanier et al. (1966).

natural sources (Véron and Berche, 1976). Variation of the large type to the small is rather common but the reverse variation is extremely rare. A third colony type (mucoid) often can be obtained from respiratory and urinary tract secretions and was first observed by Sonnenshein (1927). Mucoid mutants can be divided into two groups according to the capacity of forming mucus (alginate) in chemically defined media (Fyfe and Govan, 1980). Aside from pyoverdine and pyocyanin, other pigments may be produced by some strains, including a dark red pigment (see above section on pigments).

Denitrification and gelatin liquefaction is present in the great majority of strains. The hydrolysis of Tween 80 is weak and the egg-yolk reaction is negative. Optimum temperature, 37°C. *P. aeruginosa* is probably the most widespread of all bacterial species. It can be isolated from soil and water, particularly from enrichment cultures for denitrifying bacteria. Commonly isolated from clinical specimens (wound, burn, and urinary tract infections). Causative agent of "blue pus", which accounts for the origin of the synonym pyocyaneus. Occasionally pathogenic for plants. Strains isolated from leaf spot of tobacco, identical with or similar to *P. aeruginosa* have been named *"P. polycolor"* (Clara, 1930). The species can be internally divided into a number of subgroups (types) useful for epidemiological purposes.

The mol% G + C of the DNA is: 67.2 (Bd).

Type strain: ATCC 10145, DSM 50071, NCIB 8395, NCTC 10332.

GenBank accession number (16S rRNA): X06684, Z76651.

2. **Pseudomonas agarici** Young 1970, 985[AL]
a.gar′i.ci. M.L. n. *Agaricus* a genus of fungi; M.L. gen. n. *agarici* of *Agaricus.*

The following description is a summary of the one presented by Young (1970).

Short rods (no dimensions given), motile by one or, rarely, two polar flagella. Green diffusible pigment with weak fluorescence under ultraviolet light of unspecified wavelength (in our experience, the maximum intensity of fluorescence is observed at low wavelength UV, ~257 nm). Acid is produced from arabinose, glucose, and mannitol; little acid from fructose, galactose, and ribose, and no acid from rhamnose, xylose, mannose, lactose, sucrose, maltose, trehalose, melibiose, cellobiose, raffinose, starch, inulin, dextrin, glycogen, adonitol, sorbitol, inositol, and salicin.

Acetate, benzoate, citrate, formate, fumarate, gluconate, lactate, propionate, and succinate are utilized. Galacturonate, oxalate, and tartrate are not. Oxidase and catalase reactions positive; nitrate reduction, pectate liquefaction, starch hydrolysis, esculin hydrolysis, levan production, and growth factor requirements are all negative. Further extensive phenotypic studies on strains of this species in comparison with other fluorescent organisms have been published (Fahy, 1981). Some of the reported properties are summarized in Table BXII.γ.115. Details of its fatty acid composition are known (Stead, 1992).

The organism causes drippy gill of mushrooms, and one of the main differences with another mushroom pathogen, *P. tolaasii*, is in the utilization of benzoate. Catechol is oxidized to a black pigment diffusing into the medium, a character also present in *P. agarici*. The species was tentatively assigned to RNA group I by Byng et al. (1980), and this position was further confirmed by rRNA–DNA hybridization (De Vos et al., 1985) and by rDNA sequencing (Moore et al., 1996).

The mol% G + C of the DNA is: 58.8–61.1 (T_m).

Type strain: ATCC 25941, DSM 11810, LMG 2289.

GenBank accession number (16S rRNA): Z76652.

3. **Pseudomonas alcaligenes** Monias 1928, 332[AL]
al.ca.li′ge.nes. M.L. adj. *alcaligenes* alkali-producing.

Characteristics useful to differentiate the species from other *Pseudomonas* species are given in Tables BXII.γ.116 and BXII.γ.117. For further descriptive information see Ral-

TABLE BXII.γ.115. Characters distinguishing some fluorescent *Pseudomonas* species associated with mushroom culture[a]

[b]Lateral flagella of short wavelength may be produced under certain conditions.

ston-Barrett et al. (1976) and Stanier et al. (1966). The nutritional spectrum is very narrow, resembling that of highly mutated fluorescent organisms. The gelatinase reaction is negative. The type strain was isolated from swimming pool water (Hugh and Ikari, 1964).

The mol% G + C of the DNA is: 64–68 (Bd).

Type strain: Stanier 142, ATCC 14909, LMG 1224NCIB 9945, NCTC 10367.

GenBank accession number (16S rRNA): Z76653.

4. **Pseudomonas amygdali** Psallidas and Panagopoulos 1975, 105[AL]

a.myg′ da.li. L. n. *amygdalum* almond; L. gen. n. *amygdali* of the almond.

The following description is taken from Psallidas and Panagopoulos (1975).

Rods, 0.7 × 1.7 μm or much longer (filaments can be 10–15 times the length of normal cells). Motile by means of one to six polar flagella. No PHB accumulated. Grows better in potato-dextrose medium than in nutrient agar. Growth range, 3–32°C. No growth below pH 5. No fluorescent pigment produced. Acid is formed from D-ribose, L-arabinose, glucose, mannose, galactose, fructose, sucrose, mannitol, and sorbitol. No utilization of xylose, L-rhamnose, L-sorbose, cellobiose, lactose, maltose, melibiose, trehalose, raffinose, inulin, esculin, amygdalin, arbutin, salicin, dulcitol, erythritol, glycerol, inositol, dextrin and α-methyl-D-glucoside. Malate, citrate, succinate, and fumarate are utilized. Gluconate is slowly assimilated. Acetate, propionate, oxalate, maleate, malonate, tartrate, lactate, sulfanilic acid, picrate, hippurate, and benzoate are not utilized. Among the natural amino acids, serine, aspartate, glutamate, arginine, asparagine, proline, and histidine are utilized. Not used as carbon and/or nitrogen sources are glycine, β-alanine, leucine, isoleucine, valine, lysine, ornithine, tyrosine, phenylalanine, tryptophan, cystine, cysteine, methionine, and creatine.

Some isolates are urease positive. Tween 80 and tributyrin are rapidly hydrolyzed. Lechithinase and arginine dihydrolase negative. Gelatin, casein, esculin, arbutin, and starch are not hydrolyzed. Nitrates are not reduced. Rotting of potato slices does not occur, but the organism is positive

TABLE BXII.γ.117. Nutritional characteristics of some nonfluorescent species of *Pseudomonas* [a]

[a]For symbols see standard definitions. Data from Palleroni (1984) and Sutra et al. (1997).

[b]The following compounds were not used by any of the species: adonitol, anthranilate[d], D-arabinose, benzoyl-formate[d], benzylamine, cellobiose, citrulline, erythritol, hexadecane[d], hippurate[d], *o*-hydroxybenzoate, *m*-hydroxybenzoate, isopropanol, 2-ketogluconate, kynurenate[d], lactose, maleate, mandelate, D- and L-mandelate, naphthalene[d], nicotinate[d], oxalate, panthothenate[d], phenol[d], phenyl-acetate, phenyl-ethanediol[d], phthalate, pimelate, L-rhamnose, salicin, suberate, testosterone[d], and L-threonine.

[c]*N*-acetylglucosamine, D-arabitol, diaminobutane are all positive for *P. corrugata* (other species untested). D-lyxose was variable for *P. corrugata* (other species untested). Substrates not used by *P. corrugata* (other species not tested) are adonitol, 2, 3, and 4-aminobenzoates, amygdalin, L-arabitol, arbutin, creatine, cysteine, dulcitol, ethylamine, D- and L-fucose, gentiobiose, glycogen, inulin, 5-ketogluconate, melezitose, melibiose, methionine, methylglucoside, methylmannoside, methylxyloside, norvaline, isophthalate, terephthalate, raffinose, tagatose, turanose, urea, and xylitol.

[d]Compounds not been tested for *P. corrugata*.

in the hypersensitivity test on tobacco leaves. Further details are given in the original paper. Assignment to rRNA group I has been decided based on rRNA–DNA hybridization studies (De Vos et al., 1985), and later confirmed by rDNA sequence analysis (Moore et al., 1996; Anzai et al., 1997). The fatty acid composition places the species in one of the subgroups of group I (Stead, 1992). Pathogenic for the almond tree (*Prunus dulcis*, family Rosaceae), in which it produces a hyperplasic bacterial canker. Not pathogenic for other fruit trees.

The mol% G + C of the DNA is: 57.7–58.5 (T_m); strain NCPPB 2610, 52.2.

Type strain: ATCC 33614, DSM 7298, LMG 2123 , NCPPB 2607.

GenBank accession number (16S rRNA): D84007, Z76654.

Additional Remarks: The DNA similarity studies of Gardan

et al. (1999) have included the type strains of this species as well as those of *P. ficuserectae*, *P. meliae*, and *P. savastanoi*. They indicate that these names should be considered as synonymous, and that *P. amygdali* is the correct one. Unfortunately, no decision on this point seems advisable in view of the similarity in known phenotypic properties among these organisms.

5. **Pseudomonas anguilliseptica** Wakabayashi and Egusa 1972, 584[AL]
an.guil.li.sep' ti.ca. L. n. *anguilla* eel; Gr. adj. *septica* putrefactive; M.L. adj. *anguilliseptica* pertaining to diseased eels.

The description below is taken from the original paper.

Rods, 0.4 × 2.0 μm, with a tendency to become filamentous. Motile by a single polar flagellum; motility is better at 15°C than at 25°C. Catalase and oxidase reactions positive. Gelatin is liquefied. Nitrate reduction, urease, fluorescent pigment production, and starch hydrolysis are all negative. There is no acid production from arabinose, xylose, rhamnose, fructose, galactose, glucose, mannose, sorbose, lactose, maltose, raffinose, sucrose, starch, dextrin, salicin, glycerol, mannitol, or inositol. rDNA sequencing studies place this species close to *P. aeruginosa* (see Fig. BXII.γ.124). Isolated from diseased pond-cultured eels (*Anguilla japonica*).

The mol% G + C of the DNA is: unknown.

Type strain: ATCC 33660, DSM 12111, NCMB 1949.

GenBank accession number (16S rRNA): X99540.

6. **Pseudomonas asplenii** (Ark and Tompkins 1946) Săvulescu 1947, 11[AL] (*Phytomonas asplenii* Ark and Tompkins 1946, 760.)
a.sple' ni.i. M.L. neut. n. *Asplenium* genus of ferns, spleenworts; M.L. gen. n. *asplenii* of *Asplenium*.

A description is given by Haynes and Burkholder (1957) in the seventh edition of the *Manual*.

The species was tentatively placed in RNA group I by Byng et al. (1980), an assignment confirmed by nucleic acid hybridization studies (De Vos et al., 1985; Kersters et al., 1996). Pathogenic for the bird's-nest fern (*Asplenium nidus*), which has been the source of isolation.

The mol% G + C of the DNA is: unknown.

Type strain: ATCC 23835, LMG 2137.

GenBank accession number (16S rRNA): Z76655.

7. **Pseudomonas aurantiaca** Nakhimovskaya 1948, 64[AL]
au.ran.ti' a.ca. M.L. adj. *aurantiaca* orange colored.

The description is taken from the original paper.

Rods, 0.3–0.5 × 0.8–2.0 μm; motile, lophotrichous, with four to six flagella. Two main diffusible pigments, green and orange, are produced. The colony may remain orange, while the medium is stained green and fluoresces. Colorless colonies are also produced, presumably by mutation. Gelatin liquefaction is rapid. Starch is not hydrolyzed. Growth is good in complex and synthetic media. Nitrogen sources assimilated include ammonia, nitrate, amino acids, and peptone. The organism has been described as "oligonitrophilic", that is, its nitrogen requirements are satisfied by the traces of nitrogenous compounds that are contained in the "nitrogen-free" medium used in the experiments (Nakhimovskaya, 1948). Optimum temperature 25°C. Capable of growth and acid formation from arabinose, xylose, glucose, galactose, sucrose, raffinose, glycerol, and mannitol. Lactose, maltose, and starch are not utilized.

Studies on the type strain of this species have shown that it actually corresponds to *P. chlororaphis* subsp. *aureofaciens* (Kiprianova et al., 1985). These authors propose to retain the name *P. aurantiaca* for pigmented strains of biovar II of *P. fluorescens*.

The mol% G + C of the DNA is: unknown.

Type strain: NCIB 10068.

8. **Pseudomonas avellanae** Janse, Rossi, Angelucci, Scortichini, Derks, Akkermans, De Vrijer and Psallidas 1997, 601[VP] (Effective publication: Janse, Rossi, Angelucci, Scortichini, Derks, Akkermans, De Vrijer and Psallidas 1996, 594.)
a' vel.la.nae. L. adj. *avellana* the species name of the host, *Corylus avellana*.

The following description is taken from Janse et al. (1996), who transcribed the information from the original paper by Psallidas (1993).

Rods occurring single or in pairs. Motile by means of one to four polar flagella. PHB is not accumulated. Slow growth in nutrient agar. On sucrose-containing media they form circular, dome-shaped, glistening, semitranslucent, butyrous, radially striated, cream-white or pearl-white colonies, 2–2.5 mm and 3.5–4 mm in diameter after 3 and 7 d, respectively. A levan is formed on nutrient medium plus 5% sucrose. Weak, blue-green fluorescent diffusible pigment formed in King B medium. Pantothenate is required for growth. 4% NaCl in the medium is tolerated. Catalase and lipase (Tween 80 hydrolysis) are positive. Urease, oxidase reaction, tyrosinase, arginine and ornithine dihydrolase, amylase, gelatin liquefaction, hydrolysis of casein, and protopectinase reaction (rotting of potato slices) are all negative. Nitrates are not reduced. Hydrolysis of esculin and arbutin are negative. H_2S is not produced from peptone, cysteine, or thiosulfate. Ammonia and 2-ketogluconate are not produced.

The following carbon compounds are used for growth: L-arabinose, D-ribose, D-xylose, D-glucose, D-fructose, D-galactose, D-mannose, sucrose, glycerol, mannitol, *meso*-inositol, citrate, formate, fumarate, maleate, malate, malonate, mucate, nonanoate, propionate, and succinate. Some strains use D-alanine, L-alanine, L- and DL-aspartate, L-glutamate, glutamine, L-proline, and L- and DL-serine. Organic compounds not used for growth include adonitol, esculin, amygdalin, arbutin, cellobiose, dulcitol, inulin, lactose, maltose, melezitose, melibiose, *meso*-erythritol, α-methylglucoside, L-rhamnose, salicin, L-sorbose, sorbitol, trehalose, adipate, benzoate, cinnamate, hippurate, itaconate, lactate, oxalate, picrate, sulfanilate, D(−)-tartrate, L(+)-tartrate, DL-tartrate, L-aspartate, β-alanine, L-arginine, L- or DL-asparagine, L-citrulline, L-cysteine, L-cystine, glycine, L-histidine, DL-homoserine, L-hydroxyproline, L-leucine, L-lysine, L-methionine, DL-ornithine, DL-phenylalanine, L-sarcosine, DL-tyrosine, L-threonine, DL-tryptophan, and L-valine. Further details are mentioned in the original paper (Janse et al., 1996). Optimum growth temperature, 23–25°C. Maximum, 30°C. Strains contain plasmids in the range of 33–100 MDa. It causes hypersensitive reaction in tobacco leaves. Isolated from hazelnut trees (*Corylus avellana* L.), where it causes cankers and dieback on stems and branches.

The mol% G + C of the DNA is: unknown.

Type strain: F11, DSM 11809, ICMP 9746, NCPPB 3487.

Additional Remarks: Interesting additional information

on this species is found in the literature (Janse et al., 1996). Fourteen strains were analyzed for plasmid DNA, fatty acids of whole cells, whole-cell proteins, and restriction fragment patterns of 16S rRNA. In comparison with other fluorescent species of the genus *Pseudomonas*, *P. avellanae* strains are homogeneous in their properties, and the molecular approaches indicate that the species, until recently considered to be a pathovar of *P. syringae* (*Pseudomonas syringae* pathovar *avellanae*; Psallidas, 1993), warrants independent species allocation.

9. **Pseudomonas azotoformans** Iizuka and Komagata 1963b, 137[AL]
a.zo.to.for' mans. Fr. n. *azote* nitrogen; L. v. *formo* to fashion, form; M.L. part. adj. *azotoformans* nitrogen forming (by denitrification).

The description is taken from the paper by Iizuka and Komagata (1963b).

Rods, 0.6–0.8 × 1.4–2.0 μm, motile with polar flagella. Fluorescent pigment is produced. Oxidase, gelatin liquefaction, nitrate reduction, and denitrification are all positive. H_2S is not produced and starch is not hydrolyzed. Acid is produced from glucose, glycerol, xylose, sucrose, but not from lactose or starch. Glucose, gluconate, 2-ketogluconate, citrate, succinate, ethanol, *p*-hydroxybenzoate, protocatechuate, and anthranilate are assimilate, but not phenol, benzoate, salicylate, *m*-hydroxybenzoate, gentisate, *p*-aminobenzoate, or 5-ketogluconate. Additional details can be found in the original paper. Optimum growth temperature, 25–30°C. No growth at 37°C. The description suggests that this species is similar to some of the denitrifying biovars of *P. fluorescens*, but no comparative studies have been performed. Assignment to the genus *Pseudomonas* has been confirmed by 16S rDNA sequence analysis studies (Anzai et al., 1997). Isolated from Japanese rice paddies.

The mol% G + C of the DNA is: unknown.
Type strain: IAM 1603.
GenBank accession number (16S rRNA): D84009.

10. **Pseudomonas balearica** Bennasar, Rosselló-Mora, Lalucat and Moore 1996, 204[VP]
ba.le.a' ri.ca. L. fem. adj. *balearica* of the Balearic Islands, where the organism was isolated.

Description taken from the paper by Bennasar et al. (1996).

Short, straight rods, 0.3–0.5 × 1.5–3.0 μm. Motile by means of a single polar flagellum. It grows aerobically, or under anaerobic conditions in the presence of nitrate. Vigorous denitrifier, liberating copious amounts of nitrogen gas from nitrate. Nonpigmented. It shares with *P. stutzeri* some of the phenotypic and morphological characteristics, including starch hydrolysis, growth with maltose, negative arginine dihydrolase, and gelatinase reactions, and a typical wrinkled colony morphology when freshly isolated. Differences with *P. stutzeri* include the ability to grow at 46°C and to tolerate 8.5% NaCl in the medium. It is also able to grow on xylose, but it does not utilize ethylene glycol, mannitol, 4-aminobutyrate, and suberate. Table BXII.γ.114 summarizes differences with other species of *Pseudomonas*. Some characteristics that differentiate the species from other denitrifying pseudomonads are presented in the chapter on *Burkholderia*. The two strains that have been isolated are able to degrade 2-methylnaphthalene at 40°C in wastewater or marine sediment samples.

The mol% G + C of the DNA is: 64.1–64.4 (HPLC).
Type strain: SP1402, DSM 6083.
GenBank accession number (16S rRNA): U26418.

11. **Pseudomonas caricapapayae** Robbs 1956, 74[AL]
ca.ri.ca.pa' pay.ae. M.L. gen. n. *caricapapayae* of *Carica papaya*, pawpaw.

The description is taken from Robbs (1956).

Straight or slightly curved rods, 0.9–1.1 × 1.3–3.0 μm. Motile by three to six polar flagella. Green fluorescent pigment produced. Gelatin is liquefied. Starch is not hydrolyzed. Nitrates are not reduced. Acid is produced from glucose, mannose, sucrose, glycerol, and mannitol, but not from lactose, maltose, salicin, or starch. Citrate and tartrate are utilized; lactate is not. rRNA–DNA hybridization studies have confirmed the allocation of this species among the fluorescent members of the genus *Pseudomonas* (De Vos et al., 1985). Optimum growth temperature: 23–29°C; no growth below 7°C and above 45°C. Isolated from water-soaked, angular spots on leaves of pawpaw.

The mol% G + C of the DNA is: 58.9–59.4 (T_m).
Type strain: ATCC 33615, NCPPB 1873.
GenBank accession number (16S rRNA): D84010.

12. **"Pseudomonas cedrella"** Dabboussi, Hamze, Elomari, Verhille, Baida, Izard and Leclerc 1999b, 303
ced.rel' la. M.L. fem. gen. n. *cedrella* of the cedar tree.

Rods, motile by means of a single polar flagellum. Colonies on nutrient agar are circular and smooth. On blood agar there are no signs of hemolysis. Fluorescent pigment is produced on King B agar. Oxidase, catalase, and arginine dihydrolase reactions are all negative. Some strains (2/7) liquefy gelatin. Levan is produced from sucrose. Two out of seven strains liquefied gelatin. Growth occurs at 4°C but not at 41°C. No growth occurs with 5% NaCl in the medium. Various enzymatic reactions are described in the paper (Dabboussi et al., 1999b), but gelatinase is not reported. Denitrification is a variable character. Growth at the expense of various carbon sources, particularly carbohydrates and derivatives, and various enzymatic activities are reported in the description. A comparison of growth characteristics and some general phenotypic characters, with those of other fluorescent species, is presented in the paper.

The results of DNA–DNA hybridization experiments suggest that perhaps this species should be considered as a genomovar of some of the biovars of *P. fluorescens*. Isolated from Lebanese spring water.

The mol% G + C of the DNA is: 59–60.
Type strain: CFML 96-198; CIP 105541.
GenBank accession number (16S rRNA): AF064461.

13. **Pseudomonas chlororaphis** (Guignard and Sauvageau 1894) Bergey, Harrison, Breed, Hammer and Huntoon 1930, 166[AL] (*Bacillus chlororaphis* Guignard and Sauvageau 1894, 841.)
chlo.ro.ra' phis. Gr. adj. *chlorus* green; Gr. n. *raphis* a needle; M.L. fem. n. *chlororaphis* a green needle.

Fluorescent pigment is produced. Even though the species name refers to the production of the green insoluble phenazine pigment chlororaphin, which often is excreted and crystallizes around the colonies, *P. chlororaphis* has been

found to be closely related to *P. aureofaciens* Kluyver (which does not produce this pigment, but instead makes another phenazine pigment that is orange and freely diffuses into the medium. The relationship between the two species was demonstrated by a high DNA similarity as determined by DNA–DNA hybridization (Palleroni et al., 1972; Johnson and Palleroni, 1989). For this reason, *P. chlororaphis* may include two subspecies: subsp. *chlororaphis*, producing chlororaphin, and subsp. *aureofaciens*, which produces the water-soluble phenazine monocarboxylic acid. Other phenotypic properties that differentiate the two subspecies are the utilization of L-arabinose and α-amylamine by subsp. *aureofaciens*, and of D-alanine by subsp. *chlororaphis*. Optimum temperature, about 30°C. The type strain of *P. chlororaphis* subsp. *chlororaphis* was isolated from dead larvae of the cockchafer (a large European beetle). Strains of this subspecies and of subsp. *aureofaciens* have been isolated from various sources, including water. The first strain of subsp. *aureofaciens* (ATCC 13985, NCIB 9030) was isolated from clay suspended in kerosene for 3 weeks (Kluyver, 1956).

The mol% G + C of the DNA is: 63.5 (Bd).

Type strain: ATCC 9446, DSM 50083, IFO 3904, NRRL B-560, NCIB 9392.

GenBank accession number (16S rRNA): D86004, Z76657.

14. **Pseudomonas cichorii** (Swingle 1925) Stapp 1928, 291[AL] (*Phytomonas cichorii* Swingle 1925, 730.)
ci.cho' ri.i. Gr. pl. *cichora* succory, chicory; L. n. *cichorium* chicory; M.L. gen. n. *cichorii* of chicory.

Selected characteristics of the species are given in Tables BXII.γ.115 and BXII.γ.118. A fluorescent pigment is produced. The oxidase reaction is weak and slow and the gelatinase reaction is negative. Optimum temperature, ~30°C. Isolated from *Cichorium intybus* and *C. endivia*, for which it is pathogenic.

The mol% G + C of the DNA is: 59 (Bd).

Type strain: ATCC 10857, DSM 50259, LMG 2162, NCPPB 943, PDDCC 5707.

GenBank accession number (16S rRNA): Z76658.

15. **Pseudomonas citronellolis** Seubert 1960, 428[AL]
cit.ro.nel' lo.lis. M.L. gen. n. *citronellolis* of citronellol.

The following description is summarized from the original paper by Seubert (1960).

Rods, 0.5 × 1.0–1.5 μm. Motile by means of a single polar flagellum. Optimum growth temperature, approximately 31°C. Gelatin is not liquefied. Nitrates are reduced to nitrites. Growth can occur anaerobically in the presence of nitrate. H_2S is not produced. Besides citronellol, glucose, acetate, farnesol, and ionone can support growth. No growth was observed with squalene or camphoric acid. Ammonium salts, nitrate, peptone, or yeast extract can be used as nitrogen sources. Acid is produced from glycerol, but not from glucose, galactose, arabinose, fructose, sucrose, maltose, lactose, dulcitol, inositol, mannitol, inulin, or dextrin.

16S rDNA sequence analysis allocates this species in the genus *Pseudomonas* (Moore et al., 1996). Isolated from soil by enrichment with citronellol as carbon source.

The mol% G + C of the DNA is: unknown.

Type strain: ATCC 13674, DSM 50332.

GenBank accession number (16S rRNA): Z76659.

16. **Pseudomonas corrugata** Roberts and Scarlett 1981, 216[VP] (Effective publication: Roberts and Scarlett *in* Scarlett, Fletcher, Roberts and Lelliott 1978, 109) emend. Sutra, Siverio, Lopez, Hunault, Bollet and Gardan 1997, 1032.
cor.ru' ga.ta. L. v. *corrugare* to wrinkle up; part adj. *corrugatus* wrinkled up.

The following description is summarized from the original paper by Scarlett et al. (1978).

Rods motile by multitrichous polar flagella. According to the original description, the cells are reported to accumulate PHB as carbon reserve material; however, the granules are in fact poly-hydroxyalkanoates of different monomer composition (Kessler and Palleroni, 2000 . The colonies are wrinkled (the reason for the species name), yellowish, sometimes with a green center. With age, the color may change to khaki or fawn, depending on the medium. A yellow to yellow-green diffusible, nonfluorescent pigment is produced. Gelatin is hydrolyzed, but starch is not. Egg yolk (lecithinase) reaction positive. Levan production negative. There is growth at 37°C but not at 41°C. Among the characteristics that differentiate this species from *Burkholderia cepacia* and *B. gladioli* (*"Pseudomonas alliicola"*) are the absence of pectate hydrolysis and rot of onion slices, and the lack of utilization of D-arabinose, cellobiose, adipate, *meso*-tartrate, and citraconate. All these characteristics were positive for the strains of the last two species included in the study.

The above description has been emended recently (Sutra et al., 1997). This detailed study included a large number of strains of the species as well as strains of fluorescent pseudomonads also isolated from tomato pith necrosis, and the results of the analysis were studied by numerical methods, which showed that *P. corrugata* constituted a single phenon. The general phenotypic characters and nutritional properties of the strains, taken from this comprehensive report, are summarized in Tables BXII.γ.116 and BXII.γ.117. The cellular fatty acid composition places this species in a subgroup within the genus (Stead, 1992). The results of rRNA–DNA hybridization experiments allocate this species as a member of the genus *Pseudomonas* (De Vos et al., 1985), which was later confirmed by 16S rDNA sequence analysis (Anzai et al., 1997). Isolated from tomato pith necrosis.

The mol% G + C of the DNA is: 58.4–60.8 (T_m).

Type strain: ATCC 29736, DSM 7228, NCPPB 2445.

GenBank accession number (16S rRNA): D84012.

17. **Pseudomonas ficuserectae** Goto 1983a, 547[VP]
fi.cus.e.rec' tae. L. n. *ficuserectae* of *Ficus erecta*, the name of the host species.

The following description is taken from the paper by Goto (1983a)

Nonencapsulated straight rods, 0.5 × 2.0 μm. Motile by means of one to five polar flagella. The original description reports the accumulation of PHB granules by the cells. However, an examination of the type strain has shown that these granules are of poly-β-hydroxyalkanoates other than PHB (Kessler and Palleroni, 2000). Colonies on yeast extract-peptone agar at 28°C are white, transparent, circular, convex, 0.2–3.0 mm in diameter after 6 d. Growth on yeast extract-peptone agar slants becomes very viscid after several days. Denitrification, nitrate reduction, growth factor re-

[b]Data from Sands et al., 1970.

[c]Data from Sands et al., 1970.

[d]Data from Sands et al., 1970.

[e]Data from Billing, 1970b.

[f]The following compounds were not utilized by any strains of the species in the table: D-arabinose, D-fucose[g], L-rhamnose, trehalose, maltose, cellobiose, lactose, melibiose, methylglucoside[g], starch, inulin, 2-ketogluconate[g], salicin[g], *N*-acetylglucosamine[g], isobutyrate, isovalerate, linoleate[g], laurylsulfate[g], tannate[g], oxalate, maleate, adipate, pimelate, suberate, azelate, sebacate, glycolate, thioglycolate[g], levulinate, citraconate, itaconate, mesaconate, 3-phosphoglycerate[g], hydroxymethylbutyrate[g], adonitol, ethylene glycol, propylene glycol, 2,3-butyleneglycol, methanol[g], ethanol, n-propanol, isopropanol, n-butanol, isobutanol, geraniol[g], D-mandelate, L-mandelate[g], benzoylformate[g], benzoate, *o*-hydroxybenzoate, *m*-hydroxybenzoate, phthalate, phenylacetate, phenylethanediol[g], eicosenedioate[g], naphthalene, phenol, testosterone, glycine, β-alanine, L-threonine, L-isoleucine, L-norleucine, L-valine, L-lysine, L-ornithine, L-citrulline, α-aminobutyrate, δ-aminovalerate[g], L-phenylalanine, L-hydroxyproline[g], D-tryptophan[g], indoleacetic acid[g], L-kynurenine[g], kynurenate[g], anthranilate, methylamine, ethanolamine, benzylamine, spermine, histamine[g], tryptamine[g], butylamine, α-amylamine, creatine, choline[g], hippurate, urate[g], pantothenate, acetamide, nicotinate, dodecane, hexadecane, poly-β-hydroxybutyrate[g], pectate[g], chlorogenate[g], and uridine[g].

[g]Compounds not been tried by Billing, 1970b.

quirement, arginine dihydrolase reaction, starch hydrolysis, decarboxylase reaction with lysine and ornithine, phenylalanine deaminase, growth in 5% NaCl, gelatin liquefaction, hydrolysis of Tween 80, urease, and growth at 41°C are all negative. The strains grow with L-arabinose, glucose, mannose, sucrose, raffinose, glycerol, and malonate, but do not grow at the expense of galactose, maltose, trehalose, erythritol, dulcitol, xylan, inulin, glycogen, salicin, carboxymethyl cellulose, α-methylglucoside, esculin, oxalate, glycolate, butyrate, sebacate, hippurate, arginine, betaine, valine, or ethylene glycol. Additional characteristics can be found in the original paper by Goto (1983a).

A numerical analysis that included strains of this species as well as many others of aerobic pseudomonads gave results showing that *P. ficuserectae* and *P. meliae* formed a single cluster, and suggested that they may be pathovars of *P. syringae* (Hu et al. 1991). This comment hinges on the observation that the strains under study did not accumulate PHB. For the moment, the position of *P. ficuserectae* remains unsettled, and more authentic strains will be needed for examination to confirm the correct taxonomic status. However, rDNA sequence analysis confirms its allocation to *Pseudomonas* (Moore et al., 1996). See also Additional Remarks at the end of the description of *P. amygdali* in this list. Path-

ogenic for *Ficus erecta*, in which it produces leaf spots that develop beside the thick veins.

The mol% G + C of the DNA is: 59 (T_m).

Type strain: ATCC 35104, DSM 6929, LMG 5694, PDDCC 7848.

GenBank accession number (16S rRNA): Z76661.

18. **Pseudomonas flavescens** Hildebrand, Palleroni, Hendson, Toth and Johnson 1994, 413[VP]
fla.ves' cens. L. v. *flavesco* to become golden yellow; L. part. adj. *flavescens* becoming golden yellow.

The information for the following description is taken from Hildebrand et al. (1994).

Characteristics useful for differentiation from some of *Pseudomonas* species are given in Tables BXII.γ.112 and BXII.γ.113. Slightly curved rods, 0.6–0.7 × 1.6–2.3 µm. Motile by means of a single polar flagellum. No PHB accumulated. The following characteristics are negative: arginine dihydrolase, ice nucleation, hypersensitivity reaction, denitrification, and hydrolysis of gelatin, starch, or Tween 80. It grows well in nutrient agar and other common complex media. The colonies are yellow on King medium B and other complex media. In King B, a diffusible fluorescent pigment is produced. The original report gives a list of more than 50 carbon compounds that can be used individually as carbon and energy sources, and a list of more than 80 compounds that do not support growth. Optimum temperature 28°C. No growth occurs at 37°C. Isolated from walnut blight cankers.

The mol% G + C of the DNA is: 63 (T_m).

Type strain: B62, DSM 12071, NCPPB 3063.

GenBank accession number (16S rRNA): U01916.

19. **Pseudomonas fluorescens** (Trevisan 1889b) Migula 1895a, 29[AL] (*Bacillus fluorescens* Trevisan 1889b, 18.)
flu.o.res' cens. L. n. *fluor* a flux; M.L. v. *fluoresce*; M.L. part. adj. *fluorescens* fluorescing.

Characteristics of the species are given in Tables BXII.γ.108, BXII.γ.112, BXII.γ.113, BXII.γ.115, and BXII.γ.119. Optimum temperature, 25–30°C. Found in soil and water, from which it can be isolated after enrichment in media containing various carbon sources, incubated aerobically; strains of the denitrifying biovars can be enriched in similar media containing nitrate, incubated under anaerobic conditions. Commonly associated with spoilage of foods (eggs, cured meats, fish, and milk). Often isolated from clinical specimens. Some strains assigned to this species (biovar II) have been isolated from diseased plants (e.g., lettuce), and identified as *Pseudomonas marginalis* (Brown, 1918) Stevens 1925[AL]. For more details on this species see the description below. Biovar I (biotype A of Stanier et al., 1966) is considered to by typical of *P. fluorescens*, and the type strain of the species belongs to this group. Aside from *P. marginalis* strains, biovar II (previously biotype B) also includes saprophytic organisms. In their studies on the species *P. aurantiaca* Nakhimovskaya 1948, Kiprianova et al. (1985) found that the type strain was actually *P. aureofaciens* (now a subspecies of *P. chlororaphis*), but they propose to retain the name *P. aurantiaca* for the pigmented strains of biovar II of *P. fluorescens*. Within biovar III (biotype C of Stanier et al., 1966) at least two subgroups, which differ from each other in their capacity for utilization of dicarboxylic acids, can be defined. Biovar IV (biotype F of Stanier et al., 1966) contains the type strain of *"P. lemonnieri"* (Lasseur 1913) Breed 1948, 178. Several strains are known at present, and these can be grouped into at least two clusters.

The group of miscellaneous strains assigned to *P. fluorescens* biotype G by Stanier et al. (1966) constitutes the last (V) biovar of the species. The biovar is very heterogeneous in its nutritional properties, and it may consist of strains that have lost one or more of the properties considered to be of diagnostic importance in differentiating among the better characterized biovars. Among the non-authentic strains assigned to this biovar are strains labeled *"P. schuylkilliensis"* and *P. geniculata* (Wright 1895) Chester 1901, 313[AL] (see Stanier et al., 1966). The group of strains isolated from meat that eventually was described as a new species under the name *P. lundensis* (Molin et al., 1986) corresponded to a cluster identified within biotype G (Barrett et al., 1986) (see below). Strains of biovar V are common in various materials, and have been isolated from soils (Sands and Rovira, 1971). It is quite possible that isolation of more strains of each of the different biovars may result in the future in the proposal of new species with the general properties of *P. fluorescens*, but circumscribed based on genomic differences.

The mol% G + C of the DNA is: 59.4–61.3 (Bd).

Type strain: ATCC 13525, DSM 50090, NCIB 9046, NCTC 10038.

GenBank accession number (16S rRNA): Z76662.

20. **Pseudomonas fragi** (Eicholz 1902) Gruber 1905, 122[AL] (*Bacterium fragi* Eicholz 1902, 425.)
fra' gi. L. neut. n. *fragum* strawberry; L. gen. n. *fragi* of the strawberry.

The description of this species is given in the seventh edition of the *Manual* (Haynes and Burkholder, 1957).

Rods motile with a polar flagellum. The gelatinase reaction is positive. Nitrate is not reduced to nitrite. Ammonia is produced from peptone. Description of growth in various media and acid production from some sugars and sugar-alcohols are given by Haynes and Burkholder (1957). Growth occurs from 10–30°C. No growth at 37°C. The organism is very sensitive to heat.

This species was tentatively placed in rRNA group I by Byng et al. (1980), a conclusion supported by rRNA–DNA hybridization studies (De Vos et al., 1989) and by 16S rDNA sequence analysis (Moore et al., 1996; Anzai et al., 1997). Isolated from milk, dairy products, water.

The mol% G + C of the DNA is: 60.6 (T_m).

Type strain: ATCC 4973, DSM 3456, LMG 2191.

21. **Pseudomonas fulva** Iizuka and Komagata 1963b, 138[AL]
ful' va. L. adj. *fulva* tawny, yellowish brown.

Rods, 0.6–0.8 × 1.2–1.8 µm. Motile with one to three polar flagella. Fluorescent pigment is produced. Oxidase reaction feebly positive. Gelatin is not liquefied. Nitrate not reduced to nitrite or denitrified. H_2S not produced. Starch is not hydrolyzed. Acid is produced from glucose. No acid from glycerol, xylose, sucrose, lactose, or starch. Glucose, gluconate, 2-ketogluconate, citrate, succinate, ethanol, *p*-hydroxybenzoate, and protocatechuate are assimilated. Phenol, benzoate, *m*-hydroxybenzoate, gentisate, *p*-aminobenzoate, and 5-ketogluconate are not assimilated.

Optimum temperature for growth, 25–30°C. Poor growth at 37°C and no growth at 42°C. Allocation to the

[a]For symbols see standard definitions. Data from Palleroni (1984).

genus *Pseudomonas* has been confirmed by rRNA sequence analysis (Anzai et al., 1997). Isolated from Japanese rice paddies.

The mol% G + C of the DNA is: 60.6 (T_m).

Type strain: IAM 1529.

GenBank accession number (16S rRNA): D84015.

22. **Pseudomonas fuscovaginae** (ex Tanii, Miyajima and Akita 1976) Miyajima, Tanii and Akita 1983, 656[VP]

fus.co.va.gi′nae. L. adj. *fuscus* fuscous; L. fem. n. *vagina* vagina, sheath; M.L. fem. n. *fuscovaginae* of a fuscous vagina.

The following description is taken from the original paper.

Rods with round ends, 0.5–0.8 × 2.0–3.5 µm. Cells occur singly or in pairs. Motile by one to four polar flagella. Moderate growth on nutrient agar after 4 or 5 d at 28°C; white to light brown colonies, smooth, glistening, raised, translucent, circular, butyrous. A green fluorescent, diffusible pigment is produced on King's medium B. No slime is produced on nutrient agar plus 5% sucrose. Catalase and Kovác's oxidase reaction are positive. Denitrification and nitrate reduction are negative. Hydrolysis of Tween 80 and of gelatin is positive; esculin and arbutin are not hydrolyzed. Arginine dihydrolase reaction positive, but phenylalanine deaminase and formation of 2-ketogluconate and H_2S are negative. No organic growth factors are required. Citrate, malonate, succinate, urate, acetate, β-alanine, L-valine, and L-lysine are utilized for growth, but not tartrate, hippurate, 2-ketogluconate, or polygalacturonic acid. Optimal growth temperature is approximately 28°C. No growth occurs at 37°C. Additional characteristics may be found in the paper by Miyajima et al. (1983).

Pathogenic for rice (*Oryza sativa*) and various other plants of the family Gramineae. In rice it produces first water-soaked, dark green spots, which later become brown to dark brown. Characteristics differentiating this species from other fluorescent pseudomonads are mentioned in the original paper. Assignment to the genus *Pseudomonas* has been confirmed by rRNA–DNA hybridization studies (De Vos et al., 1985). Isolated from diseased leaf sheaths of *O. sativa* in Japan.

The mol% G + C of the DNA is: unknown.

Type strain: 6801, DSM 7231, NCPPB 3085, PDDCC 5940.

23. **Pseudomonas gessardii** Verhille, Baïda, Dabboussi, Hamze, Izard and Leclerc 1999a, 1566[VP]

ges.sar′di.i. gessardii of C. Gessard, French chemist who isolated "*Bacterium aeruginosum*" for the first time in 1882 and studied its pigment.

The following description is taken from the original paper (Verhille et al., 1999a).

Rods, motile by means of a single flagellum. Fluorescent pigment is produced on King B; no phenazine pigments are observed on King A. Oxidase, catalase, and production of levan from sucrose are all positive. Many compounds were tested as carbon and energy sources for growth and a number of enzymatic reactions were determined with the cultures. The results are listed in the original paper. According to the authors, the utilization of L(−)-arabitol, xylitol, *myo*-inositol, adonitol, and *i*-inositol and the absence of growth in the presence of L-arabinose, D-xylose, D-saccharate, *meso*-tartrate, tricarballylate, glucuronate, galacturonate phenylacetate, and histamine, differentiate this species from *P. migulae*, a closely related species. Differentiation from other *Pseudomonas* species is given in tables in the original report. A minority of the strains (1/13) had gelatinase activity. No growth is observed in the presence of 5% NaCl in the medium. The range of growth temperatures goes from 4°C to 35°C, and the optimum is around 30°C. Isolated from natural mineral waters.

The mol% G + C of the DNA is: 58.

Type strain: CIP 105469.

GenBank accession number (16S rRNA): AF074384.

24. **Pseudomonas graminis** Behrendt, Ulrich, Schumann, Erler, Burghardt and Seyfarth 1999, 306[VP]

gra′mi.nis. L. n. *gramen* grass; *graminis* of grass, the source of the organism.

Rods, 0.5–1.0 × 3.5–5.0 µm, motile by one polar flagellum. Colonies are yellow, glistening, moderately convex, circular, with smooth edges. Fluorescent pigment production, levan production from sucrose, starch hydrolysis, ox-

idase, nitrate reduction to nitrite, denitrification, arginine dihydrolase, lysine and ornithine decarboxylase, tryptophan deaminase, DNase, urease, β-hemolysis of sheep blood, and β-galactosidase reactions are all negative. Catalase and hydrolysis of Tweens 40 and 80 are positive. Utilization of a number of carbon compounds is listed in the original paper by Behrendt et al. (1999). Unfortunately, few of the substrates tested are the same as the ones that appear in the tables of this chapter, and the species has not been included for comparison. However, the paper gives a selection of properties that allow a differentiation of this species from others of similar characteristics. The strains use monosaccharides but not the disaccharides tested.

A comparison of rRNA sequences with those of other species of *Pseudomonas* and species of other RNA similarity groups indicates that the assignment to the genus *Pseudomonas* is correct. The creation of a new species name for the strains is supported by low DNA similarity with other species of the genus. The paper is an excellent source of taxonomic information on the allocation of this species within the group of fluorescent pseudomonads. The original description includes the presence of ubiquinone Q-9 and the hydroxy fatty acids 3-hydroxydodecanoic and 2-hydroxydodecanoic. Isolated from the phyllosphere of grasses.

The mol% G + C of the DNA is: 60–61.
Type strain: P 294/08, DSM 11363.
GenBank accession number (16S rRNA): Y11150.

25. **Pseudomonas jessenii** Verhille, Baïda, Dabboussi, Izard and Leclerc 1999b, 54[VP]
jes.sen′ni.i. M.L. masc. gen. n. *jessenii* of Jessen, named after O. Jessen, eminent Danish bacteriologist who contributed substantially to the knowledge of fluorescent pseudomonads.

Rods, motile by means of a single polar flagellum. Colonies on nutrient agar are circular, smooth, nonpigmented. Nonhemolytic when grown on blood agar. Fluorescent pigment is produced on King B agar medium. Catalase, oxidase, and arginine dihydrolase reactions are positive. Denitrification, gelatinase, and lecithinase are negative. Nitrate is reduced to nitrite. The strains grow at 4°C but not at 41°C (range: 4–35°C). Optimal: 30°C. No growth occurs in the presence of 5% NaCl. Other properties as well as the results of nutritional and enzymatic screenings are listed in the original paper. Isolated from mineral water.

The mol% G + C of the DNA is: 57–58.
Type strain: CIP 105274.
GenBank accession number (16S rRNA): AF068259.

26. **Pseudomonas libanensis** Dabboussi, Hamze, Elomari, Verhille, Baïda, Izard and Leclerc 1999a, 1099[VP]
li.ba.nen′sis. L. n. *Libanus* Lebanon, in southern Syria; L. adj. *libanensis* from or of Lebanon.

The description is taken from the original paper.

Rods, motile by means of a single polar flagellum. No poly-β-hydroxybutyrate is accumulated. Colonies on nutrient agar are smooth, circular, and nonpigmented. No hemolysis is observed on blood agar. A fluorescent pigment is produced on King B medium, and no phenazine pigments are produced on King A medium. Lipase, elastase, and tetrathionate reductase are negative. Arginine dihydrolase, lecithinase, catalase, levan formation from sucrose, and oxidase reaction are all positive. The strains do not denitrify. The majority of the strains (6/7) liquefy gelatin. A number of enzymatic reactions and the results of a nutritional screening on a number of compounds (mostly carbohydrates and derivatives) are reported in the original paper by Dabboussi et al. (1999a). The cultures tolerate 3% but not 7% of NaCl in the medium. Growth occurs between 4 and 36°C, with optimal growth at 30°C. The strains were isolated from Lebanese spring waters.

The authors of the original description (Dabboussi et al., 1999a) discuss the relationship of this species to other fluorescent organisms. *P. libanensis* seem to be closer to *P. fluorescens* biovar A, as suggested by the results of DNA–DNA hybridization experiments. This similarity extends to the main characteristics of biovar, namely, a negative denitrification test and the capacity of formation of levan from sucrose.

The mol% G + C of the DNA is: 58.
Type strain: CFML 96-195; CIP 105460.
GenBank accession number (16S rRNA): AF057645.

27. **Pseudomonas lundensis** Molin, Ternström and Ursing 1986, 339[VP]
lund.en′sis. M.L. adj. *lundensis* referring to the city of Lund, Sweden.

The following description is taken from the original paper.
